Intensive Care Medicine Experimental 2023, **11(Suppl 1)**:000265

Introduction. Previous studies showed a high prevalence of augmented renal clearance (ARC), based on high creatinine clearance, in neurocritically ill patients and lower serum levels of vancomycin in these patients with ARC (1–3). In this post-hoc analysis of the DOLPHIN trial, we aimed to describe target attainment of beta-lactam antibiotics and fluoroquinolone in neurocritically ill patients and to explore underlying associated variables for differences in target attainment.
Methods. We performed a post-hoc analysis in the neurological ICU patients who were included in the DOLPHIN trial; a multicenter, open-label RCT comparing standard dosing of antibiotics based on local guidelines and model-informed precision dosing (MIPD). In this post-hoc analysis we primarily focused on antibiotic target attainment in neurocritically ill versus non-neurological patients. Secondarily, we assessed ARC, defined as a creatinine clearance of $\geq$ 120 mL/min/1.73 m^2, and patient characteristics that may influence ARC and target attainment.
Results. In total, data of 51 neurocritically ill patients were available, versus 337 non-neurological patients. Low target attainment was more prevalent among the neurocritically ill patients (Fig. 1), with a significantly higher chance for low target attainment; adjusted OR 2.53 (95% CI 1.29–5.09). Low target attainment was predominantly seen in the early stage after antibiotic initiation. Baseline creatinine clearance was higher in the neurocritically ill patients, with half of these patients reaching levels of ARC; median creatinine clearance neurocritically ill patients 120 mL/min/1.73 m^2 (IQR 95–136), median creatinine clearance non-neurological patients 55 mL/min/1.73 m^2 (IQR 28–89) (Fig. 2). The neurocritically ill patients were significantly younger, however other factors associated with ARC including sex and trauma, did not differ between the neurocritically ill and non-neurological patients.
Conclusions. Target failure for beta-lactam antibiotics and fluoroquinolone is more frequently seen in neurocritically ill patients versus non-neurological patients and is associated with ARC. Therefore, neurocritically ill patients are at risk of suboptimal antibiotic dosing. Further research should assess the impact of adjusted antibiotic dosing, beyond the limits of the current standard dosing regimen, in the neurocritically ill patients.

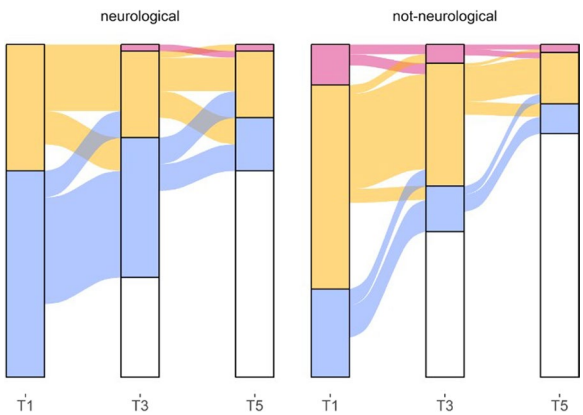

Figure 1 (abstract 000265) Alluvial plot of target attainment over time in the neurocritically ill and the non-neurological patients. T1: first moment of antibiotic sampling, one day after antibiotic initiation; T3: second moment of sampling, 48h after T1; T5: third moment of sampling, 48h after T3. Blue: low target attainment, orange: adequate target attainment, red: high target attainment

Introduction. Acute dyspnoea is one of the leading causes of emergency department (ED) admission. Emergency physicians need to detect the underlying cause and seek prompt treatment. In this context the diagnosis of hydrostatic pulmonary oedema (HPO) is challenging, as symptoms and signs are non-specific and laboratory tools are often costly and present several limitations. The variation of haemoglobin (ΔHb) concentration induced by fluid transfer through the intestitium has been proposed in the intensive care unit as a useful method to detect HPO [1]. However, its use in the ED setting still needs to be clarified.
Objectives. To test the ability of ΔHb at 4 to 8 h from ED presentation to detect HPO, by also developing a machine-learning-based predictive tool for HPO status.
Methods. In this observational retrospective monocentric study, patients admitted to ED for acute dyspnoea were enrolled. Demographic, clinical and laboratory data were collected. Hb values were recorded both at ED presentation (T0) and after 4 to 8 h (T1). ΔHb between T1 and T0 (ΔHbT1-T0) was calculated as absolute and relative value. Also, we retrieved data regarding radiological investigations and the administered therapy. Two senior investigators, unaware of Hb values, defined a posteriori the cause of dyspnoea as HPO and non-HPO. The ability of ΔHbT1-T0 to detect HPO was evaluated through a receiver operating characteristic (ROC) method. A machine learning approach was adopted to develop a predictive tool for HPO, by considering as covariate the ability of ΔHb together with the baseline patient characteristics. Different algorithms were used to train the model, in 100bootstrap runs. The leading performing algorithm according to the predictive ROC criteria was used to develop the final model. The predictive tool is available in a Shiny web application (Fig. 1).
Results. 706 dyspnoeic patients (203 HPO and 503 non-HPO) were enrolled over 19 months. Hb levels were significantly different between HPO and non-HPO patients both at T0 and T1 ($p < 0.001$). ΔHbT1-T0 were more pronounced in HPO patients than non-HPO patients, both as relative (− 8.2 [− 11.2 to − 5.6] vs. 0.6 [− 2.1 to 3.3] %) and absolute (− 1.0 [− 1.4 to − 0.8] vs. 0.1 [− 0.3 to 0.4] g/dL) values ($p < 0.001$). A relative ΔHbT1-T0 of − 4.6% detected HPO with an area under the ROC curve (AUROC) of 0.901 [0.896–0.906] (Sensitivity 83%, Specificity 90%). Among the considered models, Gradient Boosting Machine showed excellent predictive ability in identifying HPO patients (AUROC 0.916 [0.907–0.928]). According to the mean decrease in accuracy as a measure of importance, ΔHbT1-T0 was confirmed as the most important covariate for HPO prediction.
Conclusions. The developed machine learning predictive tool represents a performing and clinically handy tool for predicting HPO. Moreover, ΔHb in patients admitted for acute dyspnoea reliably identifies HPO in the ED setting.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000380

Introduction. Patients with Covid-19 related ARDS (C-ARDS) suffer from neurological and neuropsychological long-term consequences which are likely to involve disruption to the micro-structural and functional brain integrity. The mechanisms may be related to the specific neurotrophic potential of SARS-CoV-2 infection and brain injury caused by vascular damage or hypoxia.

Objectives. Determine long-term neurological and neuropsychological function and its correlation to advanced brain imaging in a cohort of C-ARDS survivors with a high rate of impaired quality of life at follow-up.

Methods. A previously described cohort of 79 C-ARDS survivors was screened for this prospective study. Brain MRI with conventional and diffusion tensor imaging (DTI) was acquired 12 months after hospital discharge in a subgroup of 24 C-ARDS patients. Regional and whole fractional anisotropy (FA) and mean diffusivity (MD) values were quantified on DTI images and analyzed vs 15 non-COVID-19 healthy controls using TBSS and tractography (Fig. 1).

The patients underwent a detailed neurological assessment and a whole battery of neuropsychological tests for memory, language, visual perception, executive function. Neuropsychiatric symptoms (anxiety, depression, and PTSD) were also explored administering questionnaires to the caregivers (Neuropsychiatric Inventory-NPI and the Frontal Behavioral Inventory-FBI). Spearman rank-correlation test was used to test for associations between variables and Mann Whitney for comparisons between groups.

Results. Participants were 24 C-ARDS patients (83.3% males; mean age 59.46 ± 8.85), with prolonged ICU and hospital stay (22 ± 11 and 41 ± 14 days, respectively) and long-term impairment in the quality of life (SF-36 physical and mental summary scores below normal in 42% and 29% of the subjects, respectively). The most frequent long-term neurological symptoms were peripheral motor deficits (62%), sleep disorders (29%) and hypogeusia and hyposmia (20%).

Neuropsychological assessment showed long-term cognitive impairment in 10/24 subjects (41.7%), with deficits at verbal short-term memory test (12.5%) and screening for executive functions deficit (20.8%). Disorders in the emotional role were found in 8/24 patients (27%), including PTSD syndrome (50%), anxious symptoms (25%) and depression (25%).

The results of questionnaires to the caregivers (NPI) showed a large presence of irritability and anxiety, followed by agitation and depression.

Brain imaging analysis showed significantly lower MD values in patients compared to healthy controls in the whole white matter skeleton ($p < 0.05$) and in the genu and splenium of the corpus callosum ($p < 0.01$). Significantly lower FA values were also found in the genu, body and splenium of the corpus callosum ($p < 0.05$), but not in the whole white matter skeleton.

We also correlated the FA and MD values in IFOF and FAT tracts with the results of the neuropsychological tests. We found significant negative correlation between verbal short-term memory and MD in the right IFOF ($rs = -0.474$, $p = 0.042$), and between PTSD symptoms ($rs = -0.702$, $p = 0.002$) and total score at FBI questionnaire ($rs = -0.484$, $p = 0.049$) and MD in the left FAT tract. Positive correlation was found between anxiety ($rs = 0.487$, $p = 0.035$), PTSD ($rs = 0.512$, $p = 0.036$) and FBI total score ($rs = 0.552$, $p = 0.022$) and FA in the right FAT tract.

Conclusions. The present study shows disruption of the white matter integrity in brain regions involved in cognitive domains and behavior. Changes in the brain structural properties correlate with reduction in short-term memory, frontal-behavioral changes and high levels of anxiety and PTSD. These findings suggest long-term cerebral consequences specific to SARS-CoV-2 infection and/or secondary to brain damage. Future studies in ARDS and other critically ill patients should carefully investigate the associations between long-term neuropsychological and mental health problems and brain microstructural integrity using DTI MRI.

Figure 1 (abstract 000380) The inferior fronto occipital fasciculus (IFOF) in "green" and the frontal aslant tract (FAT) in "violet". These tracts were segmented in C-ARDS survivors using a whole-brain probabilistic constrained spherical deconvolution (CSD) tractography using an in-house processing pipeline and FA (fractional anisotropy) and MD (mean diffusivity) were calculated for each bundle to assess their microstructural properties

Utility of tracheal pressure to estimate the muscle pressure index

G. Guidetti[1], J. F. Martínez Carmona[1], C. Joya Montosa[1], M. Mora Moreno[1], A. Rodríguez Carmona[2], J. M. Serrano Simón[3]

Introduction. During Pressure support ventilation (PSV), the difference between Pplateau and Ppeak in airway pressure (Paw), at a stable inspiratory hold, is the conventional method to obtain the muscle pressure index (PMI). However, the absence of inspiratory resistance in the tracheal pressure signal (Ptrach) and its relationship with alveolar and pleural pressure could more accurately estimate PMI.
Objectives. To evaluate the PMI with both signals (Ptrach vs. Paw) about inspiratory effort parameters.
Methods. Analysis of prospective collected data of 10 patients, admitted to the polyvalent ICU of a tertiary hospital (37 beds), from March to May 2020. Patients with hypoxemic acute respiratory failure of different causes were included during the weaning period, receiving pressure support ventilation (PSV), with 3 levels of assistance (baseline setting ± 5 cmH2O). Respiratory signals of Flow, Paw, Ptrach, and esophageal pressure (Pes) were registered at 1045 Hz, for 60 min. Ptrach was measured using a specific dedicated intratracheal catheter. Measurements: Drive and Effort parameters: P0.1, PTP/min, Delta Pes. Respiratory mechanics were calculated: Elastance (Ers) by holds, and resistances (Rrs) by the time constant. PMI was obtained through the signal of Paw and Ptrach for each level of assistance. Three inspiratory and expiratory holds were performed at each level of support, separated by 1 min. For analysis, 90 data were obtained, 30 at each level of PSV. A correlation between the effort parameters and the PMI calculated with both signals was performed.
Results. Characteristics of patients. Age 64 ± 11 years. Males 68%. Days MV 7 (4.15–9.12). PaO2/FiO2 188.21 ± 42.32. Diagnoses (N): Pneumonia-COVID 3. Postoperative Abdominal 2. Lung transplant 2. Trauma 3. Baseline PSV 10 ± 2.3, Peep 5.5 ± 2.2 cmH2O. Ers: 24.14 ± 5.3 cmH2O/L. Rrs 11.15 ± 7.3 cmH2O/l/s. For any level of assistance, the correlation of the effort parameters was better between PMI for Ptrach than Paw (Fig. 1). The most relevant data on the methods and results of the respiratory components are shown in Figs. 2, 3.

Conclusions. The tracheal pressure signal allows the calculation of the muscle pressure index with higher precision than the airway pressure, for all and the different levels of assistance during PSV. Ptrach reflects elastic components and could be considered an alternative to Pes.

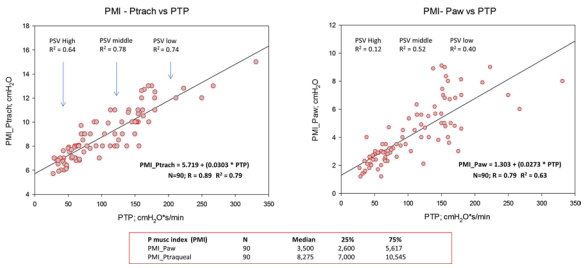

Figure 1 (abstract 000612) Correlation between muscle pressure index (PMI) and effort by Ptrach and Paw

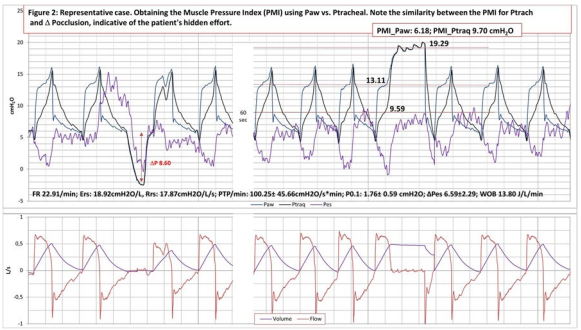

Figure 2 (abstract 000612) Representative case. PMI obtained by Ptrach and Paw

Enhancing early rehabilitation across two adult critical care units

A. Makower-Jones[1], D. Glenn[1], D. Barghouthy[1], D. McWilliams[2]
[1]Physiotherapy Dept, University Hospital Coventry & Warwickshire, Coventry, United Kingdom; [2]Centre for care excellence, University Hospital Coventry & Warwickshire, Coventry, United Kingdom
Correspondence: A. Makower-Jones
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000709

Introduction. Patients admitted to critical care and requiring invasive mechanical ventilation (IMV) often require prolonged sedation and associated immobility [1]. This in turn leads to increased length of stay (LOS) on both critical care and hospital wards and patients are at risk of long term physical and non-physical morbidity [2]. The delivery of early and structured rehabilitation has been demonstrated to improve patient outcomes, although consistency of delivering this is often challenging [3, 4].
University Hospitals of Coventry & Warwickshire NHS Trust (UHCW) had a dedicated critical illness rehabilitation team (CIRT) to provide rehabilitation to support the transition from critical care to the wards, with limited involvement prior to intensive care unit (ICU) discharge.
Recent investment enhanced CIRT with an aim to enable earlier involvement, aiming to provide more consistent rehabilitation delivery within ICU and improvement of mobility levels prior to discharge to the ward.
Objectives. To evaluate the impact of increased investment in the critical illness rehabilitation team on length of stay and mobility levels at ICU discharge.
Methods. This project was conducted across two adult ICUs in a large university hospital in the United Kingdom. Patients were eligible for inclusion if they were ventilated for ≥ 4 days, not on an existing specialist rehabilitation pathway (e.g. major trauma or neurological pathways), and survived to ICU discharge. ICU LOS and mobility data (using the Manchester Mobility Score) were collected prospectively between Dec 2022-March 2023 and compared to historical baseline data collected retrospectively for the same period in the previous year.
Patients who met the criteria for inclusion underwent a comprehensive assessment to develop an individualised plan for treatment, including goal setting and the implementation of early, structured rehabilitation. This process was supported by education to the multidisciplinary team (MDT), introduction of safety resources, development of an MDT rehabilitation steering group, and additional investment for specialist seating.
Results. Forty-seven patients met the inclusion criteria and were seen by CIRT during the trial period and were compared to 29 patients in the baseline period. The enhancement of CIRT was associated with a significant increase in the number of patients mobilised within ICU (98% vs 71%, $P < 0.001$), higher levels of mobility at the point of ICU discharge (median MMS 5 vs 2, $P < 0.001$), and a significant reduction in ICU LOS (mean 16.7 vs 23.7 days, $P < 0.05$).
Conclusions. Enhancement of CIRT enabled timely, structured and specialist rehabilitation for patients admitted to ICUI and ventilated for ≥ 4 days. This increased involvement was associated with reduced ICU LOS and improved mobility levels at ICU discharge.

Starting with recognition: using education to improve CAMICU assessment in a District General Hospital's Intensive Care Unit

M. Salamanca[1], A. White[1], C. Coyle[2]
[1]Newham University Hospital, Barts Health NHS Trust, London, United Kingdom; [2]Royal London Hospital, Barts Health NHS Trust, London, United Kingdom
Correspondence: M. Salamanca

Introduction. Delirium is common in the Intensive Care Unit (ICU); studies suggest it can affect up to 89% of ICU. Delirium in the critically ill is associated with increased mortality, increased length of stay and nursing home placements.
The CAM-ICU (Confusion Assessment Method for Intensive Care Unit) is a well-recognised scoring system which is proven to be superior to previously recommended assessment tools for detecting delirium in ICU.
We decided to form a multidisciplinary team at our adult general ICU to systematically assess and improve upon our collective approach to delirium prevention and management. As a consequence, we recognised that our patients were not being regularly assessed for delirium.
We present an ongoing process to improve the usage of the CAM-ICU assessment.
Objectives. To evaluate whether a multi-faceted approach implemented by a newly established multidisciplinary taskforce would improve frequency of CAM-ICU assessments.
Methods. We recruited doctors, nurses, physiotherapy and occupational therapists to create a multidisciplinary task force to address delirium prevention and management comprehensively. We identified a lack of understanding of the purpose of the CAM-ICU assessments and how to carry them out.
We provided in-person tutorials to doctors, nurses and allied healthcare professionals regularly working in our unit; these focused on the impact of ICU delirium, the benefits of the regular CAM-ICU assessment and how to use it. We agreed that all eligible ICU patients should have a CAM-ICU assessment documented each day.
We retrospectively measured how many patients had a daily CAM-ICU assessment one week before and one week after the staged intervention.

Results. Prior to the educational intervention, in a week there were 11 to 14 patients on the unit each day. This created 92 patient days where we believed the patient should have a CAMICU assessment. No CAM-ICU assessments were documented. During a week after the intervention there were documented CAM-ICU assessments for 16/75 patient days. Rate of CAM-ICU assessments per patient day therefore improved from 0% to 21.3%.
Conclusions. Our educational intervention has significantly improved the departments frequency of documented CAM-ICU assessments and therefore recognition of delirium. However, there is still much improvement to be had. The creation of a multidisciplinary taskforce is allowing us to rapidly provide more interventions to iteratively meet our objective. The formation of the taskforce is allowing multiple other interventions to run in parallel to improve delirium prevention and management; this includes extending visitor hours, supporting family involvement, reorientation boards and promoting sleep hygiene.

Virtual Reality pre-operative immersive experience to improve patient's ICU experience and reduce post-operative delirium incidence

R. Anderson[1], P. Bauer[1], A. Arghami[2], R. Haney[2], K. Baalson[3], E. Reisdorf[3]
[1]Pulmonary/Critical Care, Mayo Clinic, Rochester, United States of America; [2]Cardiovascular Surgery, Mayo Clinic, Rochester, United States of America; [3]Critical Care, Mayo Clinic, Rochester, United States of America
Correspondence: R. Anderson
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000798

Introduction. Delirium in the intensive care unit (ICU) is frequent, especially in the cardiothoracic surgical population, affecting up to 87% of patients. Negative sequelae include increased morbidity, ventilation time, extended hospital stay, poorer discharge outcomes and increased 6-month mortality rate. Diagnosis and management of delirium is challenging. Therefore, at risk patient identification and prevention strategies are crucial.
Pre-procedural education via audio/video experiences and facility tours have been shown to improve outcomes. Presenting such education in an immersive virtual reality (VR) format has yet to be thoroughly evaluated.
Objectives. The purpose of this study was to evaluate a multisensory VR educational program for patients undergoing elective cardiothoracic surgery with planned post-operative ICU admission. The impact on the patient's overall ICU experience and post-operative delirium rates were measured.
Methods. A multidisciplinary research team of clinicians and education/simulation experts developed a novel VR simulation session to expose patients pre-operatively to planned/expected post-operative ICU experience. Educational objectives included patient safety, family presence, ICU machinery/activities, reorientation, and communication with the care team.
Baseline patients underwent medical record review and were surveyed retrospectively on their ICU admission. VR simulation patients were surveyed at a pre-operative clinic visit on their expectations of their upcoming ICU admission. They viewed the 10-min simulation via VR headset. Following, they were surveyed. Patients underwent standard of care peri and post-procedurally. After ICU discharge, a survey was performed. We hypothesized improved patient experiences and reduced delirium rates in the VR group as compared to the baseline group.
Results. A total of 138 patients were included: 94 baseline, 44 VR. Delirium incidence trended lower in the VR group ($n=1$) versus baseline ($n=4$; $p=0.911$). Reductions in antipsychotic medication administration (Baseline, $n=16$; VR $n=1$), mechanical ventilator time ($p=0.008$), and post-operative sedation were observed ($p=0.016$) despite overall longer cardiopulmonary bypass time for the VR patients ($p=0.002$). VR patients (92%) described the simulation as helpful to alleviate anxiety and provide an understanding of what they could expect in the ICU. VR patients stated: "Give this to everybody about to have an operation!", "*It prepared me in a way nothing else could have*". VR patients experienced greater feelings of safety in the ICU and "fear of the unknown" was significantly ameliorated.
Conclusions. Pre-operative VR simulation can improve the experience and outcomes of patients undergoing elective cardiothoracic surgery recovering in the ICU. All patients undergoing a medical procedure benefit from pre-procedural education. VR simulation is a multi-sensory modality to provide that education in an immersive and effective manner.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001163

Introduction. The current ERC-ESICM guidelines updated the EEG strategy for prognostication after cardiac arrest (CA) compared to the 2015 recommendations [1,2]. The new algorithm proposes the so-called *highly malignant* EEG patterns which include suppression or burst-suppression with or without discharges (see Figure) [3,4] and are defined according to the standardized EEG terminology by the American clinical neurophysiology society (ACNS) [5].

Objectives. To validate the predictive value of highly malignant EEG patterns in the latest ERC-ESICM guidelines for post-resuscitation care. Secondary aims were to investigate if hypothermia treatment or sedation impact EEG as a prognostic tool and whether unreactive EEG background increases prognostic performance.

Methods. Prospective observational multi-center sub-study of the Target Temperature Management trial 2 (TTM2 trial), that randomised comatose patients after CA to 33ºC versus early treatment of fever (37.8 ºC) [6]. EEG was mandatory in all patients still comatose between 48 and 96 h after cardiac arrest. Sedation was mandatory during the temperature intervention and kept as low as possible afterwards. We assessed the first EEG performed beyond 24 h after CA using the ACNS terminology. Presence of highly malignant EEG patterns and EEG background reactivity was prospectively reported by the trial sites. Poor neurological outcome at 6 months was defined as a modified Rankin Scale score of 4–6.

Results. 845 patients at 59 trial sites had an EEG beyond 24 h after CA and were included in the study. EEGs were recorded at a median of 71 h after CA. Highly malignant EEG had 50% (CI 46–54%) sensitivity and 93% (CI 90–96%) specificity to predict poor outcome. Specificity was similar across patients in the two temperature groups

($p = 0.149$) and with or without ongoing sedation ($p = 1.000$). Specificity improved to 97% (CI 94–99%; $p = 0.008$) using the combination of a highly malignant *and* unreactive EEG while sensitivity decreased to 46% (CI 42–50%; $p \leq 0.001$).

Conclusions. The highly malignant EEG patterns recommended in the ERC-ESICM 2021 guidelines accurately predict poor outcome after CA, but not without false positives. However, the combination with an unreactive EEG background significantly improves specificity. The prognostic ability of EEG is not affected by temperature levels or ongoing sedation in clinically used doses.

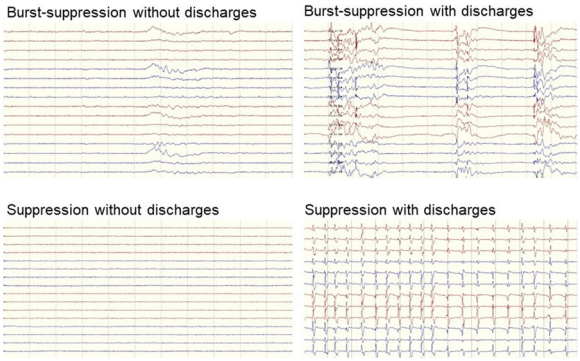

Figure (abstract 001163) Highly malignant EEG patterns

Introduction. Red blood cell (RBC) transfusion is common in patients admitted to the intensive care unit (ICU). Multiple randomized controlled trials (RCTs) have shown a more restrictive hemoglobin (Hb) threshold for RBC transfusion is safe. Whether these have been incorporated in current clinical practice is unknown. Therefore, current insight into current transfusion behavior in ICUs worldwide could facilitate the optimization of transfusion care.

Objectives. To evaluate real-world RBC transfusion practices worldwide.

Methods. The InPUT study was an international prospective cohort study, performed in 233 ICUs worldwide in 30 countries. Data were collected in prescheduled weeks between March-2019 and October-2022. All newly admitted adult patients admitted to the ICU were eligible. Patients were excluded if they did not consent for the use of data or in case the data did not fulfill quality standards. The main outcome was the incidence of RBC transfusion during ICU stay. Also, the reasons and triggers for RBC transfusion, Hb thresholds for RBC transfusion and the center-dependent probability of receiving an RBC transfusion were assessed.
Results. Out of 3,908 potentially eligible patients, 3,643 were included. A total of 894 patients (25%) received one or more RBC transfusions during their ICU stay, with a median of 4 (1st-3rd quartile 2–7) units per transfused patient. In the 1,727 RBC transfusions administered, mostly stated clinical reasons for RBC transfusion were low Hb value (N = 1,412; 82%) and hemodynamic instability (N = 406; 24%). Mostly stated physiological triggers were no trigger at all (N = 682; 40%), hypotension (N = 728; 42%) and tachycardia (N = 474; 27%). Median Hb threshold stated by the centers for RBC transfusion was 8 g/dL (1st–3rd quartile 7–9 g/dL). However, after correcting for individual-patient characteristics, centers differed significantly in their propensity to transfuse patients with a Hb of 8 g/dL (range 7–92% probability, 95% prediction interval 13–79%).
Conclusions. Despite robust literature and guidelines leaning towards more restrictive transfusion of RBC, this is only partly reflected in daily practice. RBC transfusion in the ICU remains common, and there is significant unexplained variance in transfusion behavior between centers.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001387

Introduction. Subject-ventilator dyssynchrony following prolonged invasive mechanical ventilation is common and associated with extubation failure, extended ICU length of stay and mortality (1–5). Ineffective effort and double triggering are the two main dyssynchrony patterns (4). The direct impact of dyssynchrony on diaphragm function and structure after prolonged invasive mechanical ventilation is unknown.

Objectives. To assess the effect of dyssynchrony after prolonged totally controlled mechanical ventilation (CMV) on diaphragm function and structure in a piglet model of eccentric contraction (assimilated to ineffective efforts) and overdistension (assimilated to double triggering).
Methods. In this experimental study, 10 Large-White piglets were sedated and maintained under totally CMV during 72 h followed by 2 h of dyssynchrony with ineffective efforts and double triggering patterns. Diaphragm function (as previously described (6–9) supramaximal diaphragm force assessed by negative tracheal pressure (Ptrach) after phrenic nerve transvenous stimulation) was recorded at baseline (start of sedation), after 72 h of CMV and after additional 2 h of dyssynchrony. Diaphragm structure (sarcomeric injuries) was evaluated by electronic microscopy from biopsies harvested after 72 h of CMV and after additional 2 h of dyssynchrony.
Results. Of all the piglets, initially healthy, one died of sudden cardiac arrest following severe ARDS and was therefore excluded. The others 9 piglets completed the experiment. Supramaximal diaphragm force decreased by 22% from 69.9 ± 12.7 to 54.9 ± 19.7 cmH2O ($p = 0.025$) after 72 h of CMV attesting the ventilatory-induced-diaphragm-dysfunction (VIDD). It dropped by an additional 29% from 54.9 ± 19.7 to 38.9 ± 15.5 cmH2O ($p < 0.005$) after the additional 2 h period of dyssynchrony (Fig. 1), with a 54 ± 15% rate of dyssynchronous cycles. Diaphragm sarcomeric injuries accounted for 13 ± 10% of the total micrograph area after 72 h of CMV and increased to 24 ± 19% ($p < 0.001$) after the additional 2 h of dyssynchrony (Fig. 2).
Conclusions. Two hours of subject-ventilator dyssynchrony in pre-existing ventilatory-induced-diaphragm-dysfunction are associated with further impairment of diaphragm function and additional damage to the diaphragm structure in this experimental piglet model.

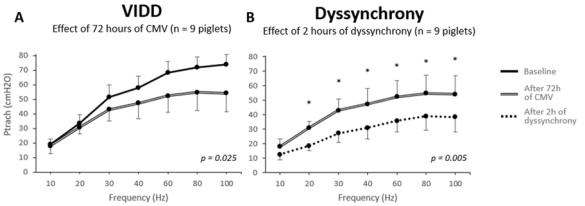

Figure 1 (abstract 001387) Diaphragmatic force frequency curves (*A*) at baseline versus after 72 h of totally controlled mechanical ventilation (CMV), (*B*) and after 72 h of CMV versus after additional 2 h of dyssynchrony, for the same piglets (n = 9)
*Force-frequency curves illustrates supramaximal diaphragm force represented by negative tracheal pressure in airway occlusion condition (Ptrach), after different frequencies of bilateral phrenic nerve stimulation. After 72 h of CMV the force frequency curve showed a decrease in supramaximal diaphragm force of 22% and after additional 2 h of dyssynchrony the supramaximal diaphragm force dropped by an additional 29%. VIDD: Ventilatory-Induced-Diaphragm-Dysfunction. CMV: Totally controlled mechanical ventilation. Ptrach: tracheal pressure. Posted p-values between two periods were obtained after two-way ANOVA. * $p < 0.01$ between two periods using paired t-test with Bonferroni correction for* post hoc *analysis.*

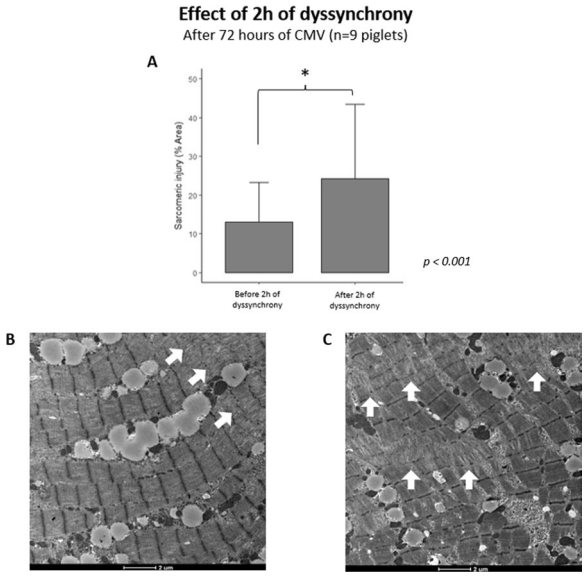

Figure 2 (abstract 001387) (*A*) percentage area of diaphragm sarcomeric injury after 72 h of totally controlled mechanical ventilation (CMV), before versus after additional 2 h of dyssynchrony. Representative electron microscopy images of longitudinal ultrathin sections obtained from the diaphragms after 72 h of CMV (*B*) before and (*C*) after additional 2 h of dyssynchrony. White arrows show disorganization of sarcomeric structure

*After 72 h of CMV, diaphragm sarcomeric injuries represented 13 ± 10% of total area of the micrographs. This rate rises to 24 ± 19% after additional 2 h of dyssynchrony. CMV: Totally controlled mechanical ventilation. Posted p-values between two periods was obtained after paired t-test. * p < 0.05 between two periods.*

Effect of regional nerve block on postoperative delirium or cognitive dysfunction after cardiothoracic surgery: a systematic review and meta-analysis

H. J. Shin[1], H. S. Na,[1], S. Lee[1], C. H. Koo[1]
[1]Department of Anesthesiology and Pain Medicine, Seoul National University Bundang Hospital, Seongnam, Republic of Korea
Correspondence: H.J. Shin
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000006

Introduction. Regional nerve blocks reduce the incidence of postoperative delirium (POD) and postoperative cognitive dysfunction (POCD) in adult patients undergoing cardiothoracic surgery. However, conflicting results have been reported in several randomized controlled trials (RCTs).
Objectives. This systematic review and meta-analysis was conducted to identify the benefits of regional nerve blocks, focusing on the effects of nerve blocks on postoperative cognitive function in patients after cardiothoracic surgery.
Methods. Electronic databases, including PubMed, EMBASE, CINAHL, Scopus, and Web of Science, were searched to identify studies that evaluated the effects of regional nerve blocks on POD and POCD. The primary outcome was the incidence of POD or POCD during the postoperative recovery period. The secondary outcome was postoperative pain scores at 24 and 48 h after surgery. We estimated the log odds ratio (LOR) and standardized mean difference using the Hedges' g method with 95% confidence intervals (CIs) to determine the effect size using a random-effect model. The LOR was converted to an OR when describing the effect size of categorical data.
Results. A total of 1010 adult patients from seven randomized controlled trials were included in the final analysis. The incidence of POD and POCD was 14.1% and 16.7%, respectively, in the regional nerve block group, and 27.3% and 35.2%, respectively, in the control group. The pooled effect size revealed that regional nerve blocks significantly reduced the incidence of POD (OR, 0.44; 95% CI 0.30 to 0.64; $P < 0.001$; $I^2 = 0.00\%$) and POCD (OR 0.43, 95% CI 0.24 to 0.76; $P < 0.001$; $I^2 = 0.00\%$) in adult patients undergoing cardiothoracic surgery. Additionally, adults in the regional nerve block group reported significantly lower pain scores than those in the control group at 24 h (SMD, − 2.60; 95% CI − 3.90 to − 1.30, $P < 0.001$; $I^2 = 97.68\%$) and 48 h (SMD − 1.80, 95%CI − 3.18 to − 0.41, $P = 0.01$; $I^2 = 98.14\%$) postoperatively.

Conclusions. Regional nerve blocks can reduce the incidence of POD and improve POCD in adult patients after cardiothoracic surgery.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000007

Introduction. Right ventricle (RV) dysfunction in ARDS increases the morbidity and mortality by causing hemodynamic instability and refractory hypoxemia.In spite of changes in ARDS management such as lung protective low tidal volume ventilation and early prone ventilation, the prevalence of RV dysfunction still ranges between 22%-50%. Early prediction of RV dysfunction in high-risk patients is possible by assessing various predictors which contributes to increase in RV afterload. We used 2D transthoracic echocardiography (TTE) to assess RV function in moderate to severe ARDS. We intend to assess prevalence of RV dysfunction, early predictors and outcome of RV dysfunction.
Objectives. A prospective observational study to evaluate the impact of clinical parameters, demographic andetiological factors on RV dysfunction in patient with ARDS admitted in main ICU, Postgraduate Institution of Medical Education and Research, Chandigarh.
Methods. This was a prospective observational study conducted between January 2021 to October 2021 in main ICU, PGIMER. Based on BERLIN definition, 118 patients were screened for eligibility and 80 moderate to severe ARDS patients included in this study. Low tidal volume ventilation by limiting plateau pressure of less than 30 cmH2O and restrictive fluid strategy were followed in all the patients. 2D TTE was used to assess RV function at admission, daily till first week and weekly till ICU discharge. We used RV end diastolic area/LV end diastolic area cut off of 0.6 to confirm RV enlargement. All the ventilatory parameters, gas exchange parameters (pH, PaO2, PaCO2) and outcome parameters (mechanical ventilation days, ventilator free days, all-cause mortality at 28 days, over-all ICU mortality) were observed. All patients were followed up till discharge from hospital.
Results. Out of 80 patients, 38 patients found to had RV dysfunction with median delay of 5 days from initiation of mechanical ventilation. Our study showed observed prevalence of RV dysfunction of 47.5% (95% CI: 36.2–59.0%). Patients admitted with viral pneumonia and known history of chronic obstructive pulmonary disease had higher risk of RV dysfunction with relative risk (RR) of 2.98 (95% CI: 1.43–6.21) and 3.83 (95% CI: 1.54–9.52) respectively. On multivariate regression analysis, we found that high PaCO2 (OR: 1.37, 95% CI: 1.01–1.26) and high mean airway pressure (OR:1.57, 95%CI:1.15–2.16) in first three days of mechanical ventilation were independently associated with RV dysfunction. Out of 38 patients who developed RV dysfunction, 20 (52.6%) patients died within 28 days. However, our study did not reveal any association between RV dysfunction and 28 days mortality. Patients developed VAP/HAP in the first week and low PaO2/FiO2 in first three days had increased odds for 28 day mortality.
Conclusions. To conclude, our study revealed that high mean airway pressure and high paCo2 on the first three days of mechanical ventilation are independent predictors of RV dysfunction in ARDS. This study also revealed that a low PF ratio on the first three days of mechanical ventilation and HAP/VAP in the first week of ICU stay are independent predictors of 28 days mortality.

Novel, simple and useful smartphone indirect ophthalmoscope for intensivists

K. Hayashi[1], F. Araki[2], T. Toyama[3], S. Temma[4], Y. Sato[5], G. Yamazaki[6], H. Matsui[1]
[1]Pediatrics, The University of Tokyo Hospital, Bunkyo City, Japan; [2]Opthalmology, Showa General Hospital, Kodaira, Japan; [3]Opthalmology, The University of Tokyo Hospital, Bunkyo City, Japan; [4]Resarch & Development Center, Nipro Corporation, Shiga prefecture, Japan; [5]Department of Emergency Medicine and Critical Care Medicine, The University of Tokyo Hospital, Bunkyo City, Japan; [6]Faculty of Medicine, The University of Tokyo, Bunkyo City, Japan
Correspondence: K. Hayashi
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000010

Introduction. Examination of the retina and preservation of retinal images can be quite informative in the management of severely comatose patients in critical care. Although indirect ophthalmoscopy is the gold standard for retinal examination, it still requires an expensive device to store images and highly specialized skills of ophthalmologists. Establishment of bedside retinal point-of-care testing using a commonly available tool will be useful for critically-ill patients with impaired consciousness requiring rapid diagnosis and evaluation of treatment efficacy.
Objectives. We innovated a novel non-ophthalmologist friendly smartphone indirect ophthalmoscope (SO) and examined its feasibility in eyeball models by non-ophthalmologists and medical students.
Methods. We conducted a single-center, cross-sectional, observational study with subjects of non-ophthalmologists including pediatricians, emergency physicians, junior residents and medical students from October 22, 2022 to March 31, 2023. We developed a novel SO consisting of 3D printed attachment device with technical support by Nipro Corporation (Shiga, Japan), (Fig. 1), a 40-diopter

lens and an iPhone 7 (Apple, Tokyo, Japan). The source of the light for retinal images is a LED light on the smartphone. We tested subjects for utilization of SO by imaging two mydriatic adult and pediatric eyeball models (a pupil diameter of 10 mm and 7 mm, respectively) (Fig. 2). Retinal images in the models were optic papilledema in the adult model and retinal hemorrhage in the pediatric model (Fig. 3). Subjects first recorded a movie image with the adult model before recording another movie image with the pediatric eye model. Instruction for participants before the test was to hold the iPhone in place for 5 s once in focus. For each model, we evaluated the percentage of retinal images suitable for diagnosis by two independent ophthalmologists, time for capturing retinal movies, and inter-rater reliability. Statistical analysis was performed by McNemer test and Wilcoxon signed-rank test. Inter-rater reliability was represented as the Gwet's AC1.

Results. Consents for the test was obtained with 99 subjects (36 medical students and 63 physicians) in 113 participants. Percentage and the median time for obtaining images suitable for diagnosis was 97% and 30 s [Interquartile range (IQR) 21–48.5] in the adult model and 99% and 18 s [14–31.0] in the pediatric model, respectively ($p = 0.48$ in the percentages and $p < 0.001$ in the median time). Inter-observer reliabilities represented by the Gwet's AC1 in the adults and pediatric model were 0.98 and 0.99, respectively.

Conclusions. The novel smartphone indirect ophthalmoscope has a significant potential for easy recording of retinal images by non-ophthalmologists, suggesting possible application for a wide range of situations including critical care and emergency treatment.

Introduction. Selective digestive decontamination and oropharyngeal (DDS-DOF) is a prophylactic strategy whose objective is to reduce the incidence of infections, mainly pneumonia associated with mechanical ventilation, preventing or eradicating the oropharyngeal and gastrointestinal carrier state of potentially harmful microorganisms pathogens.
Objectives. To expose the pathogenesis of infections in the patients ofour unit, describe the DDS-DOF, to analyze the available evidence on its efficacy inrelation to isolated colonizations.
Methods. July 22-October 22. Our unit has 22 beds. Inclusive criteria:1. Positive growth in any clinical or surveillance sample of any multi-resistant microorganism. 2. All patients in whom tracheal intubation or tracheostomy is considered with a duration greater than 72 h. 3. All non-intubated patients who present any of the risk factors for pneumonia: Low level of consciousness with$GSC \leq 11$, esophagogastrectomy. Necrotizing pancreatitis. Transplanted and/or neutropenic.1. DOF. Intubation: Wash mouth 0.1% Chlorhexidine. DOF paste (5 ml). Without intubation: Wash with 0.2% Chlorhexidine. DOF paste. 2. DDS. Antibiotics by tube nasogastric (NGS). Will be applied/8 h. Absolute diet, only DOF. Paste DOF 125 gr: colistin sulfate 2.5 gr + gentamicin sulfate 4 g + nystatin 2.5 gr + liquid vaseline + lemon essence + orobase. Antibiotic solution: same composition for every 20 ml of solution 100 mg of colistin + 80–120 mg of gentamicin and 800,000 IU of nystatin. Isolation by MARSA will add 4% vancomycin. Maintained 72 h after extubation, except MDR in which until negative in ICU.
Results. 33 patients, 24men (72%), 9women (28%), median age 59 years. Regarding the reason for admission, most frequent was PCR, 8 patients (24%) followed by respiratory failure with 5 patients (15%). APACHE II scale was 21 points and the median ICU stay was 21 days. 100% of patients received empirical antibiotic therapy, with the b-lactam group being the most used (39%). 93.9% of patients received DDS and DOF upon initiation ofmechanical ventilation.90%had no colonization. After the administration of DDS-DOF, growth was observed in 18% of the patients, not highlighting any microorganism due to its frequency.
Conclusions. No patient to whom the technique has been applied has presented colonization by multiresistant bacteria, only 1 has been infected. We demonstrate technique is worthwhile as well as the training of personnel. The success depends on the teamwork of the ICU as well as interdisciplinary with the Pharmacy Service.

Nosocomial infections in the ICU since the beginning of the COVID-19 pandemic

R. Fernández Fernández[1], P. Fernández Morales[1], M. E. Yuste Ossorio[1]
[1]Intensive Care Unit, Hospital Universitario San Cecilio, Granada, Spain
Correspondence: R. Fernández Fernández
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000012

Introduction. Bearing in mind that during the worst times of the pandemic (20 and 21) admissions in our unit doubled, requiring help of personnel who were not experts in critical care.
Objectives. We want to analyze nosocomial infections that patients have presented admitted since the beginning of pandemic and after it and study the differences between them.
Methods. Retrospective descriptive observational study. ICU admissions (cardiological, medical: polyvalent, COVID, traumatological) during 2020, 2021 and 2022, analyzing incidence density (ID): associated pneumonia mechanical ventilation (VAP), catheter-associated bacteremia (CAB) and infections urinary tract related to bladder catheterization (ITU). Nursing and auxiliary team during pandemic was ICU and Anesthesia staff with differences in experience in critical patients. Categorical variables are described as a percentage of each category and the continuous as means and standard deviation or medians and interquartile range. The statistics have been developed in programs written in asp, visual basic and SPSS. Demographic variables are collected, APACHE II, days of stay in ICU and mortality.
Results. VAP: incidence density period 1: 5.06, 2: 5.39, 3: 5.93, CAB: 5/3.58/0.67, ITU: 7.24/15.88/6.901.2020: APACHE 13.96 $\pm$ 8.27; days stay 7.15 $\pm$ 10.49, mortality 13.96%Medical: N 525 47.64%Surgical: N 140 12.70%Trauma: N 27 2.45%Coronary: N 410 37.21%2. 2021: APACHE 15.65 $\pm$ 9.35; days of stay 6.39 $\pm$ 10, mortality 12.65% Medical N 670 46.66%Surgical N 188 13.09%Trauma N 36 2.51%Coronary N 542 37.74%3. 2022: APACHE 14.66 $\pm$ 9.59; days stay 4.08 $\pm$ 5.86, mortality 8.96%Medical: N 494 39.02%Surgical: N 218 17.22%Trauma: N 53 4.19%Coronary: N 501 39.57%
Conclusions. In pandemic (2020 and 2021), nosocomial infections, especially CAB and ITUSV, exceed the incidence that we have presented later. DI has been higher possibly due to the care overload and that nursing staff were inexperienced in both the Zero programs and the job from ICU. The reasons for this increase may be different and deserve a detailed study to identify the causes and avoid them. There is no doubt that it is more fragile patients and longer stays than non-COVID patients, so extreme care should be taken them the prevention measures proposed in the different Zero Projects.

Topic: Infections and prevention.

MVP ECG risk score as predictor of postoperative atrial fibrillation in patients undergoing coronary artery bypass graft procedure

H. J. Ramos[1]
[1]Critical Care Medicine, Philippine Heart Center, Quezon City, Philippines
Correspondence: H.J. Ramos
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000015

Introduction. Atrial fibrillation (AF) is one of the most common serious cardiac rhythm disturbances and is responsible for substantial morbidity and mortality in the general population. A simpler tool to identify patients at risk for AF by only using basic, noninvasive, and easily obtainable electrocardiographic markers known as the MVP ECG risk score (morphology-voltage-P-wave duration) was proposed by Alexander et al. to predict occurrence of AF in patients with known or suspected coronary artery disease who underwent coronary angiography. Results of this study showed that the high- and intermediate-risk groups were more likely to develop AF than the low-risk group.
Objectives. The purpose of this study was to determine if there is association of the MVP ECG risk score in predicting Postoperative Atrial Fibrillation (POAF) in patients who underwent Coronary Artery Bypass Graft (CABG) procedure, which may be a useful tool for preoperative risk stratification.
Methods. A total of 118 patients without previous AF undergoing CABG were retrospectively studied. The MVP ECG risk score allocated points to their baseline ECG's based on P-wave morphology in the inferior leads, P-wave voltage in lead 1, and P-wave duration in the inferior leads. The scores were classified under three risk groups either low, moderate or high risk for developing AF. Finally, patients were followed postoperatively until their last available ECG record to document presence of AF.

Results. Mean age was 65 yearsand 89% were male. The incidence of POAF in this population was 25.42%. Patients with intermediaterisk score were more likely to develop POAF compared to low risk group (odds ratio [OR] 9.4203, 95% confidence interval [CI] 3.37–26.4; $p \leq 0.001$) and for every score increase, the odds of having POAF also increases (OR 2.8281, 95% CI 1.83–4.37; $p \leq 0.001$).
Conclusions. This study demonstrates that the MVP ECG Score composed of easily measured electrocardiographic variables can predict the risk of having AF in patients who undergo CABG procedure.

Comparison of cardiac output measurements in septic shock and hemorrhagic shock patients between Flotrac/Vigileo and transthoracic Doppler echocardiography

V. Piccoli[1], P. Grassi[1], T. Pellis[2], A. De Luca[3], G. Sinagra[3], G. Berlot[1], U. Lucangelo[1]

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000016

Introduction. Whether the ability of haemodynamic monitoring devices in patients with altered elastance may be effective is unclear.
Objectives. The primary outcome of this prospective observational study was to monitor stroke volume (SV) and cardiac index (Ci) comparing a mini-invasive haemodynamic monitoring system (Flotrac/Vigileo) and trans thoracic Doppler echocardiography (Echo) in septic patients or patients with hemorrhagic shock.
Methods. This study enrolled 47 patients older than 18 years in circulatory shock requiring cardiac output monitoring and prolonged administration of norephinephrine (> 0.25 mcg/Kg/min) and eventually another vasopressor. Patients with atrial fibrillations or arrhythmia, severe aortic stenosis, women in pregnancy and patients with an expectation of survival < 24 h (or requiring urgent surgery) were excluded. Echo was performed by a cardiologist.
Results. On a Bland–Altman graph the mean and SD between the two devices were − 9 ± 15,1 ml in terms of SV (LOA − 38,7 20,6) and − 0,42 ± 0,48 L/min/m2 in terms of Ci (LOA − 1,38 0,53). Flotrac/Vigileo had good correlation with Echo. 4 patients had atrial fibrillation during this study and the collection of data stopped. Considering Echo as reference method, a larger sample (101 measurements) was divided into two groups: in the subgroup with haemodynamics supported by more than one vasopressor the bias and SD were 8,1 ± 9,1 ml (LOA − 9,8 26) while in the subgroup with one vasopressor the bias and SD were 8,1 ± 12,9 ml (LOA − 17,2 33,3).
Conclusions. Among these patients with haemodynamic instability (34 in septic shock and 13 in hemorrhagic shock) the two devices correlated well, although Flotrac/Vigileo slightly overestimated Sv and Ci. However, in the subgroup with haemodynamics sustained by two vasopressors, measurements of the two devices appeared to diverge compared to subgroup with one vasopressor, using Echo as reference method.

The value of mottling score in evaluating tissue hypoperfusion in cardiac surgical critical ill patients

J. C. Luo[1]
[1]Cardiac Intensive Care Center, Zhongshan Hospital, Fudan University, Shanghai, China
Correspondence: J.C. Luo
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000019

Introduction. Skin mottling is a common clinical feature of tissue hypoperfusion. The mottling score is a semi-quantitative description of the severity of mottling.
Objectives. The aim of this study is to evaluate the value of mottling score in critically ill patients after cardiac surgery.
Methods. Critically ill patients after cardiac surgery with the risk of tissue hypoperfusion were enrolled. The mottling score, capillary refill time

(CRT), mean arterial pressure (MAP), lactate, urine output, vasopressor dose, and other parameters reflecting tissue perfusion were recorded, and patients were followed up until death or discharge. Patients with and without mottling were compared in terms of characteristics, and survival curves were compared to assess the impact of skin mottling on clinical survival. The accuracy of mottling score and other tissue perfusion parameters in predicting clinical outcomes was also compared.

Results. A total of 373 patients were enrolled, and only 13 patients had skin mottling, with mottling scores ranging from 1 to 5 (5, 1, 2, 2, and 3 cases, respectively). Mottling patients had lower MAP, higher vasopressor dose, less urine output, higher CRT, and higher lactate levels. There were significant correlations among mottling score and urine output, lactate, vasopressor dose, and CRT. There were also widespread correlations between other tissue perfusion paameters, and the correlations were more significant in patients with skin mottling. The optimal threshold of mottling score for predicting mortality was 1, with a sensitivity of 20 (95% CI: 10–33), specificity of 99 (95% CI: 98–100), positive predictive value of 85 (95% CI: 55–98), and negative predictive value of 88 (95% CI: 84–91).

Conclusions. In cardiac surgical critical ill patients, mottling score is a specific but not sensitive parameter for assessing the severity of tissue hypoperfusion.

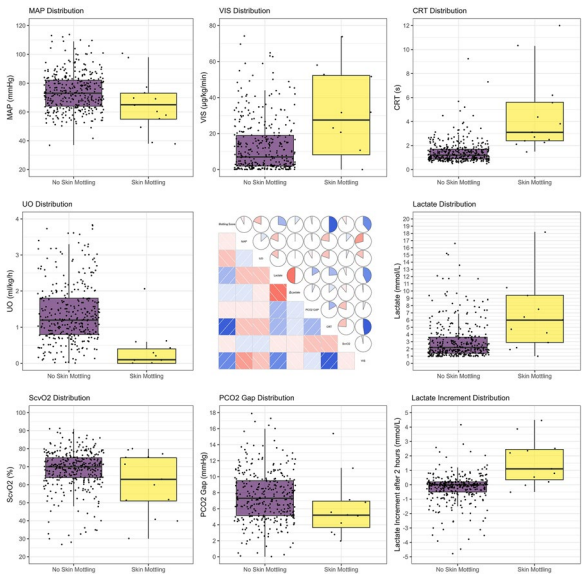

Figure 1 (abstract 000019) Distribution of tissue perfusion parameters between patients with and without mottling

Correspondence: J. Masterson

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000020

Introduction. For each maternal death, 70–90 mothers experience critical illness [1,2] and with rising maternal age and obesity rates the incidence may increase [3]. Evidence from general ICU populations demonstrates an increase in physical and psychological morbidity, healthcare resource use and mortality following critical illness [4,5,6]. However, there is a paucity of research considering the outcomes of women who experience critical illness during pregnancy.

This study aimed to report short- and long-term maternal and fetal outcomes following pregnancy in women admitted to critical care during their pregnancy and to compare this with women who did not require admission.

Methods. A retrospective cohort study using Scotland's national healthcare databases. The population included all women delivering between 01/01/2005–31/12/2018 in a Scottish hospital. Critical illness was defined as an Intensive Care Unit (ICU) admission during pregnancy. Outcomes included hospital readmission (short-term $\leq$ 42d; long-term 43-365d post-discharge), mortality (short-term $\leq$ 42d; long-term 43-365d post-delivery), psychiatric admission, stillbirth, and neonatal critical care admission. Cox regression was used to estimate the hazard ratio (HR) for hospital readmission, mortality, and psychiatric admission. Logistic regression was used to identify the risk of stillbirth and neonatal ICU admission.

Results. Of 762,918 pregnancies included in our study 1,449 (0.18%) required ICU care. Short-term readmission was more common in the ICU cohort compared with the non-ICU cohort (26.7%, n = 383 vs 5.3%, n = 40,556; unadjHR 4.5, 95%CI (3.3, 6.0), p < 0.001). Findings were similar for long-term readmission (14.1%, n = 201 vs 4.1%, n = 30,915; unadjHR 1.80, 95%CI (1.32, 2.45), p < 0.001). Readmission risk was greater in the ICU vs non-ICU cohort after confounder adjustment (short-term adjHR 4.33 (2.79, 6.72), p < 0.001; long-term adjHR 1.93 (1.25, 2.93), p = 0.003).

Increased mortality was seen in the ICU cohort for both short-term (1.4%, n = 21 vs < 0.01%,n = 20) and long-term (0.6%, n = 8 vs < 0.01%,n = 172) outcomes, which persisted after confounder adjustment (adjHR = 34.7 (20.15, 59.73), p < 0.001). Psychiatric admission within 1-year of delivery occurred in 0.7% (n = 10) of the ICU cohort and 0.3% (n = 2157) of those not requiring admission (unadjHR 2.35 (1.12, 4.94), p = 0.024). This association was attenuated after confounder adjustment (adjHR 1.34 (0.56, 3.25), p = 0.51).

The odds of stillbirth (OR 8.41 (6.05, 11.70), p < 0.001) and neonatal critical care admission (OR 9.20 (8.02, 10.57), p < 0.001) were significantly increased in the cohort admitted to ICU after adjustment.

Conclusions. Women admitted to critical care during pregnancy have a significantly increased risk of adverse short- and long-term maternal and fetal outcomes. Consequently, optimising the prevention of and aftercare for critical illness during pregnancy may reduce the health impact for these women and their offspring.

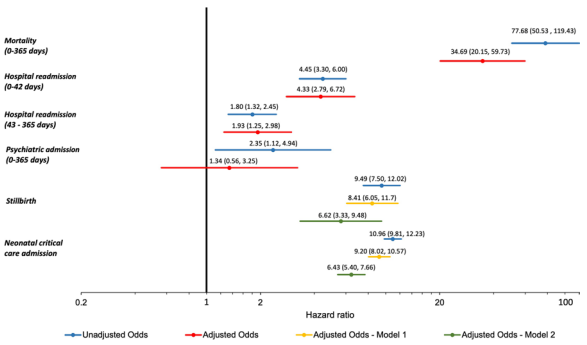

Figure 1 (abstract 000020) Forest plot comparing the hazard/odds ratios of each outcome between women who were admitted to critical

care during their pregnancy compared to those who were not. Unadjusted hazard ratios (blue) and adjusted ratios (red) are presented for each maternal outcome. Unadjusted odds ratios (blue) are presented for birth outcomes and adjusted model 1 (yellow) and model 2 (green)

Severe burned patients should receive enternal nutrition within 72 hours of injury

Z. Yin[1]
[1]Burn & Plastic Department, Ruijin Hospital, School of Medicine, Shanghai Jiaotong University, Shanghai, China
Correspondence: Q. Zhang
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000022

Introduction. The International Society for Burn Injuries (ISBI) recommends that severely burned patients start enteral nutritional therapy as early as possible. However, patients with severe burns usually suffer from delayed enteral nutrition. Gastrointestinal reflux and dynamic intestinal obstruction such as decreased bowel sounds and the disappearance of intestinal peristalsis increase the risk of respiratory tract infections. However, gastrointestinal mucosal edema may lead to poor absorption of nutrients by the gastrointestinal tract. Consequently, the timing of early enteral nutrition is still uncertain.
Objectives. To analyze the main factors affecting the early enternal nutrition and the effect of enternal nutrition within 72 h after injury on outcomes through a retrospective cohort study of 11 years of hospitalization data, so as to provide a prove for enternal nutrition regimens for critical burn injuries.
Methods. Clinical data and methods: This retrospective cohort study of adult inpatients with a more than 30% of total burned surface area of from January 1, 2009 to December 31, 2020.
Results. The main single factors affecting gastrointestinal nutrition in one week after injury were: total burn area, full-thickness burn area, whether flame burns, and whether inhalation injury of comorbidity ($P < 0.05$). Incorporating the above single factors into multiple regression analysis found that the main influencing factors affecting enternal nutrition for intensive burned patients were full-thickness burned area ($P = 0.017$) and comorbidity of inhalation injury ($P = 0.001$). In this study, it was further analyzed the treatment outcomes of initiating enternal nutrition after 72 h after injury whether the patients with flame burns, the larger the total burn area, and the larger the area of third-degree burns.The data matched that enternal nutrition administered 72 h after injury had a lower incidence of intravenous catheters infection and a lower rate of receiving total parenteral nutrition within 7 days after injury.
Conclusions. This study found that gastrointestinal nutrition within 72 h after injury can reduce the incidence of catheter infection and the utilization rate of intravenous nutrition, thereby reducing the risk of treatment of patients with severe burns.

TIMP-2 attenuates pyroptosis in early sepsis-associated acute kidney injury by inhibiting NLRP3 inflammasome activation via cAMP-dependent pathway

D. Xu[1]
[1]Department of Critical Care Medicine, Zhongnan Hospital of Wuhan University, Wuhan, China
Correspondence: D. Xu
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000027

Introduction. The novel biomarker, TIMP-2 is used clinically to predict different types of acute kidney injury (AKI) and has drawn significant attention as a urinary biomarker. However, as a secreted protein in the circulation of patients with AKI, it is unclear whether TIMP-2 acts as a key regulator in AKI progression, and if mechanisms underlying its upregulation still need to be determined.
Objectives. The objective of this project was to: 1) study the role of TIMP-2 on inflammatory regulation following AKI; 2) elucidate the mechanism of TIMP-2 function on subsequent inflammatory and repair following AKI by modulation of cAMP signaling.
Methods. Kidney tubule specific TIMP2 knockout mice were generated to examine the importance of it during SA-AKI.
Results. In this study, kidney tubule-specific TIMP2 knockout mice exhibited more profound kidney injury than WT mice did in the early stage, accompanied by the elevation of pyroptosis marker NLRP3 and GSDMD as higher inflammatory cytokines IL-1 and IL-18 levels. Further in vitro study revealed that extracellular TIMP2 promoted the ubiquitination and autophagy-dependent degradation of NLRP3. Moreover, KH7, a cAMP inhibitor remarkably prevented, while the cAMP agonist forskolin further enhanced, the ubiquitination of NLRP3 induced by recombinant TIMP2 following LPS stimulation, demonstrating the pivotal role of intracellular cAMP in mediating the effects of exogenous TIMP2. Together, we demonstrated that extracellular TIMP2 promoted NLRP3 ubiquitination and degradation by increasing intracellular cyclic adenosine monophosphate (cAMP), attenuating downstream pyroptosis, and thus alleviating renal damage.
Conclusions. Our results revealed the renoprotective role of early secreted extracellular TIMP2 during SA-AKI by attenuating tubular pyroptosis and the viability of exogenous administration of TIMP2 as a potential therapeutic intervention in SA-AKI treatment.

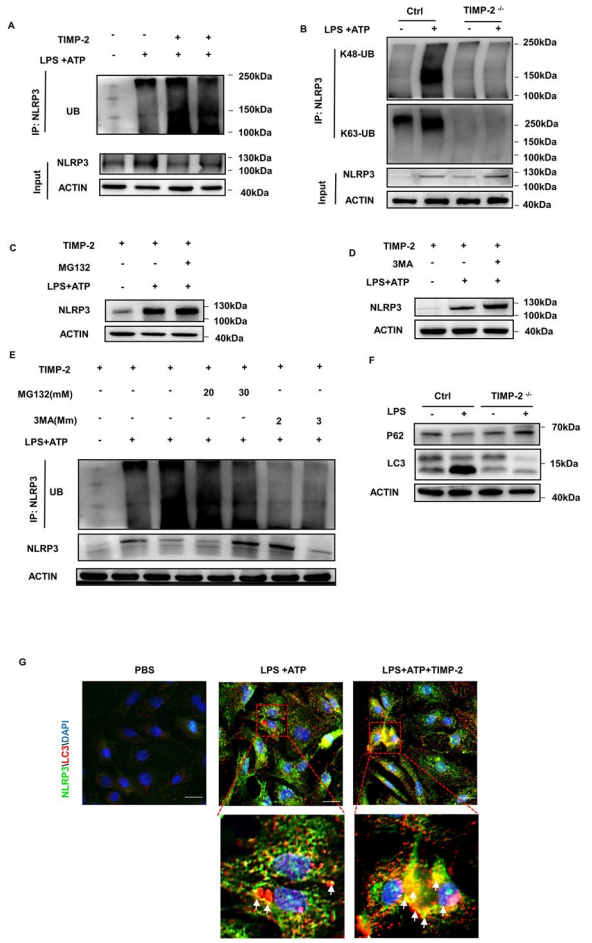

Figure 4 (abstract 000027) Forest plot comparing the hazard/odds ratios of each outcome between women who were admitted to critical care during their pregnancy compared to those who were not. Unadjusted hazard ratios (blue) and adjusted ratios (red) are presented for each maternal outcome. Unadjusted odds ratios (blue) are presented for birth outcomes and adjusted model 1 (yellow) and model 2 (green) TIMP-2 promoted NLRP3 inflammasome ubiquitination and autophagic degradation.

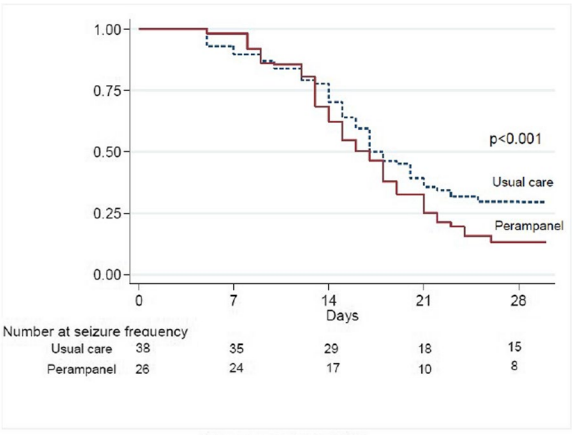
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000029

Introduction. Seizure increased mortality rates in Neurosurgical intensive care unit, it is important to achieve seizure control in these patients. AMPA receptor (perampanel therapy) was known novel target for focal-onset seizures, with or without focal tobilateral tonic–clonic seizures, and generalized tonic–clonic seizures. This study collected efficacy and safety information on clinically important treatment-emergent adverse events of perampanel as monotherapy.
Objectives. To study efficacy and safety information on clinically important treatment-emergent adverse events of perampanel as monotherapy.
Methods. This study is prospective interventional study. Data from all 64 patients were assigned to perampanel as monotherapy (intervention, n = 26) and usual care (control, n = 38). Predefined clinical outcomes were assessed by proportions of individuals with a reduction in seizure frequency of 50% (50% responder rate) in 28 days. Both groups were retrieved during December 1st, 2020 to November 30th, 2022, comparing perampanel group with usual care. Treatment outcome included retention rate, responder, andseizure-free rate at observational point 28 days, and 6 months. Treatment-emergent adverse events and adverse drug reactions were recorded.
Results. There was no difference in baseline characteristics and no difference in overall incidence of treatment-emergent adverse events and adverse drug reactions. between 2 groups. The median perampanel dosage was 4 mg (range 2-8 mg). Compared to usual care, perampanel group had proportions of individuals with a reduction in seizure frequency of 50% (50% responder rate) at 28 days, and 6 months significantly were 69% and 77% and 61% and 53% respectively and more 50% seizure frequency reduction in 28 day (Hazard ratio 1.4, p = 0.001) and no difference in ICU length of stay, ventilator free day. Common AEs were dizziness and somnolence.
Conclusions. Perampanel as monotherapy in neurosurgical intensive care unit showed good effectiveness and safety profile. Low dosage helped to minimize the impact of adverse effects, maximize adherence, and increase patient retention.



Hazard ratio 1.4,p<0.001
Value presented as median, P-value analyzed using the Kaplan-Meier survival estimates.

Introduction. Traumatic brain injury and stroke lead to a brain dysfunction and complex neurological sequelae despite aggressive surgical intervention and secondary brain injury prevention. However, alternative neuromodulation therapies can be a potential modality. Cerebrolysin is the drug which contains peptides derived from the brain of a pig that has potential neuroprotective properties and may help to protect and repair brain cells.
Objectives. To compare the efficacy and safety of Cerebrolysin with usual care.
Methods. Randomized single blind study from December 2016 to May 2022. 68 Subjects including all the adult patients with severe disability (GOS of 2 and 3) after trauma or stroke. Patients were classified to receive cerebrolysin (n = 32) and usual care (n = 36). Cerebrolysin was administered intravenously in 30 mL dosage daily for 21 days. The 6-month NIHSS, Barthel Index and modified Rankin Scale were recorded. The outcome scales, safety and complications were compared between two study groups.
Results. Baseline characteristics were comparable between two groups. We found that NIHSS and modified Rankin Scale were significantly lower in those receiving cerebrolysin [6.40 ± 2.13 vs 10.02 ± 3.75 (p = 0.013) and 2.34 ± 0.11 vs 3.2 ± 0.46 (p = 0.048)] and Barthel Index was significantly higher in those receiving cerebrolysin [77.23 ± 11.71 vs 68.82 ± 9.63 (p = 0.025)]. Cerebrolysin administration was associated with lower mortality rate, and no significant in seizure, cardiovascular complication, recurrent ischemic stroke and intracerebral hemorrhage.
Conclusions. Cerebrolysin administration is associated with improved functional neurorecovery and increased favorable outcome.

Evaluation of post-operative handover practices for critically ill patients between surgical teams and intensive care unit: an audit

S. A. Abbas[1], K. Ferenc[2]
[1]Urology, London North West University Healthcare NHS Trust, Luton, United Kingdom; [2]Intensive care unit, North Middlesex University Hospital, London, United Kingdom

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000031

Introduction. Patient handovers are crucial for the continuity of care and patient safety. Several studies have linked inadequate handovers between healthcare professionals to medical errors and patient harm [1,2,3,4,5,6]. Guidelines from the Royal College of Surgeons of England and the National Institute for Health and Care Excellence (NICE) recommend the use of structured handovers to improve communication and patient outcomes [7,8]. There is limited data available on handovers received between the operating room (OR) and the intensive care unit (ICU) [9]. This study aims to evaluate the quality of post-operative handovers provided by surgical teams to the ICU for critically ill patients being moved from the OR to the ICU.
Objectives. The objectives of this audit were to investigate current handover practices of surgical teams for patients being admitted to the ICU immediately post-surgery and to observe if NICE guidelines for structured handovers during patient transitions between specialities were being met.
Methods. A cross-sectional study was conducted to evaluate handover practices of surgical teams for patients admitted to ICU for post-operative care at a university teaching hospital in the United Kingdom. A sample size of 20 patients was selected for the audit using simple random sampling, and the study period was from December 2022 to February 2023. ICU doctors were asked to track the handovers provided by the surgical teams whenever post-operative patients were received in the department. Documented post-operative orders on electronic patient records were considered equivalent to written handovers. The required data were gathered from the EPR of patients enrolled in the audit, and a structured audit tool was developed to collect the data. Categorical data were analysed using IBM SPSS.
Results. The surgical teams provided handover to ICU for only 5% (1) of the 20 patients admitted to the ICU immediately post-procedure for observation and management. For the other 95% (19) patients, ICU did not receive a direct handover from the surgical teams. Of the 65% (13) patients who required antibiotics post-procedure, the duration of antibiotic treatment was only specified for 30% (6), and 35% (7) did not have any duration specified. Similarly, 80% (16) of the patients were allowed to have venous thromboembolism (VTE) prophylaxis post-procedure, but only 85% (17) had time-specific instructions documented for when the patient could receive VTE prophylaxis. Regarding feeding instructions, only 15% (3) of the patients had a specified time to restart feeding, while 50% (10) had no specified time documented. The type of diet was only specified for 55% (11) of the patients. Moreover, expected drain output was specified for only 5% (1) of the patients, and 75% (15) had no comments on drain output in the post-op surgical instructions. Table 1 provides a brief summary of the results.
Conclusions. This audit reveals that there are significant gaps in the post-operative handover practices of surgical teams for critically ill patients being moved from the OR to the ICU. Inadequate handovers can lead to medical errors, delays in treatment, and patient harm. Structured handovers using guidelines such as those provided by NICE, and the World Health Organization can improve communication and patient outcomes. There is a need for further education and training of healthcare professionals to ensure that effective handovers are provided for patients being transferred between specialities.

Table 1 (abstract 000031) Summary of the Audit Results

Criteria	Met Standard
Surgical Team Provided Handover	1/20 (5.0%)
Patient Require Antibiotics, Post-Procedure	13/20 (65.0%)
Duration of Antibiotics Treatment Specified	7/20 (35.0%)
Patient to have VTE prophylaxis	16/20 (80.0%)
Instructions Provided Regarding VTE	17/20 (85.0%)
Instructions When Patient Could Resume Feeding	13/20 (65.0%)
Feeding Time Specified	3/20 (15.0%)
Feeding Route Specified NG/Oral/ PEJ/TPN	13/20 (65.0%)
Type of Diet Specified? Clear liquid/soft/regular	11/20 (55.0%)
Instructions Regarding Drains	4/20 (20.0%)
Site(s) of the Drain Specified	4/20 (20.0%)

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000033

Introduction. Enternal nutrition as soon as possible in patients with severe burns is an important treatment to improve prognosis, but the pursuit of adequate gastrointestinal nutrition as soon as possible is considered harmful. In order to find out how critically ill burn patients can adapt more quickly to enternal nutrition, this study used retrospective cohort study to analyze the main reasons that influenced physicians to make two different decisions about complete fasting or adaptive feeding (feeding less than 30 ml water) for patients with severe burns from the medical history data of patients with severe burns in the past 11 years, and analyzed whether adaptive feeding in the first 24 h after injury was an appropriate pilot method.
Objectives. In order to find out how critically ill burn patients can adapt more quickly to enternal nutrition, this study used retrospective cohort study to analyze the main reasons that influenced physicians to make two different decisions about complete fasting or adaptive feeding (feeding less than 30 ml water) for patients with severe burns from the medical history data of patients with severe burns in the past 11 years, and analyzed whether adaptive feeding in the first 24 h after injury was an appropriate pilot method.
Methods. This study conducted a retrospective cohort study of inpatients in the burn center of Ruijin Hospital from January 1, 2009 to December 31, 2020. The patient population in this study was hospitalized with burns greater than 30%. The general information of the patients, the burn wound situation, the main causes of burns: flame, non-flame (thermal, chemical, electrical burns, etc.), whether there was inhalation injury, the occurrence of gastrointestinal adverse reactions after the start of gastrointestinal nutrition, and the indicators of patient outcome were studied separately.
Results. In this study, multiple regression analysis was used to find that the size of the third-degree burn area (standard regression coefficient 0.106, standard error 0.197, t-value 3.060, $P = 0.002$) and whether there was inhalation injury (standard regression coefficient 0.141, standard error 0.202, t-value 2.299, $P = 0.022$) within 24 h after injury of patients with large-scale burns were the main determinants of complete fasting or adaptive drinking of water. Further analysis of the main factors affecting the initiation of adaptive drinking within 24 h after injury in patients with severe burns and inhalation injury found that there were no significant differences in age, sex, BMI, total burn area, third-degree burn area, and whether the cause of the burn was flame. Complete fasting and initiation of adaptive drinking water 24 h after injury in patients with inhalation injury had no significant > effect on the final treatment outcome, mortality at 28 days after injury, and the occurrence of bloodstream infection and catheter infection 0.05. There was no significant difference in the incidence of gastrointestinal nutritional intolerance between the fasting group and the adaptive drinking group in patients with inhalation injury ($X2 = 2.679$, $P = 0.102$).
The study further analyzed whether patients with large third-degree burn wounds could not receive adaptive drinking water for sufficient reasons. The study found that there was no difference in age, sex, BMI, total burn area, and whether inhalation injury was combined between the two groups of patients with fasting or adaptive drinking water, while the final survival rate of patients in the adaptive drinking group was significantly higher (6.94%, 16.32%, $X2 = 3.869$, $P = 0.049$). The incidence of positive blood cultures ($X2 = 4.905$, $P = 0.027$) and the incidence of positive sputum cultures 14 days after injury ($X2 = 8.153$ $P = 0.004$).
Conclusions. From this study found that physicians made complete fasting or adaptive drinking decisions for patients with severe burns and inhalation injury, regardless of age, sex, pre-injury BMI, burn cause, burn area, and third-degree burn area were not the main influencing factors, and the administration of adaptive drinking water did not cause increased risk of treatment. Analysis showed that the overall mortality, bloodstream infection, respiratory tract infection and catheter infection in the adaptive drinking group were lower and the onset time was later. Therefore, early adaptive drinking water can be used as a leading nutritional method for severe burns and severe burns combined with inhalation injury, and improving gastrointestinal function is an important measure to improve the success rate of treatment of severe burns.

Furosemide stress test (FST) 2.0-Combining FST with the persistent AKI biomarker CCL14 improves the prediction of absolute indications for renal replacement therapy in a postsurgical cohort of critically ill patients

R. Weiss[1], M. Meersch[1], J. Gerss[2], F. Albert[2], J. Gruber[1], M. Sadjadi[1], J. A. Kellum[3], L. Forni[4], L. Chawla[5], J. L. Koyner[6], T. von Groote[1], A. Zarbock[1]

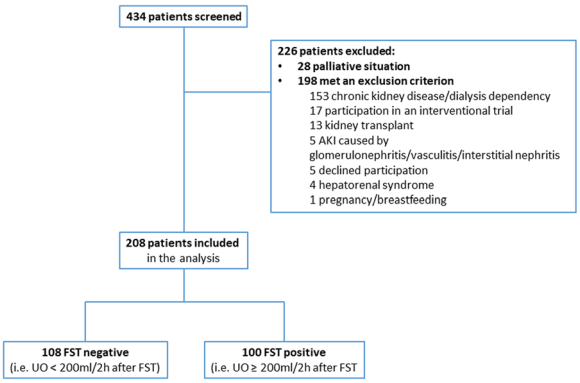
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000036

Introduction. Prediction and timing of renal replacement therapy (RRT) initiation in acute kidney injury (AKI) remains a challenge for intensivists. The furosemide stress test (FST) has been suggested as a clinical tool to predict persistent AKI with high accuracy. (1, 2) Alternatively, persistent AKI or future requirement for RRT may be predicted using renal biomarkers. Recently, urinary c-motif chemokine ligand (CCL) 14 demonstrated prediction of persistent AKI in patients with moderate AKI, AUC of 0.83 (0.78–0.87) in the critical care setting and 0.92 (95% CI, 0.86–0.97) in the cardiac surgery setting. (3, 4).
Objectives. We investigate whether the combination of FST with a renal biomarker predicts the development of absolute indications for RRT.
Methods. A prospective, single-center, observational study, conducted at the University Hospital of Münster (Germany). Critically ill patients who received an FST in the setting of both stage 2 AKI and a predefined clinical risk factor (requirement of vasopressors and/or mechanical ventilation) were included. Patients with advanced CKD ($eGFR < 20$ ml/min/1.73 m^2) or chronic dialysis dependency were excluded. FST was performed using 1.0 mg furosemide intravenously/kg body weight in diuretic-naïve and 1.5 mg/kg in diuretic pre-treated patients (1).
Urinary and blood sample collection and measurement of biomarkers (CCL14, NGAL, DPP3) was performed immediately prior to FST. The primary endpoint was the development of one or more pre-defined RRT indications: hyperkalemia ($K+ \geq 6$mmol/l), diuretic-resistant hypervolemia, urea serum levels (≥ 150mg/dl), severe metabolic acidosis ($pH \leq 7.15$), oliguria (urinary output < 200 ml/12h), or anuria.
Results. 208 patients were enrolled, of which 108demonstrated a negative FST, defined as a urinary output of less than200 ml within 2 h following the FST (Fig. 1).
Overall, 98 (47%) patients met the primary endpoint, with 82% in the FST negative cohort. The combination of a negative FST test with

higher urinary CCL14 level had a significantly higher predictive value for the primary endpoint with an area under the receiver operating characteristic curve (AUROC) of 0.87 (95%CI, 0.82–0.92), compared to FST or CCL14 alone (AUC 0.79 (95%CI, 0.74–0.85), AUC 0.83 (95%CI, 0.77–0.89), P < 0.001, respectively). In subgroup analyses, other biomarkers showed lower AUCs in the FST negative group (Table 1).
Conclusions. The combination of the FST with a renal biomarker (CCL14) predicts the development of indications for RRT better than FST or CCL14 do in isolation. Application of such a combination may obviate the variability in application of RRT in critically ill patients with AKI with the associated high mortality rate and resource utilization. (5) Moreover, these results could also support future trials investigating the optimal time point of RRT initiation. To our knowledge, this is the first study that combines a renal stress test with novel renal biomarkers.



Biomarker	FST negative (UO<200ml/2h), n=108 AUC (95% CI)	FST positive (UO>200ml/2h), n=100 AUC (95% CI)	*P*-value[a]
CCL-14	0.86 (0.77-0.94)	0.66 (0.52-0.80)	0.02
NGAL	0.72 (0.61-0.82)	0.72 (0.60-0.83)	0.98
DPP3	0.70 (0.57-0.83)	0.71 (0.57-0.84)	0.91

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000038

Introduction. Many clinicians may find it useful to investigate their experiences to do their next daily practice with a clear guide and evidence for choosing appropriate antimicrobials. The sepsis campaign guidelines, in contrast, recommend only early administration of appropriate broad-spectrum antimicrobials and covering drug-resistant pathogens if their infection is suspicious.
Objectives. We aimed to describe empiric antimicrobial choices for patients with community-onset sepsis using nationwide real-world data from Japan.We aimed to describe empiric antimicrobial choices for patients with community-onset sepsis using nationwide real-world data from Japan.
Methods. This is a retrospective cohort study that used nationwide data from Japan's medical reimbursement system. Patients were aged ≥ 20 years, had presumed infections and acute organ dysfunction, and were admitted to hospitals between 2010 and 2017. Only community-onset sepsis was chosen from among them. Then, we discussed the initial antimicrobial regimens for sepsis patients. We also classified sepsis patients who were admitted to the intensive care unit (ICU) or the ward.
Results. There were 1,195,741 people who had community-onset sepsis. Of those, 1,068,719 (89.4%) were admitted to wards, whereas 127,022 (10.6%) patients were admitted to the ICU. The participants' median age was 76 years (interquartile range: 60–84), and 55.9% were men. The lung was the most commonly infected site (38.0%), followed by the abdomen (15.7%), urinary tract (7.8%), and bone and soft tissues (5.3%).
Third-generation cephalosporins were the most commonly used antimicrobials (24.3%), followed by carbapenem (21.7%) and tazobactam/piperacillin (19.9%). In ICU, carbapenem was the most commonly used antibiotic (35.8%), followed by tazobactam/piperacillin (20.7%) and third-generation cephalosporins (16.4%); 7.7% of patients received combination therapy that excluded drug-resistant pathogens such as methicillin-resistant staphylococcus aureus (MRSA) or pseudomonas; 1.7% and 6.0% of patients initially used antimicrobials for MRSA coverage in the ward and ICU, respectively. Although antipseudomonal agents were initially used by half of the patients (47.1%), only 3.7% used antipseudomonal combinations (more than two antipseudomonal agents). Furthermore, 1.5% of patients initially used antimicrobial combinations to treat MRSA and pseudomonas.
Conclusions. Third-generation cephalosporins and carbapenem were the most commonly used as initial antimicrobials in the ward and ICU among patients with community-onset sepsis in Japan. Only a small

percentage of patients used antimicrobials to combat MRSA. Although antipseudomonal agents were initially given to half of the patients with community-onset sepsis, antimicrobial combination therapy for drug-resistant bacteria coverage was rarely given to patients with community-onset sepsis.

Proof of concept: use of a virtual reality game in rehabilitation of stroke patients in a tertiary hospital neuro intensive care unit (NICU) in Singapore

T. T. S. @ K. Cao[1], Y. L. Wong[1], S. R. Iqbal[2]
[1]Anaesthesiology, Intensive Care and Pain Medicine, Tan Tock Seng Hospital, Singapore, Singapore; [2]Physiotherapy, Tan Tock Seng Hospital, Singapore, Singapore
Correspondence: T.T.S.@.K. Cao
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000039

Introduction. Background: Patients with stroke make up the biggest proportion of admission to NICU. There are minimal physiotherapy (PT)-led rehabilitation activities currently in NICU. There is a potential to improve this by introducing virtual reality rehabilitation (VR) games for early mobilisation within the ICU. AHA/ASA recommends "range-of-motion activities, motor challenges and seated activities" within 24 h after stroke **t**o prevent deconditioning and orthostatic intolerance. We hypothesize that the use of VR games in stroke patients in NICU would improve their muscle strength and frequency of physiotherapy.
Objectives. To estimate a change in muscle strength by Medical Research Council (MRC) grading.

1. To assess the residual disability post-ICU discharge using Modified Rankin Score (MRS) and Functional Status Score for ICU (FSS-ICU)

Methods. 20 patients with a diagnosis of stroke of pure motor/sensory type affecting the limbs, Glasgow Coma Scale (GCS) 14–15, Richmond Agitation Sedation Scale (RASS) − 1 to + 1 were recruited. Eligible patients would use VR games to improve movement of upper and lower limbs daily under supervision of PT. The same PT reviewed the patients to assess MRC and FSS-ICU upon transfer out of the unit. The total number and duration of VR rehab sessions were recorded.
Results. 15 patients (75%) received 1 VR rehab in ICU, whereas 6 (30%) and 1 (5%) patient received 2 and 3 sessions, respectively. A total of 7 (35%), 9 (45%), and 4 (20%) patients received the first rehab session for 15, 20, and 25 min, respectively. On average, the total rehab duration was 27.5 min (Fig. 1).Majority of the patients (95%), returned to their premorbid status of physical mobility.12 patients (60%) had improvement in MRS score at hospital discharge.9 patients (45%) had improved motor strength of shoulder while 7 (35%) had improved motor strength of knee.FSS-ICU increased significantly at ICU discharge and hospital discharge (table 1).
Conclusions. Virtual Reality for early rehabilitation of stroke patients in the NICU is viable and shows promise.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000040

Introduction. Patients with COVID-19 associated acute respiratory distress syndrome (ARDS) have a high risk to develop acute kidney injury (AKI) (1, 2) and this may be associated with an up to 19-fold increased odds of in-hospital death in COVID-19 patients that develope AKI (3). Therefore, early prediction of AKI is crucial in order to implement preventive strategies. However, using current standard markers of kidney function such as serum creatinine and urinary output, the recognition of AKI is unacceptably delayed in up to 43% of hospitalized patients (4).
Objectives. This study investigates the predictive performance of tissue inhibitor of metalloproteinases 2 and insulin like growth factor binding protein 7 [TIMP-2]*[IGFBP7] in critically ill patients with COVID-19 associated ARDS.
Methods. This is a multicenter, prospective, observational study conducted at twelve centers across Europe and the United Kingdom. Critically ill patients with moderate or severe COVID-19 associated ARDS were included and serial measurements of [TIMP-2]*[IGFBP7] were performed. The primary endpoint was the development of moderate or severe AKI according to the KDIGO definition.
Results. The study enrolled 300 patients that were available for the primary analysis, and 39 met the primary endpoint. Outcome parameters differed significantly in all outcome measures between patients that developed moderate or severe AKI and those that did not (Table 1).
At enrollment, urinary [TIMP-2]*[IGFBP7] had high predictive value for the primary endpoint with an area under the receiver operating characteristic curve (AUC) of 0.89 (95% CI, 0.84 to 0.93). [TIMP-2]*[IGFBP7] was significantly higher in endpoint-positive patients at enrollment and at 12h.
Conclusions. Urinary [TIMP-2]*[IGFBP7] predicts the occurrence of AKI in critically ill patients with COVID-19 associated ARDS. In this study, we demonstrated that urinary [TIMP-2]*[IGFBP7] has an even better ability to predict AKI than in other settings (5, 6). When adding [TIMP-2]*[IGFBP7] to a clinical model, risk prediction increased significantly compared to only using clinical variables.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000044

Introduction. Coronavirus disease 2019 (COVID-19) is the result of infection with the emerged severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). The clinical spectrum ranges from mild, flu-like symptoms to a severe viral pneumonia in a minority of cases, resulting in an acute respiratory distress syndrome (ARDS). ARDS due to COVID-19 is characterised by a high risk of venous thromboembolisms (VTE), especially pulmonary embolism (PE) in at least 25% of ICU patients (1, 2). This occurs primarily in the absence of immunity acquired through vaccination or previous infection and in the presence of a hyperinflammatory innate immune responses to SARS-CoV-2, which fail to adequately limit viral replication (3). Timely recognition and treatment of PE is vital to improve survival. To study the role of peripheral blood mononuclear cells (PBMC) in the procoagulant state of COVID-19 patients, we performed a functional bioassay and related outcomes to the occurrence of PE. The currently used methods for diagnosing PE rely on detecting the end net result of the immunothrombosis pathway, i.e. the presence of macrothrombi and resultant organ dysfunction. The aim of this study was to determine whether an assay measuring the procoagulant properties of PBMC, which drive immunothrombosis in COVID-19, could show potential for early detection of PE in critically ill COVID-19 patients, especially, compared to data from computed angiography (CTA) and end-tidal to arterial carbon dioxide gradient. The latter is known as a sensitive measure of ventilation to perfusion mismatch (4).

Methods. PBMC were obtained from 20 patients with a computed tomography angiograph (CTA) proven PE and compared to 15 COVID-19 controls without a proven PE. Functional procoagulant properties of PBMC were measured using a modified fibrin generation time (MC-FGT) assay (5). Tissue factor (TF) expression on monocyte subsets were measured by flow cytometry. Additional clinical data were obtained from patient records including end-tidal to arterial carbon dioxide gradient.

Results. MC-FGT levels were highest in the samples taken closest to the PE detection, similar to the end-tidal to arterial carbon dioxide gradient (ETCO2–PaCO2), a measurement to quantify ventilation-perfusion mismatch. In patients without proven PE, peak MC-FGT relates to an increase in end-tidal to arterial carbon dioxide gradient. We identified non-classical, CD16 positive monocytes as the subset with increased TF expression.

Conclusions. We show that the procoagulant state of PBMC could aid in early detection of PE in COVID-19 ICU patients. Combined with end-tidal to ETCO2–PaCO2 gradient, these tests could improve early detection of PE on the ICU.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000045

Introduction. Patients presenting the most severe form of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) disease 2019 (COVID-19) pneumonia have a prolonged intensive care unit (ICU) stay and are exposed to broad-spectrum antibiotics, but the impact of COVID-19 on antimicrobial resistance is unknown.
Objectives. Primary objective: To investigate the association of COVID-19 with the cumulative incidence of ICU-acquired colonization and infection related to multidrug-resistant (MDR) bacteria (ICU-MDR-col and ICU-MDR-inf, respectively).
Secondary objectives: To describe the microbiology of ICU-MDR-col and ICU-MDR-inf in COVID-19 patients, and to determine whether COVID-19 modifies the impact of ICU-MDR-col and ICU-MDR-inf on ICU length-of-stay, invasive mechanical ventilation (IMV) duration and 28-day mortality.
Methods. Observational prospective before-after study in 7 ICUs in France. All consecutive patients with an ICU stay > 48 h and a confirmed SARS-CoV-2 infection were included prospectively and followed for 28 days. Patients underwent systematic screening for colonization with MDR bacteria upon admission and every week subsequently. COVID-19 patients were compared to a recent prospective cohort of control patients from the same ICUs [1]. Screening for MDR bacteria was similar in COVID-19 and control patients.
Results. During the first and second waves of the pandemic, 367 COVID-19 patients were included, and compared to 680 controls. After adjustment for prespecified baseline confounders, the cumulative incidence of a composite outcome including ICU-MDR-col and/or ICU-MDR-inf was not significantly different between groups (adjusted sub-hazard ratio [sHR] 1.39, 95% confidence interval [CI] 0.91–2.09). When considering both outcomes separately, COVID-19 patients had a higher incidence of ICU-MDR-inf than controls (adjusted sHR 2.50, 95%CI 1.90–3.28), but the incidence of ICU-MDR-col was not significantly different between groups (adjusted sHR 1.27, 95%CI 0.85–1.88).
Among MDR bacteria responsible for ICU-MDR-col and ICU-MDR-inf, third generation cephalosporins (3GC)-resistant *Enterobacteriaceae* were the most frequently isolated organisms (~75% in the overall cohort). Among patients with ICU-MDR-inf, COVID-19 patients had a higher incidence of ventilator-associated pneumonia (VAP) related to MDR bacteria than controls (65.7% vs. 36.5%).
The occurrence of ICU-MDR-col and/or ICU-MDR-inf was associated with a decreased survival (adjusted cHR 3.19, 95%CI 2.04–4.98) and a decreased duration of IMV (i.e., a higher probability of extubation alive, adjusted cHR 1.23, 95%CI 1.13 to 1.33) in COVID-19 patients, but not in controls. There was no impact of the occurrence of ICU-MDR-col and/or ICU-MDR-inf on ICU length-of-stay.
Conclusions. COVID-19 patients had an increased incidence of ICU-MDR-inf compared to controls, but the difference was not significant when considering a composite outcome including ICU-MDR-col and/or ICU-MDR-inf.

"Braking" the expiration: two diaphragms

G. Tagliabue[1], M. Ji[1], D. Zuege[2], P. A. Easton[1]
[1]Critical Care, Cumming School of Medicine U C, Calgary, Canada; [2]Department of critical care medicine, University of Calgary and Alberta Health Services, Calgary, Canada
Correspondence: G. Tagliabue
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000046

Introduction. There is growing clinical interest in understanding the role of the diaphragm in early expiration during mechanical ventilation (1,2). However, the current animal (1,2) and human (3,4) experimental evidence is inconclusive as to whether the "braking" activity is an inherent physiological function of the diaphragm, or if it is due to the experimental model adopted. Additionally, given the evidence of differences between the costal and crural segments (5,6) of the diaphragm, it is unclear if this activity is homogeneously distributed throughout the entire diaphragm.
Objectives. 1) Is the diaphragm normally active into expiration during spontaneous breathing and hypercapnic ventilation? 2) Is expiratory diaphragmatic activity distributed equally among the segments of the diaphragm, costal and crural?
Methods. In 13 spontaneously breathing canines, awake without confounding anesthetic, we measured directly both the inspiratory and expiratory electrical activity (EMG), and corresponding mechanical shortening of costal and crural diaphragm, at room air and during several levels of hypercapnia (RoomAir ~ 38 mmHg; LowPETCO2 ~ 46 mmHg; MidLowPETCO2 ~ 53 mmHg; MidHighPETCO2 ~ 58 mmHg; HighPETCO2 ~ 63 mmHg).
Results. During eupnea, costal and crural diaphragm are active into expiration, showing significant and distinct expiratory activity, with crural expiratory activity greater than costal, for both magnitude and duration (Fig. 1,2). This diaphragm segmental difference diverged further during progressive hypercapnic ventilation: crural expiratory mechanical activity progressively increased, while costal mechanical expiratory activity disappeared (Fig. 3).
Conclusions. 1. The diaphragm plays an active role during expiration, and its expiratory activity, commonly referred to as "braking," is routinely expressed during spontaneous breathing.
2. However, this activity is not equally distributed between the costal and crural segments of the diaphragm. Studies have shown that the "braking" activity of the crural diaphragm is greater in magnitude and duration than that of the costal segment.
3. As hypercapnia leads to an increase in ventilation, the expiratory activity—"braking"- diverges notably between the two diaphragm regions. Indeed, crural expiratory activity greatly increases, while costal expiratory decreases in magnitude and duration, and tend to disappear.
The distinct expiratory response for each diaphragm segment would suggest a differing neural activation of the two segments.

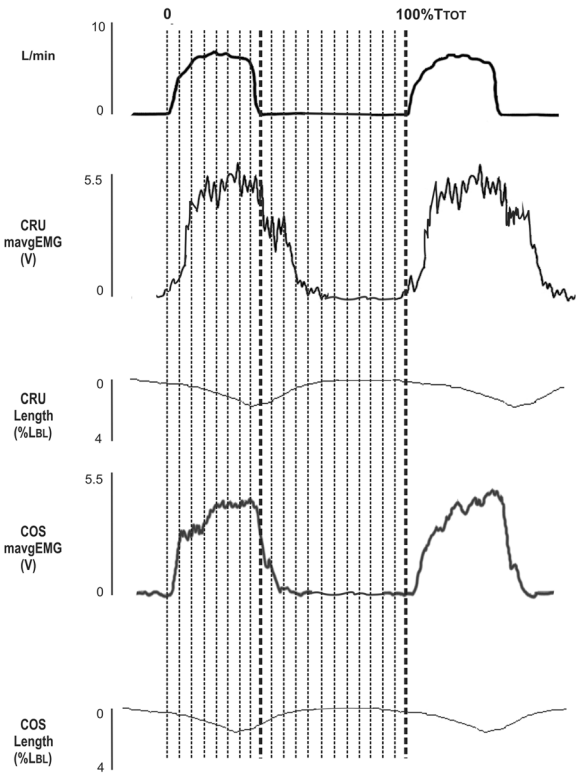

Figure 1 (abstract 000046)
The expiratory activity of crural diaphragm, is greater than costal, during eupnea.
Visualization of intrabreath analysis with percentage of Total time (%TTOT) slices of the whole breath. Typical recording of airflow, Crural, Costal diaphragm EMG (Volt, V) activity, and Shortening, during baseline room air (mean ~ 38 PETCO2 mmHg).
From *top* to *bottom*: airflow, moving average EMG (mavgEMG), and Shortening (%LBL) of Crural (CRU) and Costal (COS) diaphragm, respectively.

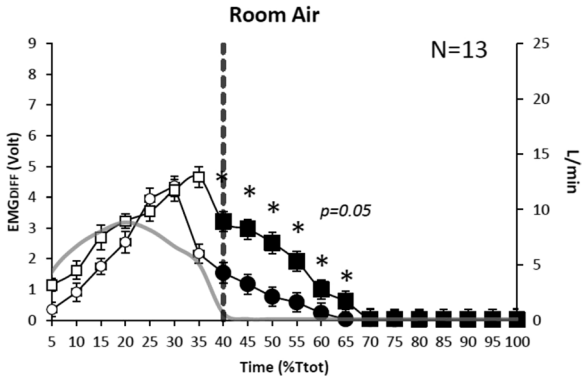

Figure 1 (abstract 000046)
Intrabreath profile of Crural (black square) and Costal (black dot) EMG activity. The "braking" activity of Crural is significantly greater than Costal, at room air.

EMG activity (Volt) is expressed in absolute values, at Room Air. Airflow, gray line; onset of expiration, vertical dot line. Significance, * $P < 0.05$.

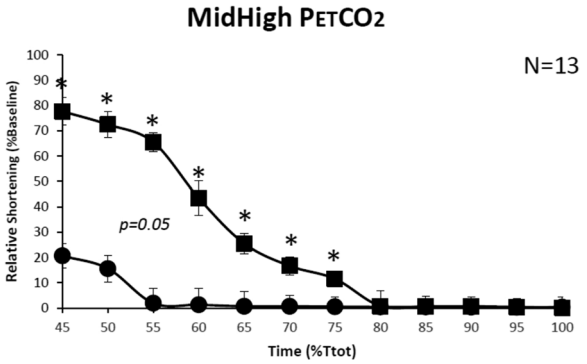

Figure 3 (abstract 000046)
During hypercapnia, the relative mechanical action of Crural (black square) is significantly greater than Costal (black dot). Diaphragm Shortening is expressed as relative values. Significance, *$P < 0.05$.

Oxygen debt as a predictor of high-flow nasal cannula therapy failure in SARS-CoV-2 patients with acute respiratory failure: a retrospective cohort study

M. Pérez-Garzón[1], C. Poveda-Henao[1], A. Rozo-Salinas[1], M. Diaz-Ardila[2], H. Robayo-Amortegui[3]

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000049

Introduction. Severe acute respiratory syndrome coronavirus type 2 (SARS-CoV-2) is characterized by its rapid progression to acute hypoxemic respiratory failure (AHRF) (1), with a prevalence between 20 and 40% 2. It requires increased oxygen therapy and, in the case of progression, there is the need for orotracheal intubation (OTI) and early invasive mechanical ventilation (IMV) to avoid self-inflicted lung injury (SILI) (2).

High-flow nasal cannula therapy (HFNC) is increasingly used in the treatment of ARTI, secondary to SARS-CoV-2 infection, as a potentially attractive strategy to avoid IMV (3). Multiple predictor indices of OTI requirement and the need for admission to the intensive care unit (ICU) have been developed (1), such as the 4C (4) and the ROX index (iROX) (5), with a failure of 29% of these scales in the population (6). They have a sensitivity of 86.8%, a specificity of 52.2%, and an AUROC of 0.759 (6).

The oxygen debt (DEOx) determines the total amount of oxygen molecules that does not supplement excessive oxygen consumption (VO2) at rest, without being altered by body temperature, age, and body surface area (7,8), indicating an increase in oxygen demand to tissues below the critical oxygen delivery (DO2) (7,8). Studies have proposed simplified formulas, with the use of base excess (BE) and lactate in comparison with other variables. They have an adequate correlation and easy clinical application (7), as a perfusion parameter and management center of the critical patient (7,9), acquired in arterial gases for a quantitative, reproducible, feasible, and easily accessible measurement.

Given the uncertainty surrounding the decision to advance OTI in patients with SARS-CoV-2 who were under management with HFNC, it is important to develop and validate stratification tools to define when to initiate IMV (7).

Objectives. The aim of the study was to determine the validity of quantitative measurement of oxygen debt (DEOx) according to arterial gases compared to the use of iROX in patients with high-flow nasal cannula (HFNC) therapy requirement, presenting with acute respiratory failure as a consequence of SARS-CoV-2 infection. In addition, we aimed to identify the factors associated with the need for orotracheal intubation (OTI).

Methods. This is a retrospective observational cohort study of a database collected from patients with SARS-CoV-2 infection admitted to intensive care units with hypoxemic acute respiratory failure and had received HFNC upon admission during the Covid-19 pandemic (March 23, 2020 through August 02, 2021). The variables of interest were factors determining the predictive ability of DEOx and iROX. We used a multiple logarithmic regression model to correct for confounding and mixed-effects variables, and validated for OTI in patients treated with HFNC.

Results. From a total of 373 patients treated with HFNC, 317 patients (84.9%) required invasive mechanical ventilation. APACHE II (AOR 1.44; 95% CI: 1.14–1.83, p 0,032), vasopressor use (AOR 27.7; 95% CI: 1.83–420,63, p 0,017), and DEOx (AOR 1.26; 95% CI: 1.10–1.44, p 0,001) were associated with the need for intubation. The predictive model between iROX and DEOx evidenced an AUC of 0.535 vs. 0.606, respectively, with a DEOx cut off point of 7.14 ($\pm$10.16, $p < 0.01$). DEOx as an independent factor of OTI presents an OR 2,48 with cut point 4.5 mlO2/kg (AUC 0.780, CI 95%, 0.753–0.808, $p < 0.01$).

Conclusions. Our study is the only one that documents the usefulness of DEOx as a quantitative measurement to predict the need for OTI in patients with acute respiratory failure associated with SARS-CoV-2 infection who were being managed with HFNC according to the models established in multiple logarithmic regression with the correction of confounding variables with a good predictive value above iROX. This could be a reproducible and valid method to implement its use and extrapolate to other populations. Oxygenation was not a good factor for failure in HFNC, whereas APACHE II, vasopressor use, and albumin were independently associated with intubation. Further studies and data from other centers are needed to characterize the usefulness of DEOx more precisely in view of the possibility of further expanding a term with global characteristics in intensive care and of great clinical relevance.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000052

Introduction. Brain death triggers an inflammatory cascade that damages organs before harvesting, affecting the quality of grafts and, consequently, transplantation outcomes. This randomized clinical trial aims to compare the effect of liraglutide versus placebo in attenuating brain death-induced inflammation and oxidative stress in brain-dead donors.

Methods. We conducted a double-blinded, placebo controlled, randomized clinical trial involving brain-dead donors. Subjects were randomized to receive either liraglutide or placebo after completion of brain death protocol and where followed until organ retrieval. Primary outcome was the reduction in interleukin-6 (IL-6) serum levels. Secondary outcomes were changes in other serum pro-inflammatory (IL-1β, INF-δ, TNF-α) and anti-inflammatory cytokines (IL-10), expression of antiapoptotic (*BCL-2*, *BIP*, *CHOP*) and antioxidant (*SOD-2*, *UCP-2*) genes, and expression of inflammatory (TNF), antiapoptotic (CHOP) and antioxidant (SOD-2) proteins in liver biopsies. Cytokines were measured using multiplex ELISA method. Gene expression was evaluated by RT-qPCR in liver tissue, and protein quantification was performed by immunohistochemistry in paraffin-embedded liver sections.

Results. From September 2018 to December 2020, a total of 50 brain-dead donors were randomized to receive subcutaneous liraglutide or placebo. Liraglutide group had lower cytokine levels compared to placebo during the follow-up: Δ IL-6 (− 28 [− 182 to 135] *vs*. 32 [− 10.6 to 70.7] pg/mL; p = 0.041) and Δ IL-10 (− 0.01 [− 2.2 to 1.5] vs. 1.9 [− 0.2 to 6.1] pg/mL; p = 0.042), respectively. Gene and protein expression were not modified by liraglutide. Treatment with liraglutide did not increase organ recovery rate OR 1.24 (CI95% 0.18–8.64), p = 0.82.

Conclusions. The use of liraglutide reduces IL-6 and prevented the increase of IL-10 levels in brain-dead donors. [T1] Expression of genes and proteins related to inflammation, apoptosis and oxidative stress were not modified by treatment with liraglutide. ClinicalTrials.gov ID: NCT03672812.

[T1]Cris, ajuda a descrever melhor isso: a IL-6 cai, mas a IL-10 sobe menos com liraglutida.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000055

Introduction. Coronavirus disease 2019 (COVID-19) has spread around the worldwide since its initial outbreak in Wuhan China in December 2019, with a global mortality rate of 5% (1). Observing severe clinical forms that require management in an intensive care unit (ICU) and those presenting with adult respiratory distress syndrome (ARDS) and/or Multiple organ dysfunction syndrome (MODS) (2), highlights the importance of ICU in the assessment, stabilization and management of these patients during the pandemic.

One of the main goals of patient care in the ICU is to maintain an adequate delivery of oxygen (DO2) to the tissues, which allows sufficient production of cellular energy to guarantee adequate organic functioning; in other words, to correct the oxygen debt (DEOx) generated during critical conditions to maintain the basic cellular processes that allow the patient to survive (3). The DEOx concept is commonly used in the ICU to indicate a change from aerobic to anaerobic metabolism (3), but its clinical utility is not completely clear (3), being a little used tool and in many places a " end forgotten." However, in studies of hemorrhagic shock (4) and postoperative states (5,6), DEOx has shown a correlation with the clinical outcomes of MODS and mortality (6,7).

In patients with severe SARS-CoV-2 (Severe acute respiratory syndrome coronavirus 2) infection, there may be a deficit in oxygen consumption (VO2) (6) and wide variability in the patient's clinical

condition; DEOx measurement is not is altered by factors such as age, body surface area, and temperature (4), and can be used as a prognostic tool in these patients. DEOx has a simple and reproducible calculation that indicates the critical DO2 at rest (8), calculated from equations where the levels of lactate and base excess (BE) obtained from arterial gases are used (4). DEOx is not included in general prognostic scores such as the SOFA Score (Sequential Organ Failure Assessment score) (8), APACHE II Score (Acute Physiology and Chronic Health Evaluation II) (9), or in specific scores for COVID-19 such as the 4C (10), which opens the possibility that this value can generate additional, useful and complementary information to that provided by these scores. However, DEOx has not been widely and reliably studied in severely ill COVID-19 patients. The aim of this study was to determine the validity of DEOx through indirect quantitative calculation to predict MFO and 28-day mortality in patients admitted to the ICU.

Objectives. The main goal of critical patients is to maintain an adequate tissue DO2, avoiding DEOx as an indicator of critical DO2. The objective of this study was to determine the validity of DEOx through indirect quantitative calculation to predict MODS and 28-day mortality in patients admitted to the ICU for SARS-CoV-2 infection in relation to the APACHE II, SOFA, and 4C Scores.

Methods. Retrospective cohort study included patients with SARS-CoV-2 infection admitted to the ICU between 2020 and 2021. Acute Physiology and Chronic Health Evaluation (APACHE II), Sequential Organ Failure Assessment (SOFA) and 4C mortality scores were calculated upon admission to the ICU, comparing its accuracy in predicting mortality at 28 days and FOM with DEOx.

Results. 708 patients were included, with a mortality rate of 44.4% (n = 315), of these, 72.5% were men, with a DEOx value of 11.16 ml O2/kg. The mean age was 58.7 (SD 14.51) years. Multivariate analysis independently related DEOx to mortality, as well as intubation with an OR of 8.69 (95% CI, 4.28–17.62) and renal injury of 3.35 (95% CI, 2.40–4.68), and for each point increase in creatinine the risk of MODS increased with an OR of 4.1 (95% CI, 1.87–8.98). To determine the precision of the scores, an AUROC analysis was performed with weak discrimination and similar behavior for the primary outcomes. The most accurate scale for mortality and MODS was 4C with an AUC of 0.683 (95% CI, 0.64–0.72) and APACHE II with an AUC of 0.814 (95% CI, 0.77–0.85), while that of AROC of DEOx was 0.612 (95% CI, 0.57–0.65) and 0.646 (95% CI, 0.57–0.71), respectively.

Conclusions. DEOx as a predictor of MODS and 28-day mortality in a critically ill patients with SARS CoV-2 was similar to the APACHE II, SOFA, and 4C scores. The correlation of the DEOx with these scales can be useful for early interventions in the critically ill patients.

Sirt3 deficiency influences spontaneous recurrent seizures and exacerbates hippocampal cell death

W. J. Kim[1]
[1]Neurology, Yonsei University Hospital, Seoul, Republic of Korea
Correspondence: W.J. Kim
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000056

Introduction. Status Epilepticus (SE) is kind of common neuronal disorders that accompanied with persistence seizure with oxidative damage, and consequently it can be acquired chronic epilepsy, goes through the latent period. Excessive oxidative stress can cause neuronal cell death in acute epileptic phase that is key factor in progression of epileptogenesis. Sirtuin 3(Sirt3) is NAD+-dependent histone deacetylases, has been considered as an important role through regulating manganese superoxide dismutase (Mn SOD), which is major antioxidant enzymes that contributes to aging and neurodegeneration. In present study aims to investigate the effect of Sirt3 deficiency on neuronal damaged and epileptogenesis following pilocarpine-induced SE.
Methods. Sirt3 KO on a C57BL/6 background and wild-type (WT) C57BL/6 mice were administrated to pilocarpine. Seizure onset, spontaneous recurrent seizures and mortality are assessed. At 2 months after pilocarpine-induced SE, hippocampal damage assessed. In addition, alteration of astrocyte and MnSOD activity were assessed in latent period.
Results. Sirt3 deficiency showed increased mortality rate, but no difference detected in seizure onset time after pilocarpine injection. Interestingly, total numbers of spontaneous recurrent seizures were increased, and hippocampal neuronal loss remarkably exacerbate in chronic epileptic period in Sirt3 deficiency. Also, severe gliosis and decreased MnSOD activity was detected in Sir3 deficiency rather than WT.
Conclusions. This study suggest that Sirt3 deficiency could be related with development and severity of spontaneous recurrent seizures during epileptogenesis in pilocarpine – induced seizure model.

The role of pulmonary endothelial cell-derived extracellular vesicles in acute respiratory distress syndrome

L. Wang[1], Y. Tang[1], C. Jie[1], H. Qiu[1]
[1]Jiangsu Provincial Key Laboratory of Critical Care Medicine,Department of Critical Care Medicine, Zhongda Hospital, School of Medicine, Southeast University, Nanjing, China
Correspondence: L. Wang
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000057

Introduction. Acute lung injury (ALI)/acute respiratory distress syndrome (ARDS) is an acute life-threatening respiratory critical syndrome with acute onset, rapid progression and high mortality. There is still a lack of effective therapeutic drugs, hence it is urgent to find new therapeutic targets. Emerging evidence indicates extracellular vesicles (EVs) play a critical role in the pathogenesis of inflammatory diseases [1]. Our earlier studies revealed that EVs isolated from the perfusate of the ex vivo perfused human ALI model could cause acute injury in naive human lung, and demonstrated that these EVs were primarily derived from endothelial cells [2], suggesting that pulmonary endothelial cell-derived EVs (EC-EVs) play an important role in ARDS. However, it is still unknown how EC-EVs aggravate lung injury.
Objectives. To clarify the role and underlying mechanisms of EC-EVs in the occurrence and development of ALI/ARDS.
Methods. Mouse pulmonary microvascular endothelial cells were stimulated with LPS or not to isolate normal EC-EVs (Con-EVs) or inflammatory EC-EVs (LPS-EVs). These EVs were injected into C57BL/6J wild-type mice intravenously and then examined for lung inflammation by qRT-PCR and histological assessment. Fluorescence labeled EVs were injected into mice, flow cytometry analysis confirmed the target cells of LPS-EVs among various immune cells. Clodronate liposome was used to reduce peripheral monocytes before injection of LPS-EVs into mice, and then the degree of lung injury and inflammation was measured. Multicolor flow cytometry was used to evaluate the phenotypic changes of pulmonary monocyte-derived macrophages in mice treated with LPS-EVs. In vitro co-culture system was applied where the mouse bone marrow-derived monocytes were co-cultured with EC-EVs to further confirm the results of in vivo studies by flow cytometry, qRT-PCR and ELISA.
Results. The mice injected with LPS-EVs exhibited varying degrees of increased respiratory rate, mental distress, and decreased food intake. Further testing revealed that the expression of inflammatory factors in the lung tissue of LPS-EV-treated mice was significantly higher than that of Con-EV-treated mice, which was consistent with the results of pathological sections of the lung tissue, indicating that LPS-EVs could lead to ALI. Flow cytometry results showed that the injected LPS-EVs were preferentially ingested by monocytes in the lung. The degree of lung injury and inflammation caused by LPS-EVs was decreased after

the depletion of monocytes. In addition, in vivo studies showed that LPS-EV treatment significantly increased the number of monocyte-derived macrophages in the lung and promoted their differentiation into the pro-inflammatory M1 type macrophages, but it was worth noting that LPS-EV treatment had no effects on tissue resident macrophages. In vitro studies also confirmed that LPS-EVs could drive mouse bone marrow-derived monocytes to differentiate into M1 type macrophages.

Conclusions. The present study demonstrated that EC-EVs generated upon inflammatory stimulation could lead to lung injury by targeting monocytes and changing their fate into pro-inflammation macrophages. This study revealed an unknown crosstalk between endothelial cells and monocytes, and clarified the important role of EC-EVs in the development of ALI/ARDS, which is expected to provide new therapeutic targets for the prevention and treatment of ALI/ARDS.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000058

Introduction. Up to 20% of patients with COVID-19 get critically ill and require intensive care unit (ICU) admission. At hospital discharge, most patients still have physical and mental limitations, which affect their quality of life. Pulmonary functional alterations in patients with COVID-19 vary from the absence of functional abnormalities to restrictive and diffusion impairments.

Objectives. We aimed to describe pulmonary function abnormalities as well as their impact on the 6-min walk test (6 MWT) and SF-36 physical component summary (PCS) score in patients with COVID-19 at $\geq$ 3 months after hospital discharge.

Methods. This retrospective observational cohort study included 65 patients 18 years and older with severe COVID-19 confirmed by real-time reverse transcriptase-polymerase chain reaction (RT-PCR), admitted to a 35-bed intensive care unit of a tertiary hospital from April 2020 to October 2021. Pregnant and breastfeeding women, palliative care as well as chronic obstructive pulmonary disease and symptomatic asthmatic patients were excluded. Patients were evaluated after at least 3 months after hospital discharge in our multidisciplinary follow-up clinic. A trained research team applied the 6-min walk test, pulmonary function tests and the physical component summary (PCS) score of quality of life.. Pulmonary function tests included forced vital capacity (FVC), forced expiratory volume in the first second (FEV1), FEV1/FVC ratio and MMEF (maximal mid-expiratory flow) using spirometer Spirobank II—MIR, Italy. The standardization and categorization of functional changes were based on Brazilian guidelines for pulmonary function tests.

Results. From April 1, 2020, to October 31, 2021, 689 patients were admitted to the ICU for COVID-19 at the Hospital São Domingos. Moreover, 358 and 332 patients were discharged from the ICU and hospital, respectively. Among them, 65 discharged patients were evaluated at the hospital's ICU follow-up clinic within a median post-discharge period of 146 (120–183) days The median age of the enrolled participants was 50 years (43–60 years), with 36 (55.3%) men and 29 (44.6%) women. The most common comorbidity was hypertension (22 patients, 33.8%), followed by diabetes (13 patients, 20%) and obesity (9 patients, 13.8%). In addition, 45 (69.2%) patients underwent invasive mechanical ventilation. Furthermore, 27 (41.5%) patients had abnormal PFT findings as follows: FVC < 80% in 21 (32.3%) patients, FEV1 < 80% in 17 (26.1%) patients, FEV1 / FVC < 0.7 in 0 patients, and MMEF < 65% in 4 (6.1%) patients. Compared with patients without abnormal PFT findings, patients with abnormal PFT findings were older and had significantly higher ferritin levels [1358 (635–1807) vs. 2000 (886–3000), $p = 0.02$]. There were no significant between-group differences in invasive and noninvasive respiratory support, mechanical ventilation duration, vasopressor use, and renal replacement therapy. However, compared with the group with normal PFT findings, the group with abnormal PFT findings showed a significantly lower 6-MWT score [78% (0.0–92) vs. 95% (75–100), $p = 0.01$] and worse PCS scores [39.4 (32.1–51.3) vs. 52.0 (47.4–57.3), $p = 0.007$].

In the logistic regression model of PFT after 4 months with adjustment for independent covariates, multivariate analysis showed statistical significance for the PCS ($p = 0.01$) and a tendency toward significance for the 6-MWT ($p = 0.09$).

Conclusions. This retrospective study showed that a significant proportions of patients who are discharged from hospital after treatment of severe COVID-19 present alterations in pulmonary function tests after at least 3 months of the discharge and these alterations impact on physical functional capacity and quality of life.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000060

Introduction. Quality Improvement (QI) Project was set out in the Surgical Intensive Care Unit (SICU) with aim to improve Delirium Management. Duration of delirium is an independent predictor of long-term cognitive impairment after critical illness. Delirium in ICU results in increased morbidity and mortality, motor, cognitive and functional decline, LOS in hospital & hospital costs. 66–84% of delirium in its hypoactive form remains unrecognized. Early diagnosis of delirium improve the prognosis of the patients.

Objectives. To increase the percentage of patients (aged 65 years old and above, SICU emergency admission) receiving optimal delirium management** from 17 to 80% within 6 months.

**Optimal delirium management includes both timely detection and structured delirium intervention.

Timely detection of delirium
+ delirium risk assessment within 24h of admission to SICU.

+ accurate CAM-ICU use.
+ delirium documented as current issue in patient's notes.

Structured delirium intervention
+ correct siting of patient to receive multi-disciplinary delirium management care.

+ delirium prevention OR delirium intervention.

Methods. Methodology used for Quality Improvement Project, including macro and micro flowchart following a patient journey, root cause analysis as evidenced on the cause and effect diagram. Pareto chart to determine which root causes to embark on to target root cause for interventions. Intervention were then carried out through Plan-Do-Study-Act (PDSA) cycles to implement interventions in a step wise process and measure if there are improvements to the rates of Delirium Care management during the period of May through July 2022.

Results. With the implementation of a multi-disciplinary delirium management with the aim to improve optimal delirium management, the baseline rate for optimal delirium care increased from 17% to 31.3% on average 11 weeks after initiation of the quality improvement. This includes timely detection of delirium onset as well as structured delirium management strategies based on risk categories—with patients at lower risk into delirium prevention or higher risk patient receiving delirium intervention.

There was also 1 day reduction in delirium duration of 4 to 3 days for those who developed duration after the interventions has been introduced, and these could translate to potential cost savings of SGD $44,255. ICU length of stay is also reduced by 1 day.

We recognize that delirium is also multifactorial, and data from retrospective collection of data could have its limitations as well, and results showed are of association rather than casusation. There are also other benefits of having a structured management plan which includes better coordination and awareness among various multidisciplinary care teams—including the nursing, physiotherapist, occupational and medical team in managing the patient.

Conclusions. In conclusion, delirium which has a multifactorial cause, would benefit from a structured management plan. Patients at risk of delirium should be assessed for delirium routinely and multi-disciplinary structured intervention targeted to patients based on their risk categories. This could help to reduce delirium duration, potentially length of ICU stay and significant cost savings.

Risk prediction for subsequent infection after colonization with carbapenem-resistant Enterobacterales

G. Zheng[1], H. Bai[2], C. Jiaqi,[3], H. Juan[4]
[1]School of Public Health, Li Ka Shing Faculty of Medicine, The University of Hong Kong, Shanghai, China; [2]Pharmacy, Chongqing University Cancer Hospital, Chongqing, China; [3]Clinical Laboratory, Kunshan Hospital Affiliated to Nanjing University of Chinese Medicine, Kunshan, China; [4]Pharmacy, Ruijin Hospital Affiliated to Shanghai Jiao Tong University School of Medicine, Shanghai, China
Correspondence: G. Zheng
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000063

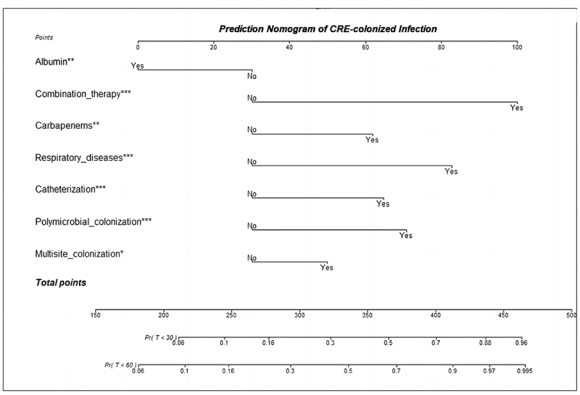
Introduction. Colonization of carbapenem-resistant *Enterobacterale* (CRE) is considered as one of vital preconditions for infection, with high morbidity and mortality. Identifying potential risk factors for the switch from CRE colonization to infection is significant for early detecting high-risk patients and developing effectively preventive and therapeutic strategies.

Objectives. To construct a reliable prediction model and develop preventive and therapeutic strategies for those high-risk infected CRE carriers.

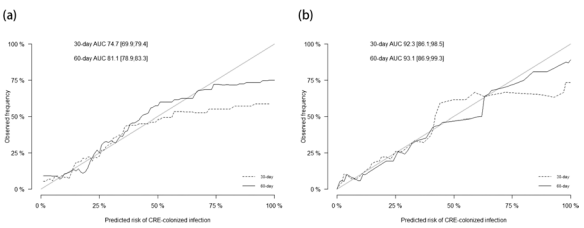
Methods. A retrospective cohort study was conducted in two Chinese tertiary hospitals for patients with CRE colonization from 2011 to 2021. Univariate analysis and the Fine-Gray subdistribution hazard model were utilized to identify potential risk factors for CRE-colonized infection, while death was the competing event. A nomogram was established to predict 30-day and 60-day risk of CRE-colonized infection.

Results. 879 eligible patients were enrolled in our study and divided into training (n = 761) and validation (n = 118) group, respectively. There were 196 (25.8%) patients suffered from subsequent CRE infection within 20 (interquartile range [IQR], 14–32) days after detection of colonization. Multisite colonization, polymicrobial colonization, catheterization and receiving albumin after colonization, concomitant respiratory diseases, receiving carbapenems and antimicrobial combination therapy before CRE colonization within 90 days were reserved in final model. Model discrimination and calibration were acceptable for predicting the probability of 60-day CRE-colonized infection in both training (area under the curve [AUC], 74.7) and validation dataset (AUC, 81.1). Decision-curve analysis revealed a significantly better net benefit in current model.

Conclusions. In conclusion, as a convenient clinical tool, our nomogram exhibits a good predictive performance, which could be useful to early identify CRE carriers with high risk of subsequent infection.



Model-informed nomogram for prediction of 30-day and 60-day cumulative risk of developing subsequent CRE infection. Abbreviation: CRE: carbapenem-resistant *Enterobacterales*; Pr: Probability; T: Time (days).



Calibration curves for the (a) training dataset and (b) validation dataset. The AUC is expressed as the point estimates and 95% CI. A clinical prediction model with an AUC value > 80 is deemed to have a good discriminatory accuracy. The 45° angle long black solid line indicates an ideal calibration, as predicted and observed probabilities are equal. Abbreviations: AUC: the area under the curve; CI: confidence interval; CRE: carbapenem-resistant *Enterobacterales*.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000067

Introduction. Early initiation of continuous renal replacement therapy (CRRT) improves outcomes in patients with acute liver failure (ALF), however there are no studies in patients with acute on chronic liver failure (ACLF).

Methods. ACLF patients with septic shock and Stage 3 AKI after initial fluid resuscitation underwent open-label randomization to early group (EG) wherein CRRT was initiated within 6–24 h of presentation while in the late group (LG) CRRT was initiated once the patient met absolute criteria. Dialysis response was defined as improvement in hemodynamics with lactate clearance after initiation of CRRT at 48 h. Renal recovery was defined as discontinuation of CRRT with improvement in renal functions and urine output > 400 ml/day in patients who were anuric. Urine and plasma samples (n = 30) were collected at initiation of CRRT and after 48 h for analysing the impact of CRRT on markers of inflammation and endothelial function, renal injury and repair. Primary endpoint was 28-day mortality.

Results. Fifty-one patients with ACLF (aged 41.36 ± 9.57 years, 93% males), 78% alcohol-related with mean MELD 37.72 ± 6.84, and SOFA 12.36 ± 3.10 score were enrolled. Baseline demographic and renal parameters were comparable. The cause of sepsis in the majority of patients was pneumonia [80.0% vs. 83.7%; p = 0.795] in EG vs. LG respectively. Dialysis response was associated with higher chances of renal recovery, P < 0.001, OR 0.118, 95% CI 0.061–0.226. Time to CRRT initiation from septic shock was significsntly associated with renal recovery, P = 0.011, OR 0.95**,** 95% CI 0.92–0.99. Each hour delay in initiation of CRRT from the onset of septic shock was associated with 5% decrease chance of renal recovery. The mean time to CRRT in EG (n = 50) and LG (n = 50) after vasopressors was 14.47 ± 5.38 and 47.73 ± 27.98 h respectively (p < 0.001). Mean dosage of CRRT in both group was not different [20.13 ± 0.82 vs. 20.76 ± 2.21; p = 0.135].

Mortality at 28-days [20 (48.8%) vs. 36 (81.8%); p = 0.048] was significantly lower in the EG. Patients in EG showed a significantly higher urea reduction ratio [27 (54%) vs. 14 (28.6%); p = 0.014], recovery of renal functions [22 (44%) vs. 10 (20%); p = 0.018], and a lower incidence of intradialytic hypotension (IDH) [23 (39.7%) vs. 35 (60.3%); p = 0.025]. The two groups were comparable for achievement of target ultrafiltration goals [19 (43.2%) vs. 11 (23.9%); p = 0.074], lactate clearance at 24 h [20 (45.5%) vs. 14 (30.4%); P = 0.192], and the duration of intensive care unit stay (7.12 ± 2.38 vs. 5.43 ± 1.67; p < 0.001). The dialysis response was higher in EG [36 (72%) vs 25 (50%); p = 0.031] and the duration of RRT was better in EG [60.9 ± 51.7 vs. 33.9 ± 45.9; p = 0.032]. Patients in LG showed significantly higher renal injury and decreased renal repair markers at CRRT initiation. A significant decrease in renal and endothelial injury, increase in repair markers was noted in dialysis-responders. [Figure].

Conclusions. Early initiation of CRRT restores hemodynamics, endothelial function, enhances renal recovery and improves overall outcomes and should be considered in ACLF patients with septic shock and AKI.

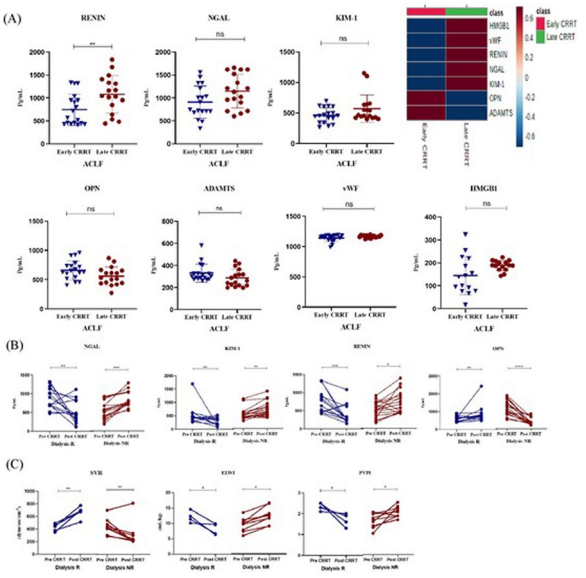

Fig 1 (abstract 000067) In baseline urine maker analysis, renal injury maker Renin were significantly high in late CRRT (continuous renal replacement therapy) with respect to patients with early CRRT. Also, heatmap depicted the segregation in their respective groups. (B) Further, urine NGAL, renin and KIM - I (Kindney injured molecule-1) were significantly elevated after post RRT in dialysis non-responder

(D-NR) patients, while these markers were declined after post therapy in case of dialysis responders (DR). ALso, the renal repair marker OPN (osteopontin) was significantly increased after post therapy in DR as compared to D-NR. In vascular functional analysis, ADAMTS (was signigficantly eleverated after RRT in DR as compared to D-NR. On the other hand, vascular injury marker vWF (Von WIillebrand factor) was significantly increased after therapy in D-NR. (C) Futhermore, patients with DR showed improvement in Pulmonary functionality [lung water (ELWI), pulmonary vascular permeability index (PVPPI) and systemic vascular resistance (SVR)].

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000069

Introduction. Bioelectrical impedance analysis (BIA) has advantages of obtaining results quickly, safely, reproducibly, and non-invasively. Phase angle (PhA) is one of the parameter of BIA, its values represent the permeability or integrity of cell membrane. With the exception of C-reactive protein (CRP), few studies have estimated an association between PhA and these conventional biomarkers. Herein, we aimed to investigate the association between the PhA value and the conventional inflammatory markers in postoperative patients in intensive care unit (ICU). Also, the correlation between the change in PhA and the occurrence of infectious complication were determined.

Methods. From July 2020 to February 2022, retrospective observation study conducted in 221 patients who admitted to ICU after abdominal surgery. BIA measurements and blood sampling were routinely performed the next morning. The relationship between PhA and the inflammatory markers were assessed after adjusting for age and body mass index (BMI). Univariate and multivariate logistic regression analysis was performed to examine the predisposing factors for postoperative infections.

Results. Among 221 patients admitted to ICU after abdominal surgery, infectious complications occurred in 62 cases. CRP, procalcitonin, or presepsin levels were negatively correlated with PhA in both gender. (− 0.295, − 0.198 or − 0.212 of partial correlation coefficients, respectively in males, and 0.313, − 0.245 or − 0.36 of partial correlation coefficients, respectively in females) But, white blood cell did not show significant association with PhA in both genders. For males, increased level of CRP on postoperative day1(POD1) was revealed as the significant predicting factor for postoperative infectious complication [odds ratio (OR): 1.184, 95% confidence interval(CI): 1.090–1.285, $p < 0.001$]. For females, increased Acute Physiology and Chronic Health Evaluation II score at admission (OR: 1.457, 95% CI: 1.068–1.987, $p = 0.018$), increased level of presepsin on POD1 (OR: 1.003, 95% CI: 1.001–1.006, $p = 0.016$) and decreased value of PhA on POD1 (OR: 0.980, 95% CI: 0.967–0.993, $p = 0.003$) were revealed as the significant predicting factors.

Conclusions. Phase angle obtained through BIA can be used as a predictor of infection as it shows a significant association with inflammatory markers. Phase angle measurements through BIA could improve patient prognosis after abdominal surgery through the careful observation of infections and early, appropriate treatment.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000070

Introduction. Cytomegalovirus (CMV) reactivation must be kept in mind in differential diagnosis over Intensive Care Unit (ICU) admitted critical patients, especially SARS-CoV-2 sufferers.
Objectives. To evaluate CMV reactivation precocity over severe COVID-19 pneumonia patients, we decided to describe incidence and time to diagnose.
Methods. A descriptive study (February 2020 to December 2022) over severe SARS-CoV-2 pneumonia admitted to Guadalajara ICU (Spain). Demographics, severity, time to CMV reactivation diagnosis and type of sample were evaluated. Samples were extracted in patients with hematologic or hepatic analytics alterations, fever or sudden respiratory deterioration. The diagnosis was made by plasma and/or bronchoalveolar lavage (BAL) polymerase chain reaction (PCR). Categoric variables were expressed as frequencies and percentages, and qualitatives as median and interquartile range.
Results. PCR for CMV was extracted from over 125 (42,4%) out of 295 patients (100%) admitted to ICU with severe COVID-19 pneumonia. The time from ICU admission to CMV reactivation suspicion median was 9 days, and 20 days from ICU admission to symptoms onset. BAL PCR was performed in 77 patients (61,6%), plasma PCR in 97 patients (77,6%) and both-acquired in 49 patients (29,2%). A positivity of 28.6% (22 patients) in BAL samples, 46.4% (45 patients) in plasma samples, and 34,7% (17 patients) in both-acquired was found (see table).

Variables	N = 125
Demographics and severity	
Age (years)	**67,0** (58,9–73,53)
Male (%)	**90** (72,0)
Charlson Comorbidity Index	**3** (2–4)
APACHE II	**18** (15–21)
SOFA	**7** (5–8)
Symptoms onset—ICU admission (days)	**10** (7–14)
ICU stay (days)	**30,8** (18,3–48,0)
ICU mortality (%)	**41** (32,8)
Related to CMV reactivation	
Symptoms—Suspicion (days)	**20** (13–25)
ICU admission—Suspicion (days)	**9** (2–12)
CMV reactivation (%)	**50** (40)
Symptoms—CMV reactivation	**20** (14–26)
ICU admission—CMV reactivation	**10** (3–13)
Samples	
BAL samples (%)	**77** (61,6)
BAL positivity (%); (n = 77)	**22** (28,6)
Plasma samples (%)	**97** (77,6)
Plasma positivity (%); (n = 97)	**45** (46,4)
BAL and plasma samples (%)	**49** (29,2)
Both-acquired positivity (%); (n = 49)	**17** (34,7)

APACHE: Acute Physiology and Chronic Health Evaluation. SOFA: Sequential Organ Failure Assessment. ICU: Intensive Care Medicine Experimental Unit. CMV: Cytomegalovirus. BAL: Bronchoalveolar Lavage

Conclusions. In our series, the time from ICU admission to CMV reactivation suspicion median was 9 days and 20 days to symptoms onset. CMV reactivation incidence was 40% in those who were suspected. CMV reactivation must be early and actively searched in severe COVID-19 pneumonia ICU-admitted patients.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000075

Introduction. Patients in intensive care units experience a sudden and critical state with high risk of death. This can lead to a post-traumatic impact potentially long-lasting. This study aims to identify traumatized patients or not following their stay, to assess their resilience skills and to have a better understanding in the involvement of some factors in the resilience process such as social support, illness perception or quality of life.
Methods. Complementary to the medical study NUTRIREA-3, RésiRéa is a prospective and longitudinal study involving 42 different units of intensive care in France. At two different times (3 months and 1 year after ICU), patient hospitalized for severe critical illness were asked to answer 5 scales assesing post-traumatic stress (IES-R), resilience (CDRISC), quality of life (SF-36), illness perception (BIPQ) and social support (MSPSS). Resilience was defined by a score at CDRISC $\geq$ 80 and a low score at IESR (absence of post-traumatic stress).
Results. A total of 380 patients have been included: 125 women (32.9%) and 255 men (67.1%), 61 $\pm$ 13 years old, IGS2 56 $\pm$ 18, SOFA 10 $\pm$ 3., 22.1% [17.9; 26.9] were suffering from post-traumatique stress at 3 months and 17.3% [12.6; 22.9] at 1 year. The rate of patients with a score of CDRISC $\geq$ 80 was 18.0% [14.0; 22.6] at 3 months and 24.3% [18.8; 30.5] at 1 year. The rate of resilient patients was 12.6% [9.5; 16.4]. In comparison to non resilient patients, resilient patients had a higher score of social support at 3 months (MSPSS 78.9 $\pm$ 9.3 vs. 70.9 $\pm$ 14.3, $p < 0.001$), a better peception of illness (BIPQ 27.7 $\pm$ 8.8 vs 38.2 $\pm$ 12.6, $p < 0.001$) and a better quality of life (PCS 44.1 $\pm$ 10.6 vs 38.9 $\pm$ 10.8, $p = 0.009$; MCS 55.3 $\pm$ 8.1 vs 47.6 $\pm$ 12.4, $p < 0.001$). These differences are still true 1 year after inclusion in the study.
Conclusions. Resilience seems to be an important indicator to consider when focusing on how to better support patients after a stay in intensive care and to reduce the risks of PTSD or increase quality of life. Resilience by patients from ICU seems to be influenced by social support and illness perception.

IRE1α-XBP1 activation elicited by viral singled stranded RNA via TLR8 may modulate lung cytokine induction in SARS-CoV-2 pneumonia

E. Bustamante-Munguira[1]; A. Francisco Amador[1]; M. Artola Blanco[1]; M. Bustamante-Munguira[1]; J. J. Fernández Rodriguez[2]; N. Mamolar Herrera[3]; S. Garcinuño Perez[4]; M. A. De Pedro Sanchez[3]; E. Portugal Rodríguez[5]; M. Sanchez Crespo[2]

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000078

Introduction. The pandemic caused by the SARS_CoV-2 coronavirus is a major healthproblem worldwide. The virus presents with variable clinical pictures, ranging from asymptomatic patients to episodes of severe pneumonia with symptoms of adultrespiratory distress (ARDS). Virus use host cellorganelles to produce their proteins and thus overwhelm the protein-folding capacity of the endoplasmic reticulum (ER). This process evokes ER stress and activation of the unfolded protein response (UPR), an adaptivesignaling pathway directed to preserve ER homeostasis.The IRE1α-XBP1 branch of the UPR is activatedin many viral diseases, and viral RNA might trigger the IRE1α-XBP1 branch via Toll-like receptors.since activation of TLR2 and TLR4 by their cognate ligands underpins cytokine expressiontrough IRE1α-driven XBP1 splicing (sXBP1).
Objectives. Analyze, through studies of molecular mechanisms, whether the transcription factors activated during the response tomisfolded proteins (UPR), inparticular SXBP1, maintain the transcription of genes thatencode the cytokines involved in hyperinflammation. associated with cytokine storm (CT).
Methods. Infection by SARS-CoV-2 causes hyperinflammation and pneumonia in severalpatients. This differs fromcommon viral respiratory infections andtherefore urges a pathophysiological analysis. Viruses use host cellorganelles to produce their proteins and thus overwhelm the protein-folding capacity of the endoplasmic reticulum (ER). This process evokes ER stress and activation of the unfolded protein response (UPR), an adaptivesignaling pathway directed to preserve ER homeostasis. Of note, the IRE1α-XBP1 branch of the UPR is activatedin many viral diseases, and viral RNA might trigger the IRE1α-XBP1 branch via Toll-like receptors. Thisis not unexpected, since activation of TLR2 and TLR4 by their cognate ligands underpins cytokine expressiontrough IRE1α-driven XBP1 splicing (sXBP1). We studied in the nasopharyngeal samples and bronchial aspirates (BAS)of patients with (60 patients) and without (59 patients) Covid-19 admitted to a critical careunit and on invasive mechanical ventilation during the 3rd and 4th wave, the presence or absence of active infection and sXBP1.
Results. After observing a high incidence of sXBP1 in RNA obtained from nasopharyngeal swabs of SARS-CoV-2 infectedpatients, a systematic study was undertaken in samples of bronchoalveolar aspirates (BAAs). Thepresence of sXBP1 and a high expression of IL1B, IL6, and TNF mRNA were detected during active infection. Monocytic/

macrophagic populations showed a reduction of markers associated with antigen presentationand survival, as well as the IFN stimulated gene MX1. In contrast, the expression of the mRNA of the serineprotease TMPRSS2 involved in S protein priming showed a high expression. TLR8 mRNA showed an overwhelmingexpression as compared to TLR7 mRNA. MDDCs activated with ssRNA40, a selective TLR8 ligandinduced sXBP1, and the expression of IL-1β, IL-6, and TNFα at mRNA and protein levels. These responseswere blunted by the IRE1α ribonuclease inhibitor MKC8866 and enhanced by the non-toxic IRE1α-XBP1 activatorIXA4.

Conclusions. The SARS-Cov-2 coronavirus infection occurs with a viral infection withvariable clinical pictures, whose pathogenic mechanisms are still not fully known, as well as its diagnostic and therapeutic management. For this purpose, the present studyintends to study the involvement of TLR 7/8 and SxBP 1 in viral sepsis, outline thetranscriptional landscape and control the inflammatory cascade, identifying a pathogenicfactor and providing an early prognostic biomarker.Experiments showed that activation of immune cell receptors by pathogen-associated molecular patterns mimickingviral RNA induced a pattern of cytokine expression like that observed in bronchoalveolar aspirates ofpatients with critical COVID-19 pneumonia.The study revealed that cell organelle overload and engagement of receptors targeted by viral RNAteam up to produce the proinflammatory cytokines commonly associated with viral sepsis.

The prognostic utility of oxygenation index in acute respiratory distress syndrome: a meta-analysis

D. Jayasimhan[1], J. Chieng[2], J. Kolbe[2], D. Sidebotham[3]
[1]Intensive Care Unit, Wellington Regional Hospital, Wellington, New Zealand; [2]Department of Respiratory Medicine, Auckland City Hospital, Auckland, New Zealand; [3]Cardiothoracic and Vascular Intensive Care Unit, Auckland City Hospital, Auckland, New Zealand

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000085

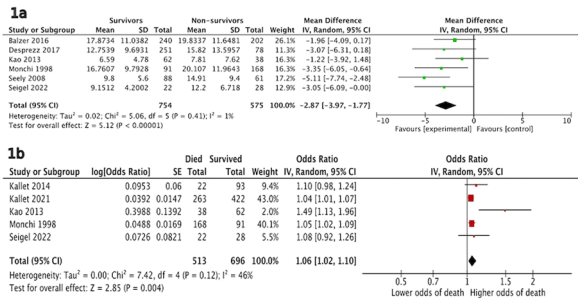
Introduction. The severity of acute respiratory distress syndrome is determined by the ratio of partial pressure of oxygen to the fraction of inspired oxygen (PaO2:FiO2), a measure that inconsistently predicts mortality. PaO2:FiO2 does not consider the effect of alveolar pressure on oxygenation, which may account for its imprecision. The oxygenation index is a simple bedside tool that incorporates mean airway pressure with PaO2:FiO2, which may reflect a more accurate measure of oxygenation. First studied as a tool in neonatal and paediatric respiratory, failure, its utility in the prognostication of adults with ARDS is unclear.

Objectives. We evaluated the ability of oxygenation index to predict mortality in adults with ARDS.

Methods. We systematically searched the MEDLINE, CENTRAL, and Google Scholar databases. We included studies of adults with ARDS reporting oxygenation index and mortality. We performed a meta-analysis of the mean difference in survivors vs non-survivors and adjusted results from multiple logistic regression using a random effects model. We assessed heterogeneity using the I^2 statistic.

Results. We included eight studies in our meta-analysis from our search of 1248 records. In six studies reporting differences between survivors and non-survivors, oxygenation index was significantly lower in survivors than non-survivors (n, 1329; Mean Difference, − 2.87; 95%CI, − 3.97 to − 1.77; I^2, 1%). Among the six studies that controlled for confounders, oxygenation index was independently associated with mortality (n, 1209; OR, 1.06; 95% CI, 1.02 to 1.10; I^2, 46%).

Conclusions. Among adults with ARDS, surivivors have a significantly higher oxygenation index than those who died. Oxygenation index is also independently associated with mortality in adults with ARDS.



Mean difference in oxygenation index between survivors and non-survivors (Fig. 1a) and adjusted odds of mortality for every 1 unit increase in oxygenation index (Fig. 1b).

The depth of central venous catheter in left subclavian compare with supraclavicula using peres formula

B. Lubis[1], P. Mathilda[2], B. Luwih[3]
[1]Anasthesiology, Universitas Sumatera Utara, Medan, Indonesia; [2]Anesthesiology, laksana 15, Medan, Indonesia; [3]Anesthesiology, haji medan, Medan, Indonesia

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000087

Introduction. Central Venous Pressure (CVP) is the measure most often used to guide fluid resuscitation in critically ill patients. CVC placement has become common practice for anesthesiologists and intensivists in operating theaters and intensive care units. It is very important to position the catheter tip in the correct position to avoid the consequences of malposition.
Objectives. To determine the comparison of the accuracy of the tip depth of central venous catheterization in the left subclavian using the Peres formula with evaluation of the radiological images between the supraclavicular and infraclavicular.
Methods. This study used a *double blind* RCT (*Randomized Clinical Trial*) design, i.e. the research subjects and observers did not know the treatment or intervention given. Sample study are patients who have a *central venous catheter installed* in the emergency room, ICU, or surgery at the Adam Malik Haji Center General Hospital in Medan who fulfillcriteria inclusion and exclusion.
Results. The frequency of Supraclavicular samples with incorrect tips was 36 samples (42.4%) and 9 samples (10.6%) were correct. Furthermore, for the experiment using the inflaclavicular as many as 32 samples (37.6%) were not correct, while 8 samples (9.4%) the tip was correct. It is known that the analysis was carried out using the Chi-Square test and it was known that there was no significant relationship between groups with the level of accuracy of central venous catheter tip depth ($p = 1.000$).
Conclusions. The accuracy of central venous catheterization in the left subclavian using the Peres formula supraclavicular and infraclavicular is known to be the same, namely 20.0% or 1 out of 5 procedures directly reaches the carina/region about the fifth thoracic vertebra which does not have a significant difference between infraclavicular and supraclavicular.

Table 4. 5 Analysis of average tip distance for central venous catheterization

Data	Means	±SD	Accuracy
Supraclavicular	2.55	1.00	20%
Infraclavicular	2,33	0.79	20%
Total	2.44	0.89	20%

Table (abstract 000087)

Effect of thermocycling on the reflection of volatile anesthetics after applying carbon dioxide

D. Brauchle[1], N. Rosinus[1], A. Kermad[2], A. Brauchle[1], T. Volk[1], A. Meiser[1]
[1]Department of Anaesthesiology, Intensive Care and Pain Therapy, Saarland University Medical Center and Saarland University Faculty of Medicine, Homburg, Germany; [2]Department of Cardiac Anaesthesiology and Intensive Care, German Heart Institute Berlin, Berlin, Germany
Correspondence: D. Brauchle
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000088

Introduction. During intensive care therapy, there is often a need for sedation to reduce emotional load and negative memories. With a reflection device, such as the Sedaconda-ACD-S (Sedana Medical, Danderyd, Sweden), it is possible to apply volatile anesthetics efficiently. Most of the agent is adsorbed in the reflection device during expiration and released back to the patient during inspiration. As volatile anesthetics are potent greenhouse gases, it is urgent to reduce their consumption by improving the reflection efficiency of the device.
Objectives. We therefore tested, whether warming the reflector during inspiration and cooling it during exspiration (thermocycling) has influence on reflection efficiency.
Methods. A test lung was ventilated with a tidal volume of 500 ml and a respiratory rate of 10/min with an intensive care ventilator. Constant body conditions (37 °C and humidity over 95%) were implemented in the test lung.
Isoflurane was applied with a syringe pump via a Sedaconda-ACD-S with different infusion rates (0.5, 1, 2 and 5 ml/h). After achieving a steady state, isoflurane concentration was measured in the test lung and the reflection efficiency was calculated.
Furthermore, a physiological carbon dioxide concentration (35–45 mmHg) was created in the test lung. The reflector was warmed up to 37 °C during inspiration and cooled down to either 12 °C or 1 °C in expiration (Thermocycling), resulting in a temperature difference of 25 °C (Δ25) and 36 °C (Δ36).
Results. After adding carbon dioxide, lower isoflurane concentrations were measured in the test lung. Thermocycling (Δ25) lead to a significantly higher concentration of isoflurane for every infusion rate even though carbon dioxide was added. Intensifying thermocycling by using a greater temperature difference (Δ36) resulted in even higher isoflurane concentrations for 0.5, 1 and 2 ml/h. Interpolation of data showed that for achieving 0.4 (0.6) vol% isoflurane, infusion rates can be lowered from 1.17 (1.86) ml/h to 0.77 (1.14) ml/h with thermocycling Δ25 and to 0.60 (0.90) ml/h with thermocycling Δ36. To achieve clinical target concentrations, isoflurane consumption may thus be reduced by 34 (39) % and 48 (52) %, respectively. In thermocycling Δ36 reflection efficiency increased up to 10% resulting in an reflection efficiency of 91%.
Conclusions. The addition of carbon dioxide decreases the reflection efficiency of the Sedaconda-ACD-S. However, its reflection efficiency can be restored and even further improved by thermocycling with temperature differences of 25 °C and of 36 °C. Thereby, isoflurane consumption can be halved.

Correspondence: H. Kim

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000089

Introduction. The neurological pupil index (NPi) is calculated based on automated pupillometric parameters and predicts clinical outcomes in critically ill patients. However, there are few data on the association of intraoperative NPi and postoperative clinical outcome after cardiac surgery. We investigated the relationships between intraoperative NPi and postoperative delirium and neurologic outcome after cardiac surgery.

Methods. This study was a sub-analysis of the Registry of Perioperative Data in Cardiovascular Surgery at Seoul National University Hospital. We included patients who underwent pupillometric assessment during cardiac surgery. NPi was measured using an automated digital pupillometer at baseline, after anesthesia induction, at 30 min intervals during cardiopulmonary bypass or anastomosis of coronary artery bypass graft, at protamine infusion, and at skin closure. The worst NPi was recorded, and multivariate logistic regression analysis was performed to evaluate the relationships between abnormal intraoperative NPi and postoperative delirium, neurologic adverse events, and composite outcome, including stroke, acute kidney injury, continuous renal replacement therapy, mechanical circulatory support device, and in-hospital mortality.

Results. Among 123 patients, 19.5%, 24.4%, and 40.7% developed postoperative delirium, neurologic adverse events, and composite outcome, respectively. The worst intraoperative NPi was lower in patients who developed postoperative delirium compared to those who did not (median [IQR], 3.2 [0.0–3.4] *vs* 3.3 [3.0–3.6], respectively; P = 0.009; Fig. 1). Compared to baseline, NPi decreased greater in patients with postoperative delirium at the end of surgery than those did not (P = 0.025 between the groups, Mann–Whitney *U* test; Fig. 2). After adjustment, intraoperative NPi < 3.0 was significantly associated with postoperative delirium (adjusted odds ratio [OR]: 5.314, 95% confidence interval [CI]: 1.280–22.067, *P* = 0.021) and neurologic adverse events (adjusted OR: 6.689, 95% CI: 1.591–28.124, *P* = 0.009), but not with postoperative composite outcome (adjusted OR: 2.102, 95% CI: 0.555–7.963, *P* = 0.274).

Conclusions. Abnormal intraoperative NPi measured using automated pupillometry independently predicted postoperative delirium and neurologic adverse events, but not the composite outcome, following cardiac surgery. Intraoperative pupillometric measurements may predict postoperative neurologic events and may facilitate early intervention after cardiac surgery.

Prevention of delirium in the intensive care unit

A. Hagana[1], S. Sivanesan[2], G. Bhardwaj[2], T. Ali[1]
[1]Anaesthetics and Critical Care, Stoke Mandeville Hospital, Aylesbury, United Kingdom; [2]Anaesthetics and Critical Care, University of Buckingham, Eaglestone, United Kingdom
Correspondence: A. Hagana
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000091

Introduction. Delirium is characterised as a fluctuating disturbance of consciousness and cognition that develops over a short period of time, with a reported prevalence in nearly a third of critically ill patients (1). It is associated with prolonged mechanical ventilation and hospitalisation, as well as increased risk of hospital mortality and long-term cognitive impairment (1, 2). Various interventions have been proposed in literature to prevent delirium in the intensive care unit, including environmental changes, cognitive stimulation, and addressing factors such as dehydration, constipation, nutrition, and pain (2, 3) Given the high prevalence of delirium in critically ill patients and the associated adverse outcomes, consideration of risk factors to prevent delirium is a crucial component of the care provided in ICU.
Objectives. To investigate the consideration of risk factors by doctors and nurses in preventing delirium in critically ill patients.
Methods. An audit was performed on patients admitted to the ICU between 22/09/22-5/10/22 at Buckinghamshire Healthcare NHS Trust. Daily reviews performed by doctors and nursing notes were assessed to identify whether factors that prevent delirium were considered on each day of the patient's admission. Risk factors that were assessed were selected based on NICE CKS guidelines (4).
Results. The data consisted of 38 patient admissions across two intensive care units.

Table 1 (abstract 000091) Summary of results

Addressing risk factors	Doctors	Nurses
Addressing cognitive impairment/disorientation:	–	–
- Environmental (lighting, signage, clocks, calendars, sleep environment)	0%	5.7%
- Reorientation	1.9%	5.2%
- Cognitively stimulating activities	2.4%	2.4%
- Family/ friend visitation	6.1%	46.2%
Hydration	78.3%	92.9%
Constipation	47.2%	65.1%
Hypoxia	85.4%	90.1%
Immobility	21.7%	88.2%
Pain	62.3%	65.1%
Medication reviews	30.7%	0%
Nutrition	76.4%	91.5%
Sensory impairment	0.5%	0.9%
Sleep	2.4%	13.2%

Conclusions. This audit highlights that factors preventing delirium are poorly considered and implemented by both doctors and nurses in the ICU, with doctors having lower rates across almost all factors in comparison to nurses. This is particularly noted for aspects not commonly considered in a standard medical review, such as addressing cognitive impairment and disorientation through environmental optimisation, as well as active reorientation of patients and improving sensory impairment. These results highlight aspects in the care of critically unwell patients that can be improved to prevent delirium and improve patient outcomes.

CAM-ICU compliance in the intensive care unit

G. Bhardwaj[1], A. Hagana[2], S. Sivanesan[1], T. Ali[2]
[1]Anaesthetics and Critical Care, University of Buckingham, Eaglestone, United Kingdom; [2]Anaesthetics and Critical Care, Stoke Mandeville Hospital, Aylesbury, United Kingdom
Correspondence: A. Hagana
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000092

Introduction. Delirium is a commonly occurring clinical syndrome in the intensive care unit associated with various adverse outcomes, including increased length of hospital stay, increased risk of hospital mortality and cognitive impairment (1). Early diagnosis through serial assessments to screen for delirium is a crucial component of caring for critically ill patients (2). This can be achieved by utilising The Confusion Assessment Method for the ICU (CAM-ICU), a monitoring and diagnostic tool for delirium, performed twice daily on ICU patients with RASS greater than − 3 (3). Below this, 'unable to assess' (UTA) is assigned due to patient unresponsiveness, although it is suggested this is often inappropriately overused due to misunderstanding surrounding the diagnostic tool and how it is performed (3,4).
Objectives. To assess frequency of daily CAM-ICU measurements performed by nursing staff to evaluate the compliance with guideline recommendations for twice daily CAM-ICU assessments.
Methods. An audit was carried out across two sites at Buckinghamshire Healthcare NHS Trust evaluating the frequency of CAM-ICU measurements performed daily for patients admitted to the intensive care units, consisting of a total of 212 ICU days. UTA inputs were also measured independently, interpreted as an attempt to perform CAM-ICU.
Results. The results show that CAM-ICU was measured at least twice daily on 30.7% of days, not including where they were unable to assess due to low RASS. When also including UTA inputs that occurred at least twice daily, CAM-ICU measurements increased to 59%.

Table 1 (abstract 000092) CAM-ICU daily measurements

No. of CAM-ICU measurements daily	% of total ICU days
0	25.9%
1	9.0%
≥ 2	30.7%
UTA	34.4%

Table 2 (abstract 000092) UTA input breakdown

No. of times UTA inputted daily	% of total UTA days
1	17.8%
≥ 2	82.2%

Conclusions. Overall, this audit highlights that twice daily CAM-ICU compliance is poorly achieved, only occurring on 30.7% of ICU days. Although this improves when UTA attempts are included, it is difficult to ascertain whether these are appropriate inputs and genuine attempts to perform CAM-ICU measurements. This is particularly important considering the high proportion of UTA assessments, at 34.4% of total ICU days, which may be explained by the simple nature of inputting UTA in comparison to performing a thorough CAM-ICU assessment. These results could be in keeping with previous literature suggesting that UTA inputs are inappropriately overused, possibly due to confusion surrounding how CAM-ICU measurements are performed (4). Investigating the accuracy of CAM-ICU measurements and the appropriateness of UTA inputs would be valuable contributions for future studies, allowing for improvements to be made in education and daily practice to optimise CAM-ICU implementation. This would consequently allow for earlier delirium identification and management.

Treatment escalation plan and CPR status documentation in intensive care

A. Hagana[1], J. Mandeville[1], P. Shanmugasundaram[1], T. Ali[1]
[1]Anaesthetics and Critical Care, Stoke Mandeville Hospital, Aylesbury, United Kingdom
Correspondence: A. Hagana
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000093

Introduction. The treatment escalation plan (TEP) and CPR status are important tools in critical care that allow for discussion and formal documentation of appropriate ceilings of care, particularly for patients at risk of deterioration. Guidelines for the Provision of Intensive Care Services states 'Patients must have a clear and documented TEP', as well as a handover on discharge from critical care units which includes 'any treatment limitations in place [and] plans if readmission to critical care becomes necessary including DNAR/TEP'.(1).

Objectives.

1. To assess documentation of TEP and CPR status on admission to ICU, review on daily ward rounds and documentation on discharge.
2. To assess whether the introduction of mandatory TEP and CPR status fields on admission and discharge forms improves completion rates.

Methods. Data was collected retrospectively across two ICUs in district general hospitals. An initial search assessed the completion rate for TEPs and CPR status on admission, one day post-admission to allow for completion of the formal TEP form, as well as consultant review on ward rounds and documentation on discharge. This was consequently repeated following introduction of mandatory fields to the TEP and CPR status fields on admission and discharge documents.
Results. Following the introduction of mandatory fields on admission and discharge forms, TEP and CPR status documentation increased significantly (Table 1). However, these results include TEP documentation on the admission form itself, rather than completion of a formal TEP document countersigned by a consultant. If focusing solely on formally completed TEP documents, the completion rate worsened.

Table 1 (abstract 000093) Summary of results

	Prior to mandatory fields N = 35	Post mandatory fields N = 20
CPR on admission	77.1%	100%
TEP on admission	31.4%	85%
TEP by day 1 of admission	45.7% formal TEP	84.2% (10.5% formal TEP)
Daily review	11.1%	84.9%
CPR on discharge	82.9%	100%
TEP on discharge	51.4%	94.4% (11.1% formal TEP)

Conclusions. The results showed overall improvement to completion rates of TEP and CPR status documentation following introduction of mandatory fields, possibly through encouraging discourse with consultants early in patient admission and documenting decisions. However, the rate of formal TEP form completion reduces, possibly due to an assumption that a form is likely to have been completed if the TEP is stated on admission. Nonetheless, the relevant information regarding TEP and CPR status is included on discharge forms, despite the lack of a formal TEP form, providing important information for the receiving team continuing the patient's care. Although formal TEPs should be completed and cross signed by a consultant, given the initial poor results and the immense pressures faced, this overall improvement in documentation allows for decisions to be communicated to the broader ICU team and on discharge to receiving teams, ensuring continuity of care.

Incidence and severity of pediatric delirium in the PICU: a single-center retrospective study

Y. Enomoto[1], T. Kido[2], T. Hoshino[3], M. Ikeda[4], M. Kotani[4], Y. Inoue[1]
[1]Department of Emergency and Critical Care Medicine, Faculty of Medicine, University of Tsukuba Tsukuba, Tsukuba, Japan; [2]Department of Pediatrics, Tsukuba University Hospital, 2 Chome-1–1 Amakubo, Tsukuba, Ibaraki, Japan, Tsukuba, Japan; [3]Departiment of Emergency and Critical Care Medicine, University of Tsukuba Hospital, Tsukuba, Japan; [4]Intensive Care Unit, University of Tsukuba Hospital, Tsukuba, Japan

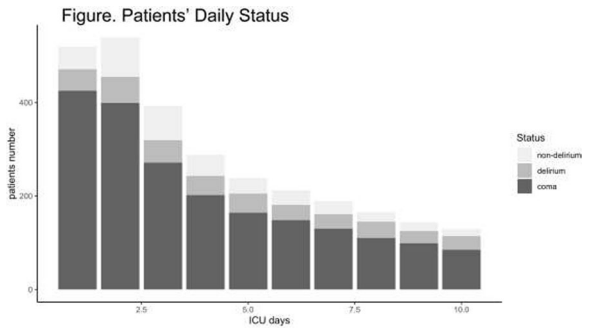
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000094

Introduction. Delirium is a complex and multifactorial acute brain disorder associated with adverse outcomes, such as increased morbidity, mortality, longer hospital stays, and cognitive impairment. However, it is often underdiagnosed in children owing to a lack of awareness and recognition of the syndrome in this population. Children admitted to the pediatric intensive care unit (PICU) are particularly vulnerable to delirium due to underlying illnesses, use of sedatives and analgesics, and other environmental factors. Although delirium is a well-recognized complication in critically ill adult patients, limited research has been conducted on its characteristics and outcomes in children admitted to the PICU. Moreover, reports on the differences in outcomes according to the severity of delirium are limited.

Objectives. This study aimed to determine the incidence, characteristics, and severity of delirium in children admitted to the PICU and to provide fundamental data for future studies on this topic.
Methods. This single-center retrospective study assessed patients ≤ 16 years old who had been admitted to the PICU between 2018 and 2022. Clinical data were extracted from electronic medical records. Delirium was assessed using the Cornell Assessment Pediatric Delirium (CAPD) scale, which was correctly translated and validated in Japanese. Consciousness during the first 10 days after admission was classified as coma (Richmond Agitation Sedation Scale [RASS] ≤ − 4), delirium (RASS > − 4 and CAPD ≥ 9), or non-delirium (RASS > − 4 and CAPD < 9). The severity of delirium was classified as mild (1 d) or severe (> 1 d) based on the number of days the delirium lasted. Data on age, sex, postoperative status, pediatric index of mortality 3, length of ICU stay, and outcomes at ICU discharge were also collected. Each data point was compared among the three groups using the Kruskal–Wallis test.
Results. A total of 619 patients were enrolled in this study, with a delirium prevalence of 58% (n = 208/357). Regarding the severity of delirium, 132 (37%) patients had mild delirium and 76 (21%) had severe delirium. The more severe the delirium, the younger the patient and the longer the ICU stay. Coma was the most common condition in the PICU (Figure). Patients with severe delirium had significantly longer ICU stay than those of patients with mild delirium or without delirium (18 days [8–94] vs 12 days [5–50] and 7 days [3–29], respectively; $p < 0.001$).
Conclusions. Delirium is prevalent in children admitted to the PICU, and the more severe the delirium, the longer the ICU stay. Further studies are necessary to explore the underlying mechanisms and identify effective interventions for delirium in this vulnerable population.



Patients' status was categorized into three groups (non-delirium, delirium, coma). coma: Richmond Agitation Sedation Scale (RASS) ≤ − 4, delirium: RASS > − 4 & Cornell Assessment Pediatric Delirium ≥ 9, non-delirium: RASS > − 4 & CAPD < 9.

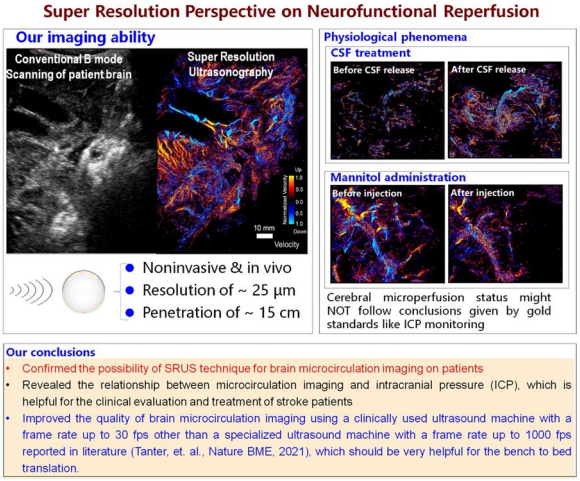
Introduction. Severe traumatic brain injury (sTBI) is a common neurosurgical disease. It has high mortality and disability rate that has brought heavy burden to the society and families. Effective and precise monitoring of intracranial pressure (ICP) is particularly crucial for the prognosis of sTBI patients. Currently, invasive ICP monitoring has been widely recognized as the gold standard to guide the treatment of sTBI patients. However, it has limited utilization in clinical practice, because it is expensive and requires a professional doctor to operate. Furthermore, multiple complications, such as infection and rebleeding, may influence the effect on reducing the mortality by ICP monitoring. More important, ICP monitoring cannot directly or completely reflect the situation of cerebral microcirculation. In clinical practice, effective cerebral microcirculation perfusion is crucial for the recovery and functional preservation of brain tissue, which directly affects the prognosis of patients. However, there remains a lack of direct and effective methods to determine the cerebral microcirculation in clinical practice.
Objectives. This study principally aims to improve the ICP monitoring on the cerebral microcirculation perfusion, which could achieve the identification of the change in the cerebral microcirculation perfusion before irreversible damage to brain tissue.
Methods. We utilized the super resolution ultrasound imaging technology to establish and validate the super resolution imaging of cerebral microcirculation of sTBI patients, and then compared its agreement with traditional ICP monitoring.
Results. In this study, a super resolution ultrasound imaging method was established to directly and non-invasively determine the cerebral perfusion. This method was further employed to compare the effect of cerebrospinal fluid drainage and mannitol on ICP reduction. It was found that it differed between these two methods; in addition, the perfusion of capillaries and large vessels also had different reactions to the ICP reduction. Furthermore, 40 sTBI patients were included to compare the agreement between the time-intensity curve (area under the curve) of super-resolution ultrasound imaging and traditional ICP monitoring results. Correlation coefficient r was determined to be 0.665 (P = 0.001), suggesting a moderate agreement.
Conclusions. Our study establishes a non-invasive super-resolution imaging technology for cerebral microcirculation, which may provide an effective tool for decision-making on clinical diagnosis and treatment and prognosis evaluation among sTBI patients.



Graphical Abstract

Introduction. Advanced age is a known risk factor for cardiovascular disease development, as aging negatively affects the proliferative and regenerative capacity of the endothelium, endothelial gene expression, and monolayer integrity [1]. By regulating leukocyte migration and blood-tissue barrier permeability, the endothelium plays an important role in the resolution of acute inflammation [2]. Endocan (ESM-1), an endothelium-derived soluble proteoglycan, participates in fundamental biological processes of endothelial cells, including cell adhesion, migration, proliferation, and neoangiogenesis [3]. ESM-1 is a marker of endothelial activation and has been recognized as a prognostic biomarker in sepsis, pulmonary, and cardiovascular diseases.

Objectives. We aimed to examine whether endotheliopathy is a consequence of critical illness or older age leading to poor outcomes.

Methods. ESM-1 levels were measured in the sera of mechanically ventilated critically-ill patients, including 154 COVID-19, 164 non-septic (24-h post ICU admission), and 79 septic (6-h after sepsis diagnosis) patients, using an enzyme-linked immunosorbent assay (ELISA). The 3 patient cohorts were divided each into two subgroups based on age: patients equal or older than 65 years of age, and patients younger than 65 years of age.

Results. Critically-ill COVID-19 patients had statistically higher ESM-1 levels compared to critically-ill septic and critically-ill non-septic patients [1527 (951.4–2406) pg/ml vs. 659.3 (389.1–941.3) pg/ml and 756.7 (369.8–1228) pg/ml, $p < 0.0001$, respectively]. In critically-ill COVID-19 patients, older patients (≥ 65) tended to have higher ESM-1 levels compared to younger patients, without reaching statistical significance ($p = 0.051$). On the other hand, older critically-ill septic patients (≥ 65) exhibited higher ESM-1 levels compared to younger septic patients [860.9 (623.2–1397) pg/ml vs. 519.8 (352.3–820.9) pg/ml, respectively, $p = 0.0013$]. No statistical difference was observed between the two age groups of the critically-ill non-septic patients ($p > 0.05$). Finally, the two age subgroups patients were further subdivided based on ICU outcome. ESM-1 levels in COVID-19 patients were similar in survivors and non-survivors, irrespective of age. Interestingly, in the ≥ 65 years old critically-ill septic patients, survivors and non-survivors had similar serum levels of ESM-1, yet in younger critically-ill septic patients (< 65), non-survivors had higher ESM-1 levels compared to survivors [760 (429–1176) pg/ml vs. 510.8 (332.2–788.8) pg/ml, respectively, $p = 0.045$]. In the non-septic survivors and non-survivors, ESM-1 levels remained unaltered in the younger critically-ill patients, and tended to be higher in the elderly ($p = 0.056$).

Conclusions. Even though endocan has been recognized as an important prognostic biomarker in critically-ill patients with sepsis, increased age, as well as the extent of endothelial dysfunction seem to impede its prognostic ability.

Introduction. Tidal volume (Vt) setting is a major determinant of ventilator induced lung injuries (VILI) in patients with acute respiratory distress syndrome (ARDS). Veno-venous extracorporeal membrane oxygenation (VV-ECMO) allows Vt decrease down to 1 ml/kg (ultra-protective ventilation, UPV) or less, while maintaining efficient oxygenation and decarboxylation.

Positron emission tomography (PET) with [11C](R)-PK11195 coupled with quantative computerized tomography (CT) allows non-invasive and specific quantification of lung macrophagic inflammation, in parallel with the determination of CT-derived parameters quantifiying VILI.

Objectives. We aimed to demonstrate that a UPV strategy decreased acute lung inflammation in animals with experimental ARDS, compared to conventional Vt settings.

Methods. We performed a randomized preclinical open-label controlled trial in swine receiving mechanical ventilation with general anesthesia and neuromuExperimental ARDS was induced by intratracheal instillation of 3 ml/kg of 0.1 M chlorohydric acid after animal conditioning. Then, animals (median weight 32 [30–38] kg) were randomised to receive during 4 h conventional protective ventilation (controls, Vt 6 ml/kg and positive end-expiratory pressure [PEEP] set to maintain plateau pressure at 28–30 cmH2O), or UPV (Vt 1 ml/kg and PEEP set to maintain plateau pressure at 20–25 cmH2O) with femorojugular VV-ECMO. After 4 h of strategy application, a 60-min PET with [11C](R)-PK11195 radiotracer injection coupled with lung CT was performed. Lung segmentation of imaging acquisitions was performed using a semi-automatic segmentation algorithm. Lung masks were divided into 8 lung regions, distributed along antero-posterior axis. The study primary outcome (i.e. regional lung macrophagic inflammation) was quantified regionally by the value of [11C](R)-PK11195 non-displaceable binding potential (BPnd) determined by a multicompartment kinetic model, describing the distribution of the PET radiotracer. The study primary outcome was compared between study groups using linear mixed effects regression analysis.

Results. Five animals were randomised in each group, after ARDS induction (median PaO2/FiO2 ratio 78 [68–104] mmHg). Vt setting in the UPV group was 1.0 [1.0–1.4] ml/kg, and 6.0 [6.0–6.0] ml/kg in the control group ($p < 0.05$). After 4 h of application, UPV animals displayed a significant decrease in the regional non-aerated compartment in the posterior lung levels at the price of a significant increase in the hyperinflated compartment in the anterior lung levels. Concomitantly, [11C](R)-PK11195 BPnd was significantly lower in UPV animals (0.35 [0.20–0.59] vs. 1.01 [0.75–1.59], $p < 0.01$), a difference that satistically present across all lung regions. Higher radiotracer lung uptake was

significantly and independently associated with increasing regional hyperinflation and dynamic strain in multivariate regression analysis.
Conclusions. In an experimental model of ARDS, 4 h of a UPV strategy with VV-ECMO induced a three-fold decrease in acute lung inflammation compared to conventional protective ventilation.

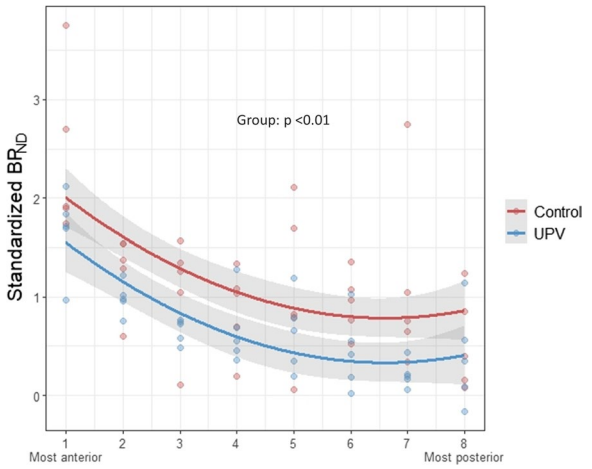

Figure 1 (abstract 000102) [11C](R)?PK11195 BPnd in each lung level in the 2 study groups
The figure shows the BPnd of [11C](R)?PK11195 in each of the 8 levels, in animal in the UPV group (blue dots and line) and those in the control group (red points and line). Dots represent experimental data collected after 4 h of strategy application in all animals. The predicted values of the mixed effects model describing the fixed effect of the study group (UPV vs. control) on BPnd is represented by the two curves. Shading along the lines represent the 95% confidence interval of the model. The p value examines the association between the study group and lung level BPnd (no significant interaction with lung level). BPnd: non-displaceable binding potential; UPV: ultra-protective ventilation strategy.

Introduction. Although adjuvant corticosteroids have the potential to improve outcomes in community-acquired pneumonia (CAP), their effectiveness has yielded inconsistent results, and routine usage is not recommended [1]. Heterogeneity in the treatment effect (HTE) among CAP patients may offer an explanation, with the hypothesis that severe CAP patients benefit more from corticosteroids [2].
Objectives. To create and validate a model that predicts individualized treatment effects (ITEs) of corticosteroids on mortality rate in patients with CAP, in order to personalize treatment.
Methods. Our systematic literature search identified ten eligible trials that investigated corticosteroid adjuvant therapy versus placebo in CAP. From seven trials, we received baseline clinical characteristics, consisting of demographics, vital signs and laboratory test results. The endpoint was 30-day mortality. The ITE, ie, the probabilistic difference in predicted 30-day mortality under corticosteroid versus placebo treatment for an individual patient, was modelled through effect modelling [3] using logistic regression. The modelling process had five steps: (1) dividing patients into development and validation cohorts, (2) pre-selecting variables based on data availability, (3) data normalization and imputation, (4) selecting main effects and interaction terms through multi-penalty LASSO regression, and (5) fitting the effect model to predict ITEs for the validation cohort. To externally validate our procedure, we employed cross-validation, where in each iteration, patients from six trials formed the development cohort and patients from one left-out trial formed the validation cohort. Patients with negative and positive predicted ITEs were assigned to the "predicted harm" and "predicted benefit" group, respectively. Subsequently, we

compared observed treatment effects between groups, and tested for HTE between the groups using an interaction test.

Results. From the 1925 CAP patients included, 1,077 were assigned to the predicted harm group, and 848 to the predicted benefit group. We found a significant HTE between the groups (p for interaction = 0.013). In the predicted benefit group, corticosteroids were associated with substantially lower mortality, while in the predicted harm group corticosteroids were associated with higher mortality (Fig. 1). Compared with the predicted harm group, the predicted benefit group was defined by higher concentrations of C-reactive protein, leukocytes and glucose and lower concentration of sodium (Fig. 2).

Conclusions. Our modelling approach demonstrated ability in identifying CAP patients, at baseline, who would benefit from the investigated corticosteroid treatment and those who would not. To further validate the model's robustness, we will test its performance in the two most recent trials [4,5]. If the model proves robust, we intend to include patients with predicted benefit in future randomized trials.

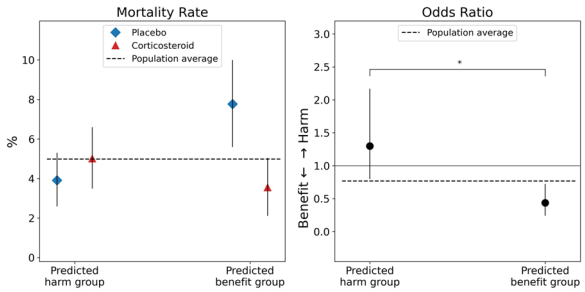

Figure 1 (abstract 000103) Results of the external validation in 7 trials (cross-validation procedure). Mortality rates (left) and treatment effect in terms of odds ratios (right) are shown with 95% CIs. *p for interaction = 0.013

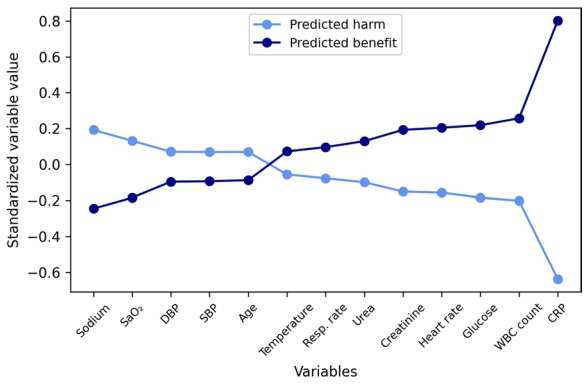

Figure 2 (abstract 000103) Differences in standardized values of each continuous variable between subgroups. The variables are sorted on the degree of separation between the harm and benefit group. For example, a value of 1 for a certain variable implies that the mean value of this variable in this subgroup is one standard deviation higher than the mean value in the cohort as a whole

Predictors of intracranial hemorrhage and ischemic stroke in venovenous extracorporeal membrane oxygenation: a systematic review and causal diagram

S. Thiara[1], A. Willms[2]
[1]Division of Critical Care, Faculty of Medicine, Vancouver General Hospital, Vancouver, Canada; [2]Faculty of Medicine, Dalhousie University, Halifax, Canada
Correspondence: A. Willms
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000105

Introduction. Venovenous extracorporeal membrane oxygenation (VV-ECMO) is a life-preserving intervention for patients with respiratory compromise refractory to mechanical ventilation. Both intracranial hemorrhage (ICH) and ischemic stroke are well-known, life-threatening complications associated with VV-ECMO. Despite this, little is known regarding the risk factors for each of these complications, and how clinicians may be able to predict and prevent them on a case-by-case basis.

Objectives. To conduct a systematic review that characterizes causal risk factors of ICH and/ or ischemic stroke during VV-ECMO, and to create a clinically-oriented causal diagram for each complication.

Methods. Using the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines, we conducted a systematic literature review through PubMed and EMBASE using controlled vocabulary and keywords.

We included randomized controlled trials, retrospective and prospective cohort studies, and cross-sectional studies that reported on predictors of ICH and/ or ischemic stroke in adult patients undergoing VV-ECMO. 248 studies met criteria for screening, which was then performed manually through abstract and subsequent full text review using the COVIDENCE online application. 26 studies met inclusion criteria for final data extraction.

Included studies were evaluated for risk of bias through the evidence-based Quality in Prognosis Studies (QUIPS) tool. Importance and certainty of predictors of ICH and/ or ischemic stroke in the literature was assessed using the evidence-based GRADE strategy.

Results. 26 studies met inclusion criteria, 22 of which reported on predictors of ICH, while 11 reported on ischemic stroke.

Predictors of both ICH and ischemic stroke include pre-ECMO reduced pH, as well as rapid rise in PaO2 and rapid decline in PaCO2 following ECMO initiation. Renal failure, use of renal replacement therapy, gastrointestinal (GI) bleed, hemolysis, and disseminated intravascular coagulopathy (DIC) were also risk factors for both neurologic complications.

Predictors of ICH only include reduced fibrinogen levels, elevated serum creatinine, thrombocytopenia, pre-existing diabetes, lymphoma, elevated BMI, previous chemotherapy, and septic shock. Furthermore, viral pneumonia and asthma as indications for VV-ECMO increased the risk of ICH. Finally, the use of larger cannulation size, as well as increased duration of mechanical ventilation prior to VV-ECMO initiation increased the risk of ICH.

Risk factors for ischemic stroke only include lower pre-ECMO PF ratio and hypoglycemia.

Conclusions. A number of factors reported in the literature increase the risk of ICH or ischemic stroke during VV-ECMO, some of which increase the risk of both complications. Identifying predictors of each complication and illustrating them in a clinically-oriented way is an important step towards developing clinical strategies that can be used to mitigate these devastating neurologic complications.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000106

Introduction. Frailty is common in critically ill patients and associated with increased morbidity and mortality. The timing and optimal method of frailty determination, frailty trajectory and relationship with care processes remain uncertain. Understanding contributory and potentially modifiable factors is essential to plan interventions which may improve outcomes.

Objectives. To describe the baseline and trajectory of frailty, as measured by the Clinical Frailty Scale (CFS) and Frailty Index (FI) among patients admitted to intensive care and the impact of care processes on the evolution of frailty during an episode of critical illness.

Methods. Multi-center prospective observational study enrolling patients > 50 years receiving at least one day of any life support intervention, defined as: 1) mechanical ventilation (MV) – invasive or non-invasive, 2) vasopressors, or 3) acute renal replacement therapy (RRT). Patients were excluded if they were > 5 days after ICU admission; had no available collateral history; predicted to be unable to complete 6-month follow-up; or were expected to survive < 72 h after enrollment. Frailty was evaluated at ICU admission, hospital discharge, and at 6 months with both the Clinical Frailty Scale (CFS), and Frailty Index (FI) derived from a modified comprehensive geriatric assessment (CGA). Processes of care (nutrition, mobility, sedation), and adverse events (nosocomial infections, delirium) were collected during ICU and ward stay, and vital status ascertained at ICU discharge, hospital discharge and 6 months.

Results. Among 2186 screened, 687 patients were enrolled in 14 Canadian centers (mean ± SD): age 69 ± 9 years, APACHE II 23.3 ± 8.1, 90% receiving MV, 74% vasopressors and 5% RRT. Frailty (CFS ≥ 5 or FI ≥ 0.2) prevalence was higher when measured with FI but was common at all time points (%): ICU admission (30, 45), hospital discharge (55, 68), and 6 months (34, 43) respectively. Aggregate frailty scores increased from ICU admission to hospital discharge but improved by 6 months; mortality was higher in patients with frailty measured at all time points (Fig. 1). Processes of care and adverse events were similar with the exception of differences in mobility and delirium (Table 1). Patients without frailty achieved higher mobility as assessed by the ICU mobility scale and as a proportion of those walking on the ward. There was no difference in delirium incidence in frail patients measured by the CFS, however more people with frailty measured by the FI had delirium.

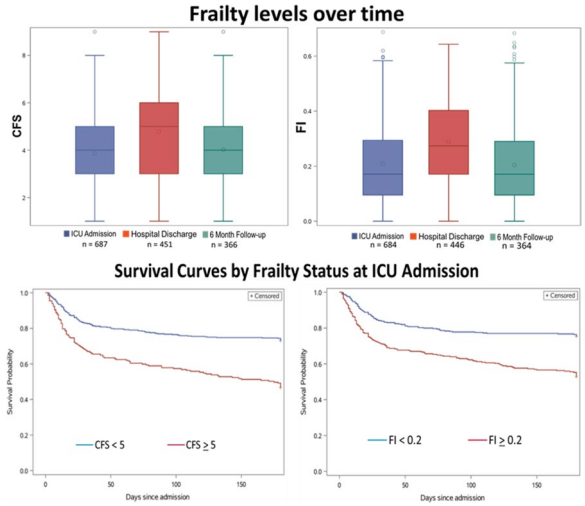
Table 1 (abstract 000106) Mobility, delirium by frailty status

Frailty Level	Max ICU Mobility Scale: *Median (IQR)*	p value	Max Ward Mobility-Ambulatory; *n (%)*	p value	ICU Delirium: *n (%)*	p value
CFS ≥ 5	2.0 (0.0–5.0)	< 0.0001	19 (15%)	0.002	107 (60%)	0.4
CFS < 5	3.0 (1.0–6.0)		110 (29%)		231 (57%)	
FI ≥ 0.20	2.0 (0.0–5.0)	< 0.0001	32 (16%)	< 0.0001	170 (62%)	0.04
FI < 0.20	4.0 (1.0–6.0)		96 (33%)		166 (54%)	

In survivors, CFS and FI scores were higher in 45% and 51%, respectively at 6 months compared with ICU admission. Compared to hospital discharge, 19% and 20% had higher CFS and FI scores at 6 months. In multivariate analysis of baseline characteristics and process measures, only age was associated an increase in both CFS and FI frailty scores.

Conclusions. Frailty is dynamic, and can be measured during recovery from critical illness. Screening for frailty at hospital discharge can inform planning of care transitions and community interventions. While the CFS can serve as a screening tool, a FI based on CGA

can measure frailty levels and specify new deficits and targets for intervention.



Frailty levels, mortality over time.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000107

Introduction. Cerebral vasospasm (CVS) remains a major contributor to increase morbidity and mortality after aneurysmal subarachnoid hemorrhage (aSAH). Delayed cerebral ischemia and cerebral infarction may occur as complications of CVS and can lead to permanent neurological impairment, severe disability, and poor quality of life [1]. Conventional approach includes serial monitoring with Transcranial Doppler (TCD), prophylactic oral nimodipine, avoid hypovolemia and vasopressor-induced hypertension, while invasive measures such as endovascular rescue treatment are reserved for CVS refractory to medical therapy [2,3].
Objectives. Compare outcomes between aSAH patients with and without vasospasm.
Methods. Retrospective cohort study of all adult patients with aSAH admitted from 1st January 2018 to 30th June 2022 at a Neurocritical Care Unit in a tertiary hospital. CVS was diagnosed with TCD or cerebral angiography. Functional outcome was defined by Glasgow Outcome Scale (GOS), considering GOS 1–3 as unfavorable and GOS 4–5 as a favorable outcome. GOS was accessed at the 28th day, 3rd and 6th months.
Results. A total of 199 patients were included, of whom 91 developed CVS. Baseline characteristics, complications, length of stay, and GOS of both groups are shown in Table 1. Considering patients with vasospasm, 67% were female, with a mean age of 54 years and 98% had a previous mRS 0–1. Initial severity evaluated by Hunt and Hess score was ≥ 4 in 35% patients (vs. 28%) and the risk of vasospasm accessed by Fisher score was ≥ 3 in 91% (vs. 83%). In vasospasm group, 28 patients required endovascular rescue therapy with intra-arterial verapamil, and 30 a combination of intra-arterial treatment of verapamil and intravenous milrinone perfusion. Although the vasospasm group had a higher incidence of complications such as delayed cerebral ischemia (50%), hydrocephalus (37%), and re-bleeding (15%), vasospasm was only an independent risk factor to develop delayed cerebral ischemia ($p = 0{,}001$). Vasospasm was not related to an unfavorable or a favorable GOS on the 28th day ($p = 0{,}007$), 3rd month ($p = 0{,}07$) and 6th month ($p = 0{,}405$) after the event. However, there is an association between the presence of delayed cerebral ischemia and an unfavorable outcome at any time accessed: 28th day ($p < 0{,}001$), 3rd month ($p < 0{,}001$) and 6th month ($p = 0{,}001$).
Conclusions. This study highlights the impact of delayed cerebral ischemia on the prognosis of aSAH patients. It was not possible to establish a positive correlation between vasospasm and unfavorable outcome, however delayed cerebral ischemia plays a major role to increase the burden of disease. This could be explained by the presence of other risk factors besides vasospasm competing to development of delayed cerebral ischemia in aSAH patients.

Table 1 (abstract 000107) Baseline characteristics, complications, length of stay, and GOS of patients with and without vasospasm. GCS—Glasgow Coma Scale, GOS—Glasgow Outcome Scale, ICU—Intensive Care Unit

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000108

Introduction. The predictive factors of tuberculosis were known as low BMI, hypoalbuminemia, longer time to diagnosis and treatment. However, there were little to validate and develop the prognostic factor of respiratory failure in tuberculosis (TB) patients. We investigated the prognostic factor of respiratory failure with TB.
Methods. This study used a retrospective cohort of TB at the Catholic Medical Center between January 2019 and December 2021. Of 488 patients diagnosed as TB, 52 patients who transferred to the other hospitals were excluded. Respiratory failure was defined as PF ratio ≤ 300.
Results. A total of 436 patients were included in analysis, and 31 (7.11%) patients developed respiratory failure during treatment. We analyzed by dividing into 405 patients who were diagnosed as TB without respiratory failure and 31 patients who were diagnosed as TB with respiratory failure. Sex was not distinctive. Age was older in the respiratory failure group (59.7 ± 16.76 vs. 67.9 ± 17.44; p-value 0.009). BMI was not different statistically. However, the respiratory failure group tended to lower BMI (22.28 ± 3.38 vs. 22.00 ± 4.33; $p = 0.0736$) The number of the patients who had underlying diseases were higher in respiratory failure with TB group (56.5% vs. 90.3%; p-value < 0.001). Respiratory failure with TB group took longer time from symptom onset to diagnosis (19.78 ± 26.67 days vs. 27.53 ± 42.44 days; $p = 0.004$). Anemia and hypoalbuminemia and severe radiologic TB involvement confirmed by radiologist were more common in respiratory failure with TB group (12.69 ± 2.15 vs. 11.93 ± 2.38; $p < 0.001$, 3.8 ± 0.68 vs. 2.35 ± 0.69; $p < 0.001$, 10.07% vs. 18.45%; $p = 0.006$). But cavitary lesion, AFB stain, culture was not different between two groups.
Conclusions. Not only low BMI, hypoalbuminemia, longer time from symptom onset to diagnosis but also anemia was associated with respiratory failure with TB. We should try to find to modifiable prognostic factor in respiratory failure with TB.

Immunosenescence and cytomegalovirus reactivation in ICU-admitted severe SARS-CoV-2 patients

V. Ruiz de Santaquiteria Torres[1], A. Estrella Alonso[1], R. Fernández Tobar[1], N. Arriero Fernández[1], M. D. M. Rubio Arroyo[2], B. Castiñeiras Amor[1], Z. Eguileor Marín[1], J. P. Copa Morales[1], W. Chas Brami[1], G. A. González Wagner[1], J. E. Romo Gonzales[1], C. Benito Puncel[1], E. Quiros Oyaguez[1], A. Albaya Moreno[1], B. Mariblanca-Nieves[1], R. Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000109

Introduction. Immunosenescence could play a crucial role in the elderly fast worsening. Cytomegalovirus (CMV) past infection is a contributing factor, but CMV reactivation could lead to an uncontrolled immune response and increase morbimortality.
Objectives. To describe the potential nexus between CMV reactivation and severe SARS-CoV-2 patients' morbimortality.
Methods. A prospective study (February 2020 to December 2021) in ICU-admitted severe COVID-19 patients. Demographics, comorbidity, severity, treatment strength, ICU stay and ICU mortality were tested. Categoric variables were expressed as frequencies and percentages, and qualitatives as median and interquartile range. Multivariate logistic regression was used to evaluate CMV reactivation. Odds ratio and confidence interval of 95% were performed.
Results. From an amount of 246 patients, 37 (15%) developed CMV reactivation with a median time of onset of 22 days (14–30) from ICU admission. Univariate analysis (Table 1) showed CMV reactivation probability multiplied by three in above-70-year patients. In addition, CMV reactivation patients had, with statistical significance, more renal failure and thrombocytopenia. No differences were found in steroid administration or mechanical ventilation indication, but a higher time of mechanical ventilation, catecholamines, renal replacement and blood transfusion were needed. Furthermore, ICU length-of-stay and mortality were increased. Multivariate analysis showed ICU length-of-stay and age above 70 were CMV reactivation independent predictors (Table 2).

Table 1	Total (N = 246)	CMV (n = 37)	No CMV (n = 209)	OR (CI 95%)	P
Age	65.4 (56,6–72,2)	71,2 (66,7–74,2)	63,5 (55,5–71,2)	1.07 (1,03–1.11)	**0,001**
< 70 years	165 (67,07)	17 (45,95)	148 (70,81)	1	
Renal failure	105 (42,7)	22 (59,5)	83 (39,7)	2,27 (1,09–4,54)	**0,028**
Thrombocytopenia	42 (17,07)	16 (43,24)	26 (12,44)	5,36 (2,48–11,57)	**< 0,001**
Time of MV	11,41 (5,7–24,6)	31,6 (24–47,8)	9,5 (4,9–18,7)	1,10 (1,7–1,13)	**< 0,001mphasis>**
Catecholamines	183 (74,4)	35 (94,6)	148 (70,8)	7,21 (1,68–30,93)	**0,008**
Renal replacement	18 (7,32)	6 (16,2)	12 (5,74)	3,18 (1,11–9,09)	**0,031**
Blood transfusion	53 (21,5)	21 (56,76)	32 (15,31)	7,26 (3,42–15,39)	**< 0,001**
ICU length-of-stay	14,8 (9,25–30,83)	47,9 (27,8–66,38)	13 (8,77–24,69)	1,07 (1,05–1,10)	**< 0,001**
ICU mortality	67 (27,24)	16 (43,24)	51 (24,40)	2,36 (1,14–4,86)	**0,020**

CMV: Cytomegalovirus. OR: Odds Ratio. CI: Confidence Interval. BMI: Body Mass Index. CFS: Clinical Frailty Scale. APACHE: Acute Physiology and Chronic Health Evaluation. SOFA: Sequential Organ Failure Assessment. ICU: Intensive Care Unit. MV: Mechanical Ventilation

Table 1 (abstract 000109)

Table 2	HR	CI 95%	p
Age > 70 years	3,88	1,48 – 10,1	**0,006**
ICU stay	1,07	1,02 – 1,12	**0,004**

HR: Hazard Ratio. CI: confidence Interval. ICU: Intensive Care Unit

Table 2 (abstract 000109)

Conclusions. In our series, age above 70 is an independent factor of CMV reactivation in severe ICU-admitted COVID-19 patients. This association could be explained by immunosenescence, however, more studies are needed to prove it.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000110

Introduction. Bacterial, viral or fungal coinfections (usually Cytomegalovirus (CMV) and Aspergillus spp.) play an important role in morbimortality in Intensive Care Unit (ICU). During severe COVID-19, steroids immunosuppressor therapy may increase the risk of developing these coinfections and, therefore, of morbimortality.

Objectives. To evaluate infectious factors as possible mortality predictors in severe SARS-CoV-2 patients.

Methods. A prospective study (February 2020 to December 2021) in ICU-admitted severe COVID-19 patients was performed. Demographics, comorbidity, severity, mechanical ventilation and steroid treatment, infectious factors and ICU stay were tested. Categoric variables were expressed as frequencies and percentages, and qualitatives as median and interquartile range. Univariate logistic regression and Multivariate cox regression was used to evaluate in-hospital mortality factors. Odds ratio, Hazard ratio and confidence interval of 95% were performed.

Results. 246 patients were evaluated. The in-hospital mortality was 30%. The deceased were elderly and with more comorbidities, as well as worse ICU admission severity, with more mechanical ventilation needs, and higher steroid cumulative dose. In relation to evaluated infectious factors, just CMV reactivation and ICU admission septic shock was associated with mortality in univariate analysis (Table 1). However, after variable adjustment, septic shock at ICU admission was an independent in-hospital mortality factor (Fig. 1).

Table 1	Total (N = 246)	Dead (n = 74)	Alive (n = 172)	OR (CI 95%)	p
Age (years)	65.4 (56.6–72.2)	71.2 (63.1–75.5)	62.1 (53.2—69.7)	1.08 (1.05–1.12)	< 0.001
Elderly (> 70 years)	81 (32.9)	41 (55.4)	40 (23.3)	4.1 (2.3–7.32)	< 0.001
Charlson (per age)	0 (0–1)	1 (0–2)	0 (0–1)	1.58 (1.24–2.02)	< 0.001
APACHE II (per age)	12 (10–15)	14 (11–17)	12 (10–14)	1.13 (1.06–1.2)	< 0.001
SOFA	6 (4–8)	7 (6–9)	5 (3–7)	1.44 (1.26–1.64)	< 0.001
MV	213 (86.6)	73 (98.7)	140 (81.4)	16.69 (2.23–124–6)	0.006
SS (ICU admission)	18 (7.3)	15 (20.3)	3 (1–74)	14.32 (4–51.23)	< 0.001
Steroids c. (mg)	850 (600–1520)	1200 (750–2300)	800 (550—1310)	1 (1–1)	0.001
CMVr	37 (15.04)	17 (23)	20 (11.6)	2.27 (1.11–4.63)	0.025
CAPA	15 (6.1)	8 (10.8)	7 (4.1)	2.86 (0.99–8.2)	ns
Candida (col)	126 (51.2)	39 (52.7)	87 (50.6)	1.09 (0.63–1.88)	ns
Bacteremia	25 (10.2)	9 (12.2)	16(9.3)	1.35 (0.57–3.21)	ns
MR (col)	33 (13.4)	12 (16.2)	21 (12.2)	1.39 (0.65–3)	ns
ICU stay (days)	14.8 (9.25–30.83)	17.3 (11–28.2)	13.7 (8.9–32.5)	1 (0.99–1.01)	ns
In-hospital stay (day)	29.9 (18.8–52.3)	25.6 (14.8–37.1)	21.6 (19.6–62.2)	0.98 (0.98–0.99)	0.003

OR: Odds Ratio. CI: Confidence Interval. APACHE: Acute Physiology And Chronic Health Evaluation. SOFA: Sequential Organ Failure Assessment. MV: Mechanical Ventilation. SS: Septic Shock. ICU: Intensive Care Unit. C: Cumulative. CMVr: Cytomegalovirus reactivation. CAPA: Covid-19 Associated Pulmonary Aspergillosis. Col: Colonization. MR: Multirresistant

Conclusions. As other series show, there is no association between CMV reactivation and in-hospital mortality. Septic shock at ICU admission is an independent in-hospital mortality factor in severe SARS-CoV-2 patients.

Early implementation experiences with a multicomponent family support intervention in adult intensive care units (FICUS Trial)

S. Oesch[1], L. Verweij[1], R. Naef[1]
[1]Institute for Implementation Science in Health Care, University of Zurich, Zürich, Switzerland

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000115

Introduction. The multicenter FICUS trial was launched in June 2022 to investigate whether a nurse-led family support intervention (FSI) increases the quality of care and reduces negative mental health outcomes for family members of critically ill patients in 16 Swiss intensive care units (ICU) (Naef et al., 2022). Successful delivery of the three FSI components, namely family engagement, support, and communication, is expected to be critically influenced by ICU contexts (May et al., 2016; Pfadenhauer et al., 2017; Skivington et al., 2021). Hence, a mixed-methods multiple case study is conducted alongside the main FICUS cluster-randomized trial with a process and summative evaluation of the implementation.
Objectives. The aim of the first process evaluation data collection time point was to assess key clinical partner's understanding and perceptions of the FSI, influencing contextual determinants, and the implementation progress.
Methods. Qualitative process data were collected three months after implementation start (September to December 2022) as part of an interprofessional meeting that was scheduled to support implementation and to ensure quality of FSI delivery. Data were collected from 30 key clinical partners (intervention nurses, implementation support persons, physicians, and nurse leaders) of the eight participating ICUs allocated to the intervention arm. Audiotaped qualitative data was analyzed inductively and deductively using a pragmatic rapid thematic analysis approach.
Results. We identified four themes with subthemes, namely 1) key clinical partner's appraisal of the FSI trough positive feedback from families (i.e., perceived fit and value of the FSI for family members and enhanced relationship between families and ICU staff trough higher continuity of care), 2) interprofessional workflow and communication (i.e., collaboration and communication between physicians and family nurses, leadership support of family nurses, culture of interprofessional communication, collaboration and involvement of bedside nurses in family care), 3) individual capacity and ICU staff resources for FSI implementation and delivery (i.e., ICU staff resources, family nurses' capacity and availability for FSI delivery) and 4) external support structures (i.e., support by the study team, ongoing exchange and reflection with peers within study).
Conclusions. Our implementation is well underway. Preliminary findings of this first process assessment demonstrate the most influencing determinants related to interprofessional coordination of family care and the necessity of individual changes in behaviour and individual workflow. Additionally, delivering the FSI as part of a clinical study was experienced as challenging.

Introduction. Agitation is a common behavioral problem following traumatic brain injury (TBI). Intensive care physicians' opinions and beliefs concerning agitation on TBI patients are unknown.
Objectives. The objective was to describe ICU physicians' beliefs and perceived importance of TBI-associated agitation in critically ill patients.
Methods. Following current standard guidelines, an electronic, self-administrated, closed-answer questionnaire was built to survey the 219 physicians working in ICU Level-1 trauma centre in Canada. Each centre was contacted to identify ICU physicians included in our participants list. The 42-items survey was pre-tested for reliability and validity. Results are reported using descriptive statistics.
Results. The overall response rate was 93/219 (42%) and the completion rate was 76/93 (82%). Responses represented all Level-1 trauma centers and all Canadian provinces. A total of 87% of respondents considered TBI agitation frequent enough to justify the implementation of management protocols. More diverse were the beliefs regarding sex, gender, age and socio-economic status. Respondents believe pre-existing dementia and regular recreational drug use are potential risk factors for agitation (90% and 86%, respectively). A total of 72% of respondents stated that alfa-2 adrenergic agonists efficacious for the management of TBI agitation, 90% believed that the severity of agitation can be reduced by the presence of family at the beside, 91% believed the use of physical restraints can worsen agitation episodes. However, 84% of respondents perceived the current level of evidence insufficient. More than 85% of respondents were worried of acute and long-term detrimental outcomes and burden to patients, health care professionals and relatives.
Conclusions. TBI-associated agitation in critically ill patients is perceived as an important issue for ICU physicians. More variability was found in their beliefs on epidemiology, risks factors and management tools.

Introduction. Traumatic brain injury (TBI) survivors often suffer from agitated behaviors and will most likely receive pharmacological treatments. Choosing an optimal and safe pharmacological treatment that will not interfere with neurological recovery, remains controversial. Despite their frequent use, there have been no randomized controlled studies of antipsychotics for the management of agitation in TBI patients. By interfering with dopaminergic circuits, antipsychotics may impede neuronal plasticity processes important to cognitive recovery. To date, there has been no systematic evaluation of the pre-clinical literature summarizing the effects of antipsychotics on cognitive and motor function following experimental TBI. We conducted a systematic review and meta-analysis of pre-clinical studies evaluating the effects of antipsychotics following TBI on both cognitive and motor recovery.
Methods. The systematic review was be carried out in accordance with Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines, the SYRCLE guidelines for animal intervention studies and the protocol was registered on the International Platform of Registered Systematic Review and Meta-analysis Protocols (INPLASY202310034). Two investigators designed the search strategy and conducted the search. The MEDLINE and Embase databases were searched and references of identified studies were screened for additional studies. All pre-clinical animal studies evaluating the effects of antipsychotics on cognitive and motor functions were considered for inclusion. We only included studies administrating antipsychotic agents after inducing a TBI. Studies, including randomized and non-randomized experiments, comparing pharmacological agents to a placebo, an active treatment or a non-pharmacological intervention were included. We considered studies with all types of mammalians reproducing any form of TBI. We included animal models measuring motor and cognitive functions. Two reviewers independently evaluated each included study with the SYRCLE's risk of bias tool for animal studies. To enable meta-analysis, we graphically extrapolated repeated data measures and standard errors of the mean using WebPlotDigitizer 4.3.
Results. The search strategy identified 924 articles. After removal of duplicates, 896 articles were screened using the title and abstract. Full text assessment of 34 studies identified a total of 15 studies meeting the inclusion and exclusion criteria. In total, 1188 rodents were included in the studies. Haloperidol was the most studied antipsychotic (10 studies) followed by risperidone (3 studies) and aripiprazole (2 studies). The systematic review and meta-analysis revealed no consistent effect of haloperidol on motor function as evaluated by the beam balance and beam walk tests. However, risperidone was associated with a significant impairment motor function on day 5 post-injury. Atypical antipsychotics (aripiprazole, olanzapine and quetiapine) were not associated with impaired motor function, with aripiprazole improving beam-walk scores. In the 9 studies evaluating the Morris Water Maze (MWM) for cognitive function with haloperidol, the haloperidol-treated animals were significantly more impaired than the vehicle controls after 15 to 18 days. The 5 studies of risperidone showed similar results with increased impairment in the risperidone-treated animals after 15 to 18 days. In one study, the effects of haloperidol administered during 19 consecutive days on the MWM task persisted one month after drug cessation. The combination of atypical antipsychotics (olanzapine, quetiapine and aripiprazole) showed no increased impairment after 15 to 18 days. When combining the two studies evaluating aripiprazole and including a group with environmental enrichment, there was a trend towards a reduction in MWM impairment. Finally, only continuous daily administration ofhaloperidol and risperidone were associated with cognitive dysfunctionwhen compared to less frequent administration.
Conclusions. Continuous administration of haloperidol or risperidone may impede cognitive recovery from TBI. Intermittent dosing seems safer but would need to be studied in humans. Clinicians should avoid the use of regular use of haloperidol and risperidone until human studies are available.

Introduction. The ROX score has been validated and is widely used as a predictor of intubation in COVID-19 pneumonia patients treated with high-flow nasal cannula (HFNC). This score is calculated using only three variables: respiratory rate, SpO2 and fraction of inspired oxygen (FiO2) [1]. However, other critical indicators such as consciousness, blood pressure and acid–base balance are also important factors in determining the need for intubation. The HACOR score is a tool for predicting failure of non-invasive ventilation (NIV) and HFNC that incorporates these additional factors [1]. However, external validation of the HACOR score for predicting intubation in COVID-19 pneumonia patients treated with HFNC is limited. Therefore, the aim of this study is to externally validate both the HACOR score and the ROX score in the Japanese population.
Methods. This retrospective, observational, multicenter study was approved by the institutional review board of Tohoku University (2022-I-265) and each participating center. Patients with COVID-19 aged 18 years or older who were treated with HFNC between 16 January 2020 and 31 March 2022 (January 2020 to 2021: B.1.1.7 (alpha), July to December 2021: B.1.617.2 (delta), January to June 2022: B.1.1.529 (Omicron), July 2022 onwards: Omicron BA.5 in Japan). Patients who used HFNC after extubation or after using NIV were excluded. HACOR

score and ROX score were calculated at 2, 6, 12, 24, and 48 h. The target condition was treatment failure (intubation or death within 7 days). We calculated the area under the receiver operating characteristic curve (AUC-ROC) and calibration as diagnostic performance. We also assessed sensitivity and specificity at the 2-h time point using the cut-off value reported in a previous study (HACOR > 5 [2], ROX < 2.85 [1]).
Results. We analyzed 300 patients from nine medical centers (median age, 60 years; 76% male; median PaO2/FiO2 ratio at the start of HFNC, 157). The 7-day mortality was 2% (6/300) and the in-hospital mortality was 14% (43/300). Within 7 days of HFNC, 127 patients (42%) either required endotracheal intubation or died. The discrimination of the HACOR score and the ROX score at the 2-h time point was AU-ROC 0.63 and 0.57, respectively. The temporal changes in the discrimination of the HACOR score and the ROX score were 0.58 and 0.62 at 6 h, 0.70 and 0.68 at 12 h, 0.68 and 0.69 at 24 h, and 0.75 and 0.75 at 48 h. Sensitivity and specificity at the 2-h cut-off values were 18% sensitivity and 91% specificity for the HACOR score and 0% sensitivity and 100% specificity for the ROX score. Visual calibration assessment (Figs. 1 and 2) showed that the HACOR score at 6 h and the ROX score were not well calibrated. At 2 h, approximately 25% of patients with a HACOR score of 0 experienced treatment failure, while about 30% of those in the low-risk group by ROX score experienced treatment failure.
Conclusions. In patients with COVID-19 undergoing HFNC in Japan, the predictive performance of the HACOR score and the ROX score was inadequate. However, the discrimination of both scores tended to improve over time.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000122

Introduction. Leptospirosis is a widespread zoonosis responsible for 60,000 deaths annually worldwide (1). Acute kidney injury (AKI) is a hallmark of the disease. In addition leptospirosis-induced AKI (AKI-L) has been entertained as a potential cause of chronic kidney injury of unknown etiology, which is a significant burden in tropical rural settings (2,3). Anecdotal evidence suggests that early renal replacement therapy (RRT) may improve mortality associated with AKI-L (4). Conversely, intensive care unit (ICU)-based trials, including the landmark AKIKI carried have disproved a positive impact of early RRT on patient mortality (5). We aimed to determine i) whether the timing of RRT positively impacts mortality ii) provide an estimation of the incidence of post-leptospirosis chronic kidney disease (CKD-L).
Methods. We conducted a retrospective study in the Reunion island (Indian Ocean) between 2010 and 2020, including adult patients with confirmed leptospirosis complicated by KDIGO 2 or 3 AKI. We collected demographic clinical data both during hospital stay and at follow-up. The primary endpoint was a composite endpoint including death and CKD-L up to 3 years after hospital discharge. Factors associated with CKD-L and death were determined using logistic regression models with different adjustment variables.
Results. Three hundred eighty patients were included, 83% of whom had KDIGO 3 AKI. 71% required ICU hospitalization, and 39% were placed on RRT with a median initiation time of 1 day (0–2 days). According to the composite criterion, there was a 4% mortality in the overall study population and 8% of CKD. On univariate analysis, factors associated with the composite criterion of CKD and death included ICU severity scores, age, baseline kidney function, oligo-anuria and the need for RRT. ICU severity score, age, baseline kidney function and the need for RRT were also associated with the criteria CKD alone on univariate analysis. Using bivariate models adjusting on age or SAPS2 or prior renal function, we showed that when compared to patients who did not require dialysis, no significant difference was found between early or late dialysis initiation on the composite endpoint (Fig. 1): OR for RRT before 24 h was 5.7 (1.9–17.9) and OR for RRT after 24 h was 5.7 (2.1–16.3). Similarly, the timing of RRT initiation, whether it was early or initiated according to AKIKI criteria was not associated with the criterion CKD alone on adjusted bivariate analysis (Fig. 2): OR for RRT early was 5.1 (1.6–17.8) and OR for RRT according AKIKI criteria was 14.1 (3.7–57.8). However, the three fold ratio between these 2 OR could suggest a beneficial association of early dialysis vs AKIKI on the CKDl.

Conclusions. In conclusion, leptospirosis accounts for significant CKD. Early RRT does not seem to improve the composite mortality-CKD endpoint. Further investigations are needed to substantiate the potentially protective effects of early RRT on CKDl.

Establishing lines of communication for rehabilitation in intensive care

K. Gollub[1], J. Zanin[1], M. Desai,[1], T. Ali[1]
[1]Intensive Care Unit, Stoke Mandeville Hospital, Aylesbury, United Kingdom
Correspondence: K. Gollub
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000129

Introduction. Rehabilitation goal setting during the ICU admission reduces the risk of Post Intensive Care Syndrome-related morbidity.1 In the UK, the National Institute of Care Excellence (NICE) Quality Statement 158 (QS158) recommends that carers/support persons of all adult ICU patients should be informed of rehabilitation goals within 4 days of admission or prior to discharge.2 During the emergency response phase of the COVID-19 pandemic, communication with carers/support persons was challenged by public health policies restricting visiting as well as the pressure on healthcare services. With services exiting the emergency response phase of the COVID-19 pandemic, it is essential to re-prioritise communication of rehabilitation goals with carers/support persons of patients admitted to ICU.
Objectives. To evaluate the documentation of communication with carers/support persons about rehabilitation goals for adults admitted to ICU, to determine the extent to which Stoke Mandeville Hospital ICU is performing in relation to the NICE Quality Statement 158 (QS158).
Methods. Retrospective observational cohort review of admissions to Stoke Mandeville Hospital ICU between 1 January 2022 and 31 March 2022. Admissions were excluded if medical records were not available, if the patient transitioned to end of life care within 4 days of admission, or if rehabilitation goals were not set. A data collection proforma was used to systematically appraise scanned medical records by 2 auditors, with 10% of records dual screened to ensure inter-rater reliability. Discrepancies were discussed with intensive care consultants. Admissions were analysed according to length of stay [short stay ($\leq$4 days), and long-stay (>4 days)]. Rehabilitation goals were defined as non-treatment goals aiming to optimise functioning or reduce disability.
Results. Of 127 ICU admissions during the study period, 41 were excluded (6 no records available; 18 end of life care, 17 no rehabilitation goal set). Notes from 86 admissions were analysed [52 (60%) short stay ($\leq$4 days); 34(40%) long stay (>4 days)]. Rehabilitation goals were documented to have been communicated to carers/support persons in accordance with QS158 timeframe for 24 (46%) and 28 (82%) for short versus long stay admissions respectively. While nurses more commonly documented informing carers/support persons about rehabilitation goals for both admission groups, they were often the only multidisciplinary team representative to do so for patients with a short stay. Doctors were significantly more likely to document information given to carers/support persons about rehabilitation goals for long stay patients, which likely represents the complexity of the treatment and rehabilitation course. Multiple members of the multidisciplinary team were frequently involved with updating carers/support persons for the long stay cohort, which is generally consistent with duration of critical illness, ICU-related interventions, and phases of rehabilitation.
Conclusions. The bedside nurse is most frequently documented conversations with carers/support persons of ICU patients. There is a need for a standardised approach to documenting the communication of holistic rehabilitation goals in a manner that has low administration burden. Such an approach should be integrated into the bedside electronic patient records, minimise duplication and be easily accessible to and editable by all members of the multidisciplinary team.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000132

Introduction. Venoarterial extracorporeal membrane oxygenation (VA-ECMO) is a form of temporary mechanical circulatory support and simultaneous extracorporeal gas exchange for acute cardiorespiratory failure (1). Its use has increased significantly in recent years, becoming an invaluable bridging strategy for the care of critically ill patients (2). According to the ELSO registry, since 1995, more than 15,000 patients have received VA ECMO with a survival rate at hospital discharge of approximately 40%(1,3). Given the high mortality, attempts have been made to predict the risk of multiorgan failure (MOF) progression and mortality using various scales such as the Sequential Organ Failure Assessment score (SOFA)(4), Acute Physiology and Chronic Health

Assessment (APACHE) (1), Survival after veno-arterial ECMO (SAVE) score(5).

The oxygen debt (DEOx) determines the total amount of oxygen molecules that do not supplement excessive oxygen consumption (VO2) at rest, without being altered by body temperature, age, and body surface area (6,7). Given the complexity of this concept, simplified formulas have been proposed for the calculation of DEOx with parameters easily obtainable from the measurement of arterial gasses (6). Showing an adequate correlation with mortality and MOF in critically ill patients (8).

Objectives. To determine the validity of the quantitative measurement of oxygen debt (DEOx) by arterial gasses and to evaluate its predictive capacity for 28-day mortality and progression to multiple organ failure (MOF) in patients with veno-arterial ECMO.

Methods. Validation study of a prognostic test in a retrospective cohort of adult patients with an indication for VA ECMO support at Shaio Clinical Foundation in Bogotá DC, Colombia between 2020–2021. The primary outcome was mortality. APACHE 2, SOFA, and SAVE score were compared with DEOx, as well as the difference in associated factors using a crude and adjusted analysis, performing the area under the curve of the receiver operating characteristic.

Results. Of the 210 patients admitted during the study, 33 were selected, of whom 13 (39%) died. The average age of the population was 46.4 years (SD 12.3), with a higher proportion in the male gender (60.6%), the multivariate analysis of the variables independently related to the primary outcome. This shows an independent statistically significant relationship for mortality with DEOx. Discrimination of the primary outcome for the APACHE score, SOFA score, SAVE score, and DEOx was AUROC 0.584 (CI 0.42–0.74), AUROC 0.461 (CI 0.38–0.53), AUROC 0.446 (CI 0, 28–0.6) and AUROC 0.623 (CI 0.47–0.77) respectively; with the DeLong test $P < 0.001$.

Conclusions. Our study shows the usefulness of the DEOx as a quantitative measurement to predict mortality in patients with VA ECMO support As it is a unique variable that is easily accessible at the patient's bedside with similar behavior to the other mortality scores, it could be a reproducible and valid method to implement its use.

Constipation in type B acute aortic dissection: a single-center retrospective observational study

T. Hoshino[1], Y. Enomoto[2], Y. Inoue[1]
[1]Department of Emergency and Critical Care Medicine, University of Tsukuba Hospital, Tsukuba, Japan; [2]Emergency Care and Critical Care Medicine, University of Tsukuba Tsukuba Campus, Tsukuba, Japan
Correspondence: T. Hoshino
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000133

Introduction. Acute aortic dissection (AAD) is a life-threatening medical emergency and requires intensive care unit (ICU) admission. It is classified as Stanford type A, requiring emergency surgery, and type B, which is generally managed with conservative medical therapy. Its complications include rupture and malperfusion of the splanchnic organ, spinal cord, and lower extremities. Intestinal ischemia due to impaired blood flow is a well-known intestinal complication requiring emergency surgery. On the other hand, a nonoperative intestinal complication associated with type B AAD is not less well-known. Several patients experienced intractable constipation during medical treatment, and their ICU stays were extended. Surprisingly, no epidemiological data were recorded regarding the incidence of constipation in patients with type B AAD.

Objectives. This study aimed to determine the prevalence and characteristics of constipation associated with type B AAD.

Methods. A single-center retrospective observational study was conducted in patients admitted to the ICU for conservative treatment of type B AAD. Inclusion criteria were patients discharged from the ICU from January 2011 to August 2022. Type B AAD was diagnosed with computed tomography. We used the following exclusion criteria: (1) impending rupture which were determined by the attending physicians, (2) patients who underwent surgery during their ICU stay, (3) ICU readmission, and (4) missing data about the ICU admission date.

<Definition>Constipation was defined as the absence of stools without obstruction for ≥ 3 but < 6 consecutive days from the ICU admission day [1], paralytic ileus was defined as the absence of stools without obstruction for ≥ 6 consecutive days from the ICU admission day [2,3]. Oxygenation impairment was defined as the need for noninvasive ventilation, high-flow nasal cannula oxygen therapy, or oxygen administration of ≥ 5 L/min.

Results. A total of 75 patients with type B AAD admitted to our ICU for extensive medical therapy were examined. Of these patients, 15 were excluded. Finally, 60 patients were included. The median age and Acute Physiology and Chronic Health Evaluation II score (APACHE II) were 72 (interquartile range [IQR], 60–79) and 10 (IQR 7.3–12.0), respectively. ICU stays were 8 days (IQR 5–12). Moreover, 36 (60%) and 11 (18%) patients had constipation and paralytic ileus, respectively (table 1). Oxygenation impairment was higher in the paralytic ileus group than in constipation and non-constipation group (82%, 36%, and 23%, respectively). The patency rate of the false lumen was higher in the paralytic ileus group than in other groups (64%, 46%, and 33%, respectively). The ICU stay was longer in the paralytic ileus group than in other groups (11, 7, and 5 days, respectively). Therefore, the length of ICU stays increased with the duration between the first defecation day and ICU admission (Fig. 1).

Table 1 (abstract 000133) Characteristics of type B AAD patients

Characteristic	Overall	Paralytic ileus	Constipation	non-constipation
Cases, n	60	11	36	13
Age (median [IQR])	72 [60, 79]	69 [57, 77]	71 [60, 78]	76 [62, 80]
Male, n (%)	43 (72)	10 (92)	22 (61)	11 (85)
Body mass index (median [IQR])	23.8 [22.3, 26.2]	24.8 [23.9, 26.5]	23.2 [22.2, 26.0]	26.2 [23.8, 28.5]
APACHE II (median [IQR])	10 [7, 12]	9 [7, 10]	10 [6, 13]	11 [11, 14]
Diabetes mellitus, n (%)	7 (12)	2 (18)	3 (8)	2 (15)
False lumen patency, n (%)	23 (48)	7 (64)	13 (46)	3 (33)
Dissection of superior mesenteric artery, n (%)	4 (8)	2 (18)	1 (3)	1 (11)

Characteristic	Overall	Paralytic ileus	Constipation	non-constipation
Dissection of Abdominal Aorta, n (%)	42 (75)	7 (64)	25 (74)	10 (91)
Opioid use, n (%)	32 (53)	6 (55)	24 (67)	2 (15)

Conclusions. Constipation and paralytic ileus were prevalent in 60% and 18% of patients with type B AAD, respectively.

Higher caloric intake was associated with lower one-year mortality in critically ill medical patients

C. Y. Wang[1], C. H. Wang,[2], F. H. Wu[1]
[1]Department of Critical Care Medicine, Taichung Veterans General Hospital, Taichung, Taiwan; [2]Graduate Institute of Education, National Changhua University of Education, Changhua Changhua County, Taiwan

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000134

Introduction. Previous studies have shown that higher caloric intake can reduce hospital mortality in critically ill patients with high nutrition risk. However, there is still ongoing debate regarding the optimal amount of caloric intake to improve short-term outcomes. Few studies have focused on the long-term effects of caloric intake in critically ill patients.
Methods. Our retrospective study was conducted at a tertiary medical center, with data collected from January 2015 to December 2019. The study included patients aged over 20 years who required mechanical ventilation in the medical ICU for acute respiratory failure. We excluded patients who had ICU stays lasting less than 48 h.
Results. A total of 3764 patients with an average age of 67.1 years and an APACHE II score of 26.5 were enrolled in our study. Multivariable Cox regression analysis revealed that older age (HR: 1.01, 95% CI: 1.00–1.01), male gender (HR: 1.128, 95% CI: 0.13–0.72), shock requiring more than two vasopressors (HR: 2.19, 95% CI: 1.92–2.50), and positive fluid balance (HR: 1.07, 95% CI: 1.07–1.08) were associated with higher one-year mortality. On the other hand, higher albumin level (HR: 0.82, 95% CI: 0.76–0.88), higher hemoglobin level (HR: 0.88, 95% CI: 0.85–0.91), and higher caloric intake (HR: 0.69, 95% CI: 0.64–0.76) were associated with lower one-year mortality. Additionally, we found that patients older than 65 years, those with an APACHE II score greater than 26, and those with shock requiring more than two vasopressors were more likely to benefit from higher caloric intake.
Conclusions. The results of our study suggest that higher caloric intake might be linked to reduced one-year mortality in critically ill medical patients.

The effect of therapeutic hypothermia on ischemic brain injury assessed by 18F-FDG PET in a rat model of cardiac arrest

M. Suh[1], D. Kim[1], Y. Haijeon[2]
[1]Department of Emergency Medicine, The Catholic University of Korea—Songeui Campus, Seoul, Republic of Korea; [2]Department of nuclear medicine, Ewha Womans University Mokdong Hospital, Seoul, Republic of Korea

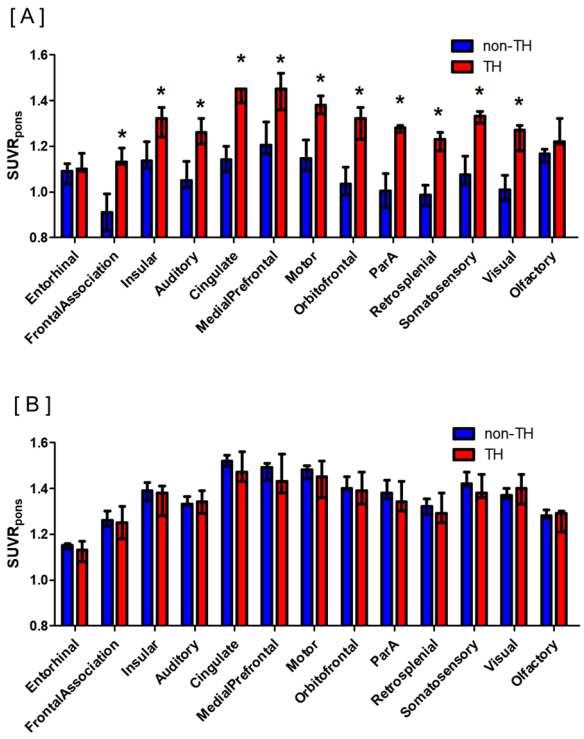
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000135

Introduction. Current guidelines strongly recommend the use of therapeutic hypothermia (TH) in comatose patients after cardiac arrest (CA) to prevent hypoxic-ischemic brain damage. However, there is recent controversy regarding its effectiveness. In this preclinical study, we evaluated the effect of TH on brain glucose metabolism, as measured by fluorine-18-fluorodeoxyglucose (18F-FDG) positron emission tomography (PET) in a rat model of CA.
Methods. CA was induced using vecuronium in Sprague–Dawley rats. 18F-FDG brain PET images were acquired from 21 CA rats, with or without TH intervention, by randomization. Between-group regional and voxel-based analyses of standardized uptake values relative to the pons (SUVRpons) were performed.
Results. Of the 21 CA rats, 9 were treated with TH, whereas 12 were simply observed without TH. The survival rates in the TH and non-TH groups were the same (67%). The SUVRpons of each brain cortical region on the PET scan did not show any difference according to the application of TH intervention. In a subgroup analysis of non-surviving rats, the SUVRpons of most brain cortical regions was significantly higher in the TH than in the non-TH group (FDR-corrected $p < 0.05$).
Conclusions. An improvement in the SUVRpons according to TH intervention was observed only in the cortical regions of the severely injured group that died. The application of TH showed protective effects in brain cortical regions but did not improve survival.

The application of TH to all CAs appears to have limited therapeutic effects.



Regional distributions of SUVpons according to the TH intervention in survived (a) and non-survived (b) subgroups
(a) When the subgroup analysis was performed regarding the 14 survived cardiac arrest (CA) rats, the SUVRpons of each brain cortical region did not show any difference in regional distribution between the TH (n = 6, red) and non-TH (n = 8) group. Data are presented as medians with interquartile ranges.
(b) When the subgroup analysis was performed regarding the 7 non-surviving cardiac arrest (CA) rats, the TH group (n = 3) showed significantly higher SUVRpons than the non-TH group (n = 4) in most brain cortical regions (*, $p < 0.05$). Data are presented as medians with interquartile ranges.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000136

Introduction. Aortic stenosis (AS) is the most common primary valve lesion requiring intervention in Europe and North America. It has a prolonged subclinical period during which, as AS worsens, left ventricular adaptation becomes inadequate, and impaired systolic and diastolic dysfunction may lead to overt heart failure (HF). The development of heart failure is an inflection point in the natural history of AS. pulmonary congestion is a cardinal feature in heart failure, and lung ultrasound (LUS) evaluation of B-lines has been proposed as a simple, noninvasive tool to assess pulmonary congestion.
Objectives. To assess the correlation of sonographic pulmonary congestion, Invasive LV pre-A pressure, and Echocardiographic estimation of LVEDP in patients with severe AS who are going to valve replacement.
Methods. Forty-eight consecutive patients with severe AS were enrolled and planned for Transcatheter aortic valve implantation (TAVI). All patients underwent comprehensive echocardiography and lung ultrasound (LUS) with the 12 scanning-site assessment. In addition, the patients underwentechocardiography before TAVI. Mitral inflow E/A ratio, E/e′, and left atrial volume index were used to estimate LV filling pressure as normal or elevated using the ASE/EACVI algorithm. Invasive LV pre-A pressure was used as a reference, with > 12 mm Hg defined as elevated.
Results. Sixty-two patients were screened from May 21 to October 2022**.** Fourteen patients were excluded from the initial population (4 patients had concomitant moderate aortic regurgitation, four patients had concomitant moderate or severe mitral regurgitation, four patients had dilated cardiomyopathy with moderate AS, four patients had low-flow, low-gradient AS, three patients had severe chronic obstructive pulmonary disease, and one patient had active lung cancer). Forty-eight patients (25 women (52%), mean age 75 years, standard deviation 7.7 years, maximum 92, minimum 55) were enrolled in the study.
The baseline characteristics of the study population and the comparisons between the different degrees of severity of ultrasound B lines are shown in Table 1.
We found a severe degree of B-lines (≥ 30) in(13) 27% and moderate (15–30) in (33)68.6% of all patients. Furthermore, the number of B-lines increased significantly along with the worsening NYHA functional classes (Fig. 1), from 13 ± 12 in NYHA Class I, through 19 ± 15 in Class II, to 43 ± 34 in Class III ($p < 0.05$, rho = 0.383).
The number of B-lines was correlated (Fig. 2) with LVEF ($R = -0.325$, $p < 0.05$), and E/E′ ($R = 0.664$, $p < 0.0001$), LVEDP ($R = 0.448$, $p < 0.001$) and Pro BNP ($R = 0.882$, $p < 0.008$). We did not find a significant correlation between E/A, DT, and LAVI.
The LVEDP correlated well with E/E′ ($R = 0.491$, $p < 0.001$). However, we did not find a correlation with E/A, DT, or LAVI.
All patients showed elevated LVEDP > 12, with a mean pressure of 26 mmHg, a minimum of 13 mmHg, and a maximum of 45 mmHg, Std-deviation 7.85428.
Conclusions. Evaluating B-lines is a simple, highly feasible method to detect pulmonary congestion in AS. The number of B-lines correlates with invasive LVEDP measurement, LVEF, E/E′, and the functional status of patients. All patients had elevated LVDEP that correlates only with E/E′.

Table (abstract 000136) The clinical characteristics of the patients in relation to ultrasound chest profile

	All	severe degree of B-lines (≥30) in(13)	moderate (15-29) in 33 68.6 %	Mild <15	P

Hyper-metabolic pattern of hypothalamus as an early biomarker of brain injury in a rat model of heat stroke

M. Suh[1], D. Kim[1], Y. Haijeon[2]
[1]Department of emergency medicine, The Catholic University of Korea—Songeui Campus, Seoul, Republic of Korea; [2]Department of nuclear medicine, Ewha Womans University Mokdong Hospital, Seoul, Republic of Korea

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000137

Introduction. Heat stroke (HS) is the most serious heat-related illness and recognized as a worldwide public concern as global temperature rise. Although the neurologic complications of HS are relatively well described clinically, there are limited number of studies regarding imaging findings. In this preclinical study, we aimed to identify the imaging findings of 18F-FDG brain PET in HS, and furthermore, to elucidate the utility of FDG PET in the evaluation of HS-induced brain injury.
Methods. HS was induced by placing Sprague Dawley rats in a hot and humid chamber maintained without food and water until meeting the diagnostic criterion of HS onset. 18F-FDG brain PET images were acquired in 7 controls and 14 HS rats three hours after the end of induction. Between group region-based (standardized uptake value normalized to the whole brain, SUVWB) and voxel-based analyses were performed.
Results. Of the 14 HS rats, 6 were non-survived, while 8 were survived. Non-survived rats showed significantly higher SUVRHB in hypothalamus and significantly lower SUVRHB in several cortical regions than controls by both of region-based and voxel-base analysis. Survived rats showed significant increase or decrease of SUVRHB compared to controls in a few cortical regions as a result of region-based analysis, but no difference was observed in voxel-based analysis.
Conclusions. The 3 h post-injury PET scan showed a distinctly different regional distribution of 18F-FDG in the brains of lethally injured HS rats compared to controls. 18F-FDG brain PET may have potential to provide early indicators of catastrophic injury as well as to reflect early neurological pathophysiology of HS.

Thrombotic and bleeding events in patients with severe COVID-19: a Japanese single center retrospective study

D. Fujita[1], A. Tsuruoka[1], R. Kuzumi[1], K. Shigemitsu[1], T. Yamashita[1], H. Rinka[1]
[1]Emergency and Critical Care Medical Center, Osaka City General Hospital, Osaka, Japan
Correspondence: D. Fujita

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000139

Introduction. In patients with COVID-19, the risk of thrombotic complications following coagulopathy are higher. As thrombotic complications can be fatal, anticoagulation therapy is recommended in moderate-to-severe patients. It has been reported that Asians have a different incidence of thrombotic and bleeding complications than Caucasians, but only limited data are available.
Objectives. This study aimed to analyze the frequency and details of thrombotic complications, as well as those of bleeding complications during anticoagulation therapy, factors associated with major bleeding, and their association with prognosis among patients with severe COVID-19.
Methods. This single center, retrospective observational study included patients with severe COVID-19 admitted to our ICU from February 2022 to January 2023. The data was collected from medical records and statistically analyzed.
Results. In total, 357 patients, comprising 281 (78.7%) males, were included; their median age was 68 years. Of them, 310 patients (86.8%) received mechanical ventilation, 27 (7.5%) received kidney replacement therapy, and 17 (4.7%) received ECMO. ICU mortality rate was 24.2% for patients receiving mechanical ventilation, excluding ECMO cases. In contrast, it was 35.2% for patients who received ECMO and 51.8% for patients who received kidney replacement therapy. Thrombotic complications were observed in 22 patients (6.1%), and further details are presented in Fig. 1. Bleeding complications were observed in 113 patients (31.8%) treated with unfractionated heparin (UFH) while monitoring APTT three times a day,

and further details are provided in Fig. 2. Patients receiving UFH were divided into two groups based on their treatment doses: prophylactic doses (PD group) and therapeutic doses (TD group). The TD group had significantly more major bleeding events (as defined by the ISTH criteria) than the PD group ($p < 0.01$). The use of unfractionated heparin exceeding 300 units/kg/day resulted in a significant increase in bleeding complications ($p < 0.01$). Age (odds ratio 1.07, 95%CI 1.03–1.12, $p < 0.01$), UFH treatment dose (odds ratio 3.95, 95%CI 1.1–14.1, $p < 0.01$), CKRT (odds ratio 11.3, 95%CI 2.61–48.9, $p < 0.01$), and ECMO (odds ratio 30.8, 95%CI 4.47–213, $p < 0.01$) were significantly associated with major bleeding events. However, neither the occurrence of thrombotic nor bleeding complications was associated with the 28-day prognosis in this study (Logrank $p = 9.93$ and 5.03, respectively).

Conclusions. In the Asian population of the study, the frequency of bleeding complications associated with anticoagulation therapy was found to be higher than the frequency of thrombotic complications. This can result in increased costs of medical care, including the need for transfusions and hemostasis. Therefore, anticoagulation therapy with lower bleeding risk and more appropriate monitoring, such as thromboelastography is necessary, particularly for Asians.

Vascular tone is heterogeneous in nascent septic shock despite a standardised faecal peritonitis model

F. Catling[1], B. Garcia[2], F. Su[2], S. Harris[3], A. Herpain[2], A. Gordon[1]
[1]Division of Anaesthetics, Pain Medicine and Intensive Care, Imperial College London, London, United Kingdom; [2]Experimental Laboratory of Intensive Care, Université Libre de Bruxelles, Brussels, Belgium; [3]Institute of Health Informatics, University College London, London, United Kingdom

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000140

Introduction. Universal resuscitation strategies have proved ineffective in septic shock [1,2], leading many to highlight patient heterogeneity and call for personalised treatment. Much heterogeneity in sepsis is obvious—patients have varied demographics, medical history, foci of infection and delays in hospital presentation—yet subgroup analyses controlling for these factors have yielded few promising signals [1,2]. Is there other, latent, heterogeneity in cohorts with nascent septic shock, which might guide individualised resuscitation?

Objectives. We report cardiovascular changes during sepsis-induced hypotension in an ostensibly homogenous cohort: a standardised, high-fidelity porcine model of faecal peritonitis.

Methods. Experiments in pigs were conducted under general anaesthesia, following EU regulations and ethical approval. Data from 64 animals were combined from several completed [3–5] and ongoing studies from a single site, which used the same protocol for all periods of the experiment described here. Continuous arterial pressure and cardiac output were monitored via aortic, femoral, radial and pulmonary artery catheters. Animals received protocolised titration of maintenance IV fluids and sedation prior to intraperitoneal instillation of 3 g/kg of autologous faeces ("insult"). Cardiovascular parameters are reported at baseline (median values 15–30 min prior to insult) and at sepsis-induced hypotension (post-insult sustained mean arterial pressure < 50 mmHg). Between these timepoints, IV fluids were reduced to 1 ml/kg/hour and no vasoactive drugs were administered.

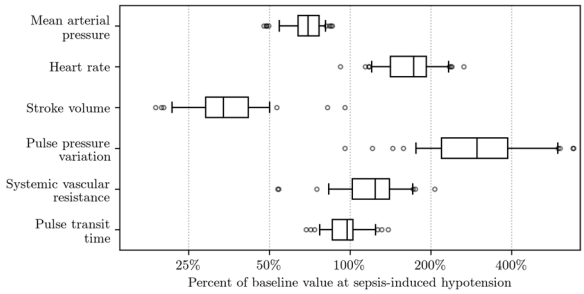
Results. Sepsis-induced hypotension occurred a median of 5.6 (IQR 4.6, 7.1) hours after insult. Large decreases in stroke volume and large increases in heart rate and pulse pressure variation were almost universal. Cohort-level summary statistics (see table) masked large, but heterogeneous, per-animal changes from baseline vascular tone (see figure). Surprisingly, but in keeping with hypovolaemia and increased sympathetic activity, systemic vascular resistance (SVR) increased in 39/49 (80%) animals, suggesting early vasoplegia in the remaining 10/49 (20%). Aortofemoral pulse transit time (PTT) shortened in 34/58 (59%). Changes in SVR and PTT were only weakly correlated (Spearman's rho − 0.26), suggesting that PTT shortening primarily reflects increased large-artery stiffness rather than decreased radius. Peripheral systolic amplification decreased in 57/58 (98%), showing that vasodilated extremities may be an unreliable indicator of total SVR [4].

Table (abstract 000140) Cohort-level parameters at baseline and sepsis-induced hypotension

Variable	n (%)	Baseline: median (IQR)	Hypotension: median (IQR)
Mean arterial pressure (mmHg)	64 (100)	69 (63, 75)	48 (47, 49)
Heart rate (BPM)	64 (100)	86 (75, 105)	151 (136, 163)
Stroke volume (ml)	49 (76)	54 (47, 60)	18 (15, 23)
Pulse pressure variation (%)	62 (96)	10 (8, 12)	32 (24, 39)
Systemic vascular resistance (dyn s cm-5)	49 (76)	1100 (961, 1484)	1258 (1081, 1695)

Variable	n (%)	Baseline: median (IQR)	Hypotension: median (IQR)
Pulse transit time (ms)	58 (90)	84 (72, 90)	80 (69, 90)
Femoral systolic—aortic systolic pressure (mmHg)	58 (90)	9 (7, 12)	− 3 (− 7, − 1)

Conclusions. We report heterogeneous vascular responses to nascent septic shock in an ostensibly homogenous cohort, where factors typically used for subgroup analysis in sepsis trials are standardised. Our results reinforce the need for early fluid resuscitation in faecal peritonitis but motivate investigation of personalised approaches to early vasopressor therapy. In particular, early vasopressors may be more likely to benefit patients with early vasoplegia and those without significant large-artery stiffening, as this latter group is less likely to experience harmful elevations in afterload [6].



Per-animal changes from baseline to sepsis-induced hypotension. 'Whiskers' indicate the 5th and 95th data percentiles.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000141

Introduction. Admission to an intensive care unit (ICU) is often a stressful experience that can negatively influence relatives´ evaluation of their satisfaction with the ICU experience (1,2). Within the factors influencing family satisfaction, relatives´ educational level has reported contradictory results (3). As a related concept, health literacy is described in terms of the subjects´ ability to obtain, process, and understand health-related information to perform adequate decision-making regarding their health (4). Health literacy may influence key family satisfaction attributes such as satisfaction with care, communication, or decision-making but to date, few studies have explored health literacy among ICU relatives, particularly its role in family satisfaction levels.

Objectives. To examine the influence of perceived stress and health literacy on family satisfaction levels among relatives of ICU patients.

Methods. An exploratory, cross-sectional, multicenter study was conducted in 3 hospitals, one in the northern, central, and southern regions of Chile respectively. Relatives of ICU patients with > 48 h of stay and with respiratory support were approached. The Family Satisfaction in the Intensive Care Uni -24 (5) questionnaire and the perceived stress scale-10 (6) were utilized. Health literacy was evaluated using 3 brief screening questions (7). Sociodemographic, communication with ICU staff, and clinical data were also collected. The relationship between family satisfaction and perceived stress, health literacy, and potential variables was guided by bivariate analyses and theory. Then, the association between selected predictors and family satisfaction was studied using a multivariate beta regression (8).

Results. A total of 101 relatives were included with 75.2% being female and a mean age of 47.3 years (SD = 14.5). 63.4% of the relatives were classified as having low health literacy. Mean perceived stress and family satisfaction levels were 16.1 (SD = 6.2) and 79.6 (SD = 17.8) respectively. Multivariate beta regression showed that low health literacy was not statistically associated with family satisfaction (exp B; 95% confidence interval; *p*-value, 1.17 [0.78–1.75], $p = 0.45$). But, family satisfaction was negatively associated with the relative's perceived stress levels (0.97 [0.94–0.99], $p = 0.04$), belonging to the central region center (0.26 [0.14–0.49], $p < 0.01$), southern center (0.28 [0.1 6– 0.50], $p < 0.01$), having a close person related to healthcare (0.52 [0.34–0.77], $p < 0.01$). Finally, the number of communications with ICU staff was positively associated with family satisfaction (1.01 [1.00–1.03], $p < 0.05$).

Conclusions. While perceived stress can be detrimental to family satisfaction, health literacy status seems not to impact family satisfaction among relatives of ICU patients. Further studies are required to confirm the influence of relatives' health literacy and the identified factors on their evaluation of the quality of their ICU stay.

Results of a bedside ultrasound in the first 24 h at admission in our Cardiologic Intensive Care Unit

O. Moreno Romero[1], G. J. M. Giménez[2], J. Pelaez Velez[1], M. T. Cruces Moreno[3]
[1]Intensive Care Unit, Hospital Universitario Clínico San Cecilio, Granada, Spain; [2]UCI, Hospital Universitario Clínico San Cecilio, Granada, Spain; [3]Intensive care unit, Hospital Universitario San Cecilio, Granada, Spain
Correspondence: O. Moreno Romero
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000144

Introduction. The evidence of bedside ultrasound performed by intensive care physicians in the management of critically ill patients has been growing in the past two–three decades, specially, in cardiologic patients in whom the use of early ultrasound and specially echocardiography, might guide or even change the actual treatment.
Objectives. First, to describe the characteristics of the acute patients admitted to our intensive care cardiologic unit in a 24-month study. Second, to describe whether the diagnosis and/or treatment at admission was modified after performing the screening bedside ultrasound in the first 24 h by our intensive care physicians.
Methods. Retrospective study of all acute patients admitted to our intensive care cardiologic unit in a 24-month period (January 2021 to January 2023) in whom an US in the first 24 h was performed (including transthoracic echocardiography, IVC ± pulmonary US). Variables analyzed: mean age, sex; diagnosis at admission (percentage): STEMI, NSTEMI, peri/myocarditis, clinical heart failure/cardiogenic shock, cardiorespiratory arrest, suspicious endocarditis, intermediate-high or high risk acute pulmonary embolism (PE) and other. Percentage of change in the diagnosis and/or treatment after performing de US.
Results. 1255 acute patients were admitted, a median of 1.8 incomes/day. Mean age 57y (14–93), 72% male. Diagnosis at admission: STEMI 329 (26.2%); NSTEMI 465 (37%); peri/myocarditis 108 (8.6%); heart failure/cardiogenic shock 92 (7.3%); cardiorespiratory arrest 58 (4.6%); suspicious infectious endocarditis IE 43 (3.4%); intermediate-high or high-risk PE 24 (1.9%) and 31 (2.5%) patients with other diagnosis. In 31% of US performed the treatment was significantly changed in the first 24 h: 68 (5.4%) emergent catheterism but not primary PCI; 8 (0.6%) urgent cardiac surgery; 4 (0.3%) urgent TAVI/valvuloplasty; 255 (20%) election/initiation of vasoactive drug; 165 (13%) guidance of liquid/diuretic treatment; 15 (1.19%) emergent pleural/pericardic drainage; 32 (2.5%) suspension of double antiagregation; 7 (0.55%) systemic trombolisys or mechanical trombectomy. Percentage change diagnosis after US was very low: in STEMI variation 1.6% (308 finally) mostly due to LHBB; in NSTEMI variation 2.5% (432 finally).
Conclusions. In our study the treatment was guided or significantly changed after the first 24 h US in 31% of patients, but for change in the diagnosis other complementary test need to be performed to asses final diagnosis (troponin, transesofagous echocardiography, catheterism…).

Percutaneous tracheostomy performed by intensive care residents guided with fiberoptic bronchoscopy in our ICU

O. Moreno Romero[1], G. J. M. Giménez[2], A. Martinez Cabezas[1], P. Fernández Morales[2]
[1]Intensive care unit, Hospital Universitario Clínico San Cecilio, Granada, Spain; [2]UCI, Hospital Universitario Clínico San Cecilio, Granada, Spain
Correspondence: O. Moreno Romero
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000145

Introduction. Percutaneous tracheostomy is an essential procedure for weaning in patients with prolonged mechanical ventilation or difficulty in weaning due to miscellaneous etiologies in our intensive care units.
Objectives. First, to describe the characteristics of all percutaneous tracheostomies performed in our ICU. Second, to analyze the complications of the technic compared with those performed by intensive care fellow physicians in the same unit.
Methods. A retrospective 24 month-study (2020 and 2021) of all patients admitted to our ICU who needed a percutaneous tracheostomy for weaning from mechanical ventilation. All tracheostomies were performed by two intensive care physicians (a resident and a fellow) and one nurse. We compared the tracheostomies performed by residents versus the ones carried out by fellows (as first intervener). Variables analyzed in both groups: patient data (sex, age, SAPS II), use of fiberoptic bronchoscopy (FOB) and complications.
Results. In 24 months we performed 82 tracheostomies, 57 by residents, 25 by fellows. Men 55 (67%), mean age 60,2 years (32–78). SAPS II of 52 (29–75). 65 patients where COVID 19 pneumonia. Mean day of tracheostomy 11 (6–16) in COVID, 14.3 (10–17) in non-COVID. FOB: 28 in the group of residents (49%), 3 in the group of fellows (12%). Complications in both groups were alike: none severe haemorrage was found; mild haemorrage, 10 (17.5%) by residents vs 4 (16%) by fellows; mild granuloma: 2 (3.5%) by residents vs 1 (1.8%) by fellows; mild wound infection: 2 (3.5%) by residents vs 1 (4%) by fellows. None fatal complication was found.
Conclusions. Percutaneous tracheostomy is an essential procedure in our daily practice and the use of FOB to support the correct needle tracheal insert ensures security when it is performed by our internal intensive care residents, as the complications comparing with the fellow pshysicians with less use of FOB have been alike.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000146

Introduction. Maintaining rapid response team (RRT)/ medical emergency team (MET) response quality is difficult. A system that supports RRT assessment could potentially contribute to medical safety. Although rapid response system (RRS) triggers have been well-studied, studies on the prediction models of short-term prognosis after RRS activation are scarce.
Objectives. We aimed to develop a model to predict short-term outcomes after RRS activation using machine learning.
Methods. This retrospective cohort study used the In-Hospital Emergency Registry in Japan, a multicentre RRS online registry. We collected

data on patient demographics, treatment before RRS, RRT/MET calls, and physiological parameters. The outcome was death within 24 h after RRS calls or unplanned transfers to an intensive care unit. To develop the eXtreme Gradient Boosted Tree Classifier (XGB) and Random Forest (RF) algorithms, a logistic regression (LR) algorithm was used. For model comparison, receiver operating Area under the curve (AUC) was evaluated and compared with those of the National Early Warning Score (NEWS) and Modified Early Warning Score (MEWS).
Results. Overall, 5414 cases were included in the study. The outcome occurred in 28.4% of the cases. The XGB model showed the highest AUC (0.798) compared to the RF model (0.796), LR model (0.785), NEWS (0.696), and MEWS (0.660). The most weighted feature in the XGB model wasdoctor activation, followed by hypotension as the activation criteria and usage ofoxygen.
Conclusions. We developed the first machine learning model for short-term prognosis after RRS. The new prediction model could prevent patients from inadequate evaluation and treatment during RRS.

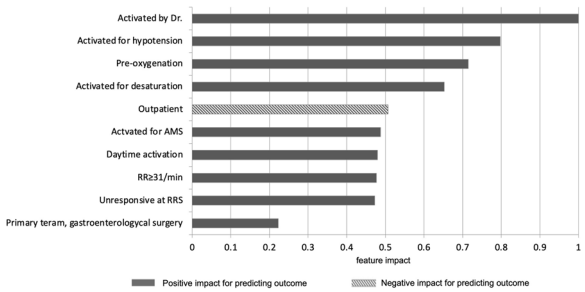

Figure 1 (abstract 000146) Feature impact for the eXtreme Gradient Boosted Tree Classifier model, top 10 features

The optimal control of veno-arterial extracorporeal membrane oxygenation and Impella (ECPELLA) considering oxygen delivery in severe cardiogenic shock: a Simulation Study

H. Matsushita[1], T. Nishikawa[2], S. Yokota[1], H. Morita[1], M. Fukumitsu[1], A. Nishiura[1], Y. Yoshida[1], K. Uemura[1], T. Kawada[1], M. Li[1], K. Saku[1]

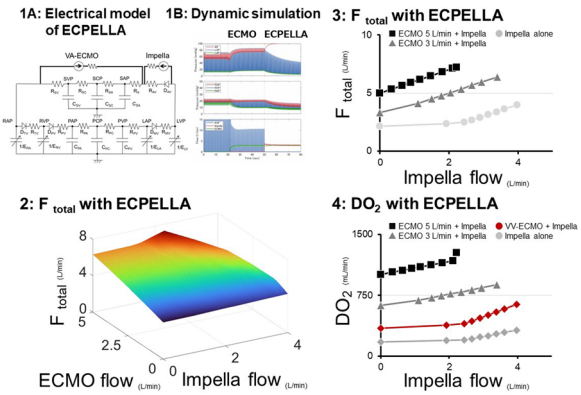
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000147

Introduction. The combination therapy of veno-arterial extracorporeal membrane oxygenation (VA-ECMO) and Impella, ECPELLA, is a powerful option for saving patients with cardiogenic shock. However, in severely compromised hemodynamics, the appropriate control of ECPELLA may vary among patients. Therefore, there is a great need in the field for the development of tools to derive optimal ECPELLA control.
Objectives. In this study, we established a mathematical hemodynamic simulator and evaluated the effects of ECPELLA on total systemic flow (F total) and oxygen delivery (DO2) in a cardiogenic shock hemodynamics.
Methods. We used Simulink® (Mathworks, Inc.) for cardiovascular simulation using a 5-element resistance–capacitance network with four ventricles represented by time-varying elastance and unidirectional valves (Fig. 1). We compared F total and DO2 in mild right ventricular dysfunction (RV end-systolic elastance (Ees): 0.4 mmHg/mL) and various left ventricular (LV) dysfunction (LV-Ees: 0.2 mmHg/mL), and VA-ECMO (0–5 L/min) and Impella flows (0–5.5 L/min), pulmonary oxygenation (SpvO2: 40–80%). DO2 was calculated by the following formula; DO2 = 1.34 * 10 * [Hb] * (CO or ECMO or Impella flow).
Results. As shown in Figs. 2 and 3, both VA-ECMO and Impella significantly increased F total, and the addition of Impella further increased F total in cases of severe LV dysfunction. VA-ECMO significantly increased DO2 (from 171 to 1,005 mL/min), and the addition of ImpellaCP further augmented DO2 (from 1,005 to 1,168 mL/min) in cases of severe LV dysfunction with lower pulmonary oxygenation. As DO2 is closely linked to F total, VV-ECMO (with SpvO2 at 80%) with Impella had limited DO2 elevation compared to ECPELLA.
Conclusions. ECPELLA significantly improved the oxygen delivery as well as total systemic flow. Through cardiovascular simulation of complex hemodynamics, the optimal control of ECPELLA can be visualized, taking into consideration oxygen delivery.



The impact of F_{total} and DO_2 with ECPELLA support in various LV dysfunction and pulmonary oxygenation.
1A: The electrical model of cardiovascular simulation. We included Impella and ECMO characteristics in the model. Impella was designed to withdraw blood from LV and returned it to aorta continuously by the axial pump. The veno-arterial ECMO was designed to absorb blood from superior vena cava and transfer to aorta continuously by the centrifugal pump. 1B: Dynamic simulation of ECPELLA hemodynamics in biventricular failure. 2 and 3: The effect of VA-ECMO and Impella flow on F total in severe LV dysfunction ($LV\text{-}E_{es}$: 0.2 mmHg/mL). Both VA-ECMO and Impella markedly increased F_{total}. 4: The impact of VA-ECMO and Impella flow on DO_2 in severe LV dysfunction and extremely lower pulmonary oxygenation ($S_{pv}O_2$: 40%). VA-ECMO and adding Impella markedly increased DO_2. Furthermore, 3 L/min of VA-ECMO with ImpellaCP(P2) raised DO_2 more than VV-ECMO ($S_{pv}O_2$: 80%) with Impella5.5(P8). DO_2 was calculated by the following formula;
$DO_{2\,(mL/min)} = 1.34 \times 10 \times Hb \times (CO \text{ or ECMO or Impella}) \times SO_{a}$
where Hb was constant at 15 g/dL, $SO_{2\,ECMO}$ was set at 1.0 and $SO_{2\,CO,\,Impella}$ was set at 0.4.
VA-ECMO, veno-arterial extracorporeal membrane oxygenation; F_{total}, total systemic flow; E_{es}, end-systolic elastance; DO_2, oxygen delivery; SO_2, oxygen saturation; $S_{cs}O_2$, cervical artery SO_2

"A prospective observational study comparing the effect of endotracheal tube with subglottic suction port (ETT SS) Vs standard endotracheal tube (ETT C) on incidence of ventilator associated pneumonia (VAP) in patients admitted to intensive care unit"

S. Ganeshbabu[1], S. Kandasamy[2]
[1]Adult Intensive Care Unit, The Madras Medical Mission Hospital, Chennai, India; [2]Surgical intensive care unit, CHRISTIAN MEDICAL COLLEGE, Vellore, India
Correspondence: S. Ganeshbabu
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000152

Introduction. One of the postulated causes of ventilator associated pneumonia (VAP) is micro-aspiration of subglottic secretions, which pool in the laryngopharynx above the cuff of endotracheal tube.
Standard endotracheal tubes (ETT C) do not have an option to remove these secretions. But, newer endotracheal tubes with a dedicated suction port just above the cuff (ETT SS), has facility to remove subglottic secretions.
While some previously studies did not show a definitive benefit, some did show benefits, with ETT SS use in VAP reduction. In our study we hypothesized the use of ETT SS will decrease the incidence of VAP.
Objectives. A Prospective Observational Study Comparing "the effect of endotracheal tube with subglottic suction port (ett ss) vs standard endotracheal tube (ett c) on incidence of ventilator associated pneumonia(vap)" in Patients Admitted To Intensive Care Unit.
Methods. Adult patients admitted to intensive care unit (ICU) with duration of ventilation more than 48 h were included in this study. The type of ET tube used for intubation was noted along with other variables like Patient details, diagnosis, pre-existing illness, APACHE II score (score based on severity of illness and any other long standing illness), number of days on ventilator, number of days of ICU & hospital stay and hospital mortality. Patients with fever, purulent respiratory secretions, increased or decreased White cell count, were screened for microorganisms from ET secretions. Surveillance for Ventilator Associated Pneumonia in this study was in accordance with the "Surveillance for ventilator-associated events in the National Healthcare Safety Network (NHSN)" guidelines released by CDC-Centers for Disease control and Prevention in Jan 2014.
Results. In total 160 patients were enrolled in the study, 80 in ETT SS group and 80 in ETT C group. The two groups were comparable in terms of age, presence of co morbid illnesses and APACHE II score.
The incidence of VAP in our ICU was 4.76 per 1000 ventilator days.

Ventilator associated events	Nil	VAC	IVAC	Possible VAP	Probable VAP	Total
ETT SS	73	4	1	0	1	79
	92.41	5.06	1.27	0.00	1.27	100.00
ETT C	72	1	4	2	2	81
	88.89	1.23	4.94	2.47	2.47	100.00
TOTAL	145	5	5	2	3	160
	90.63	3.13	3.13	1.25	1.88	100.00

The incidence of VAP was lower in ETT SS (0.76%) compared with ETT C group (2.57%) which was statistically significant.The overall incidence of VAE- Ventilator associated events (VAC + IVAC + POSSIBLE VAP + PROBABLE VAP) when both groups combined was14.27 per 1000 ventilator days. The incidence of Ventilator Associated Events VAEs between the two groups were (18.4%) in ETT SS patients and 6 (10.68%) in ETT C. The mean duration of hospital stay were in ETT SS 16.01 ± 11.06 days and in ETT C 12.83 ± 9.39 days, The duration of mechanical ventilation were in ETT SS 8.16 ± 7.76 days and in ETT C 6.53 ± 10.89 days and the mean length of ICU stay were in ETT SS 9.20 ± 6.72 days and in ETT C 7.73 ± 0.82 days. The hospital mortality were in ETT SS group (39.24%) and in ETT C group (30.86%).
Conclusions. The incidence of VAP-ventilator associated pneumonia showed a significant reduction with the use of ETT SS-Endotracheal tube with subglottic suction drainage in comparison with standard endotracheal tube ETT C.

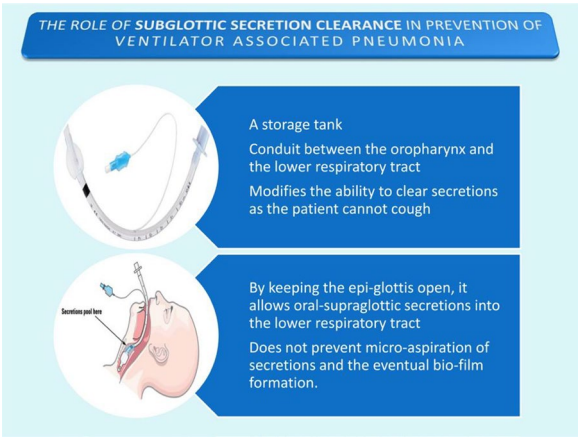

Figure 1 (abstract 000152) Micro aspiration of oral secretions in conventional endo tracheal tube

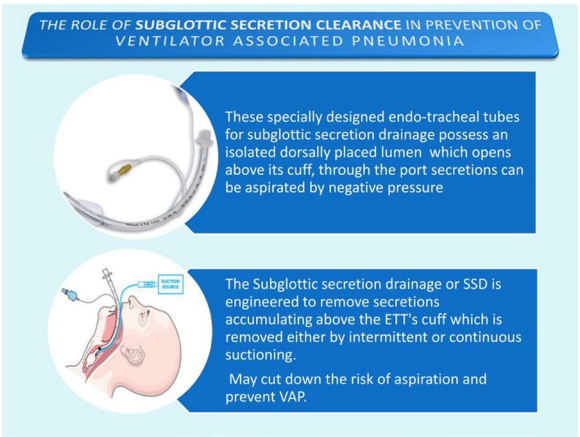

Figure 2 (abstract 000152) ETT with subglottic suction port enables subglottic drainage of secretions reducing the load of micro aspiration

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000153

Introduction. Vasopressors are used up to 85% of cases during free flap surgery. However, their use is still debated with concerns of vasoconstriction-related complications, with rates up to 53% in minor cases. We investigated the effects of vasopressors on flap blood flow during free flap breast reconstruction surgery. We hypothesized that norepinephrine may preserve flap perfusion than phenylephrine during free flap transfer.
Methods. A randomized pilot study was performed in patients undergoing free transverse rectus abdominis myocutaneous (TRAM) flap breast reconstruction. Patients with peripheral artery disease, allergic to study drugs, previous abdominal operation, left ventricular dysfunction, or uncontrolled arrhythmias were excluded. Twenty patients were randomized to receive either norepinephrine (0.03–0.10 μg/kg/min) or phenylephrine (0.42–1.25 μg/kg/min) (each $n = 10$) to maintain mean arterial pressure 65–80 mmHg (Fig. 1). Primary outcome was differences in mean blood flow (MBF) flap vessels after anastomosis measured using transit time flowmetry in the two groups. Secondary outcomes included pulsatility index, flap loss, necrosis, thrombosis, wound infection, and reoperation within 7 days postoperatively.
Results. After anastomosis, MBF showed no significant change in the norepinephrine group (mean difference, -9.4 ± 14.2 mL/min; $p = 0.082$), whereas it was reduced in the phenylephrine group (-7.9 ± 8.2 mL/min; $p = 0.021$) (Fig. 2). There were no differences in secondary outcomes between the groups.
Conclusions.: During free TRAM flap breast reconstruction, norepinephrine seems to preserve flap perfusion compared to phenylephrine. However, due to the small sample size and preliminary nature of data, further validation studies are required.

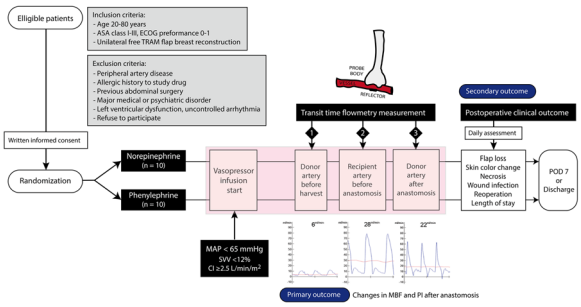

Figure 1 (abstract 000153) Study design. ASA, American Society of Anesthesiologists; CI, cardiac index; ECOG, Eastern Cooperation Oncology Group; MAP, mean arterial pressure; MBF, mean blood flow; PI, pulsatility index; POD, postoperative day; SVV, stroke volume variation; TRAM, transverse rectus abdominis myocutaneous

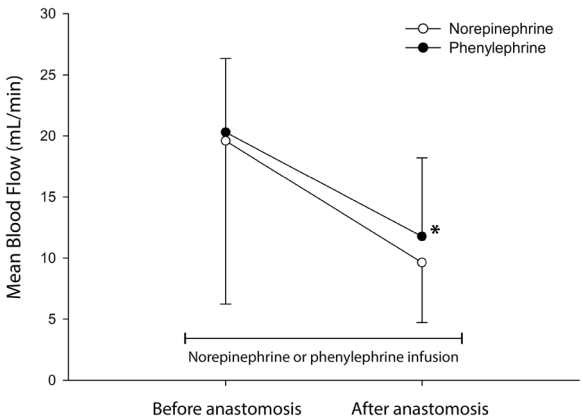

Figure 2 (abstract 000153) Changes in mean blood flow of flap before and after anastomosis in patients received norepinephrine or phenylephrine during breast reconstructive surgery. *$p < 0.05$ compared to before anastomosis in the phenylephrine group. Data points and error bars represent mean and standard deviation, respectively

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000154

Introduction. Subdural empyema is a servious complication of bacterial meningiits, a therapeutic challenge to clinicians and associated with long-term neurological sequelae.
Objectives. To evaluate the clincial features, therapeutic strategies, and outcome of subdural empyema complicating acute bacterial meningitis in neonates.
Methods. Case series from a retrospective cohort study conducted in two medical centers in Taiwan between 2003 to 2020.
Results. During the study period, a total of 153 neonates with bacterial meningitis were identified and enrolled. Among them, a total of 24 cases with subdural empyema or abscess were identified. Streptococcus agalactiae (Group B Streptococcus, GBS) and E. coli accounted for 37.5% (n = 9) and 29.2% (n = 7) of all neonatal bacterial meningitis with subdural empyema, respectively. Neonates with subdural empyema usually had more severe clincial manifestations than those with acute bacterial meningitis without subdural empyema, including more likely to have consciousness changes, focal seizures, and paresis. The cerebrospinal fluids findings cannot be predictive for occurrence of subdural empyema. Surgical intervention was performed for all cases with subdural empyema, and longer therapeutic duration of antibiotics was also noted. A higher percentage (70.8%, n = 17) of them had neurological sequelae at discharge, although the final mortality rate was comparable to those without subdural empyema.
Conclusions. Subdural empyema and abscess is not uncommon in neonates with acute bacterial meningitis. Both GBS and E coli are important pathogens to cause subdural empyema in neonates with acute bacterial meningitis. Neurosurgical intervention with longer broad-spectrum antibiotics are required to optimize the outcomes. Long-term follow-up is indicated for high risk of neurological sequelae.

Topic: Neurointensive care.

Critical care nurses' perceived end of life care competencies and nursing performance based on Nursing Intervention Classification (NIC)

Y. Woo[1]
[1]Emergency Intensive Care Unit, Seoul National University Hospital, Seoul, Republic of Korea
Correspondence: Y. WOO
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000156

Introduction. During the last days of patients' lives, invasive treatment to extend their lives causes pain and hinders human dignity and a peaceful death. In Korea, the death of patients usually occurs at medical institutions. Intensive care unit(ICU) nurses who provide care to end-of-life patients complain of difficulties in providing such care for a dignified death in the ICU environment where there are many medical devices, noises, and lights.
Objectives. This survey study analyzed the factors influencing the frequency of nursing performance based on nursing intervention classification (NIC) and the nursing competency of end-of-life nurses in ICUs.
Methods. The subjects were nurses in ICUs at each of the tertiary hospitals and general hospitals in Seoul, who provide independent and direct care, and have experience in caring for end-of-life patients. The data were collected after the researchers distributed the questionnaire themselves. Of the 230 questionnaires distributed, 181 were returned. After excluding three incomplete questionnaires, only 178 were used for research analysis. Using the SPSS version 25 program, the difference and correlation between nursing competency of end-of-life nurses in ICUs and the frequency of nursing of end-of-life patients according to the general characteristics were analyzed. The factors affecting the frequency of performance were analyzed using multiple return analysis.
Results. 1. The nursing competency of ICU nurses was statistically significantly higher when a nursing guideline reference forend-of-life patients ($p \leq 0.001$)was available at work.
2. The frequency of nursing for end-of-life patients was significantly high when the respondent said there was a nursing guideline for end-of-life patients available while working($p = 0.013$).
3. The nursing capacity of end-of-life patients is the frequency of nursing($p \leq 0.001$). There was a significant correlation with the lower factors such as knowledge (< 0.001), attitude competency (< 0.001), and acting capacity (< 0.001).
4. The factors influencing the frequency of nursing for end-of-life patients is the act of nursing ($p \leq 0.001$) and nursing knowledge (< 0.001), respectively.
Conclusions. Based on these findings, ICU nurses need to overhaul specific systems, such as providing education to enhance nursing capabilities, and providing practical support for nursing staff with end-of-life nursing expertise in the work environment, in order to protect the dignity and value of patients. In addition, as one of the core competencies of ICU nurses at the actual medical site, practical guidance needs to be provided to identify nursing capabilities for quality end-of-life care and to gauge the frequency of performance. It is also expected that the results of this study will be used as basic data for future standardized life care guidelines and improvements in ICUs.

Topic: Ethics and end of life care.

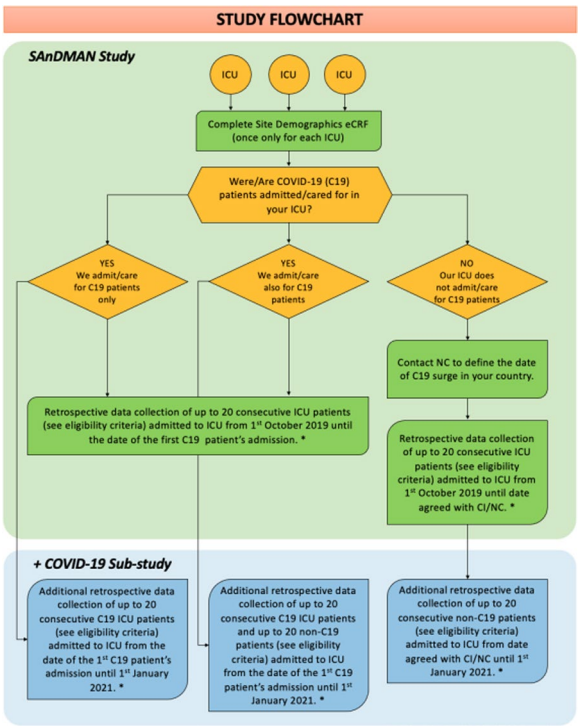
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000159

Introduction. Despite compelling evidence and guidelines recommending light sedation in critically ill patients, pain, analgesia and delirium (PAD) management likely variesinternationally. SANDMAN is an international retrospective observational study which evaluated sedative, analgesic, and antipsychotic administration practices in critically ill, mechanically ventilated adults, and adherence to PAD guidelines.
Objectives. The primary SANDMAN objective was to describe international practice variation in the use of medications and monitoring for PAD in mechanically ventilated adults prior to and during the COVID-19 (C19) pandemic. In this abstract we describe preliminary data on the 1) characteristics of participating ICUs; 2) self-reported adherence to evidence-based and guideline-directed PAD practices; 3) perceived changes in drug availability and sedation management during the C19 pandemic.
Methods. Multiple ICUs in each participating hospital were invited via the European Society of Intensive Care Medicine to contribute data on eligible patients. Ethics approval was obtained locally at all sites. Site data included hospital and ICU characteristics, common PAD therapeutic options, and use of PAD protocols and scales. Patient data were collected retrospectively, including baseline demographics, and PAD management for the first 7 consecutive days of invasive mechanical ventilation. All sites contributed data for the main cohort (20 consecutive patients admitted to ICU from 1st October 2019 to date of first C19 admission), and participation in the COVID-19 sub-cohorts was voluntary (20 consecutive C19 patients and up to 20 non-C19 patients admitted to ICU during the pandemic period).
Results. Across 27 countries and 4 continents 3008 patients were enrolled. 91 ICUs and 67/91 ICUs contributed patient data for the main cohort and C19 sub-cohorts respectively. 59 (65%) were university-affiliated hospitals, and 29 (31%) were community hospitals. 55/91 (60%) were closed ICUs, and 73/91 (81%) managed a mixed patient population. 24/90 (27%) had an open 24/7 visitation policy.
37 (41%) ICUs had 11–19 staffed beds, and 23 (25%) had $\leq$10 beds. Most ICUs (70/91) had $\geq$11 ventilators available. Nurse:patient ratio for mechanically ventilated patients was most commonly 1:2 (43%) or 1:1 (39%); and 1:2 (54%) for non-ventilated patients. Most ICUs had dedicated physiotherapists (80%) and pharmacists (65%), and < 50% had respiratory therapists or a mobility team.
Commonly available intravenous analgesics (> 80% ICUs) were fentanyl, morphine and paracetamol; > 80% ICUs reported intravenous midazolam, propofol, dexmedetomidine and ketamine were available. PAD assessment scales were in use in more than 75% of ICUs. The most common scales for each of these were RASS (94%), Numeric rating scale for pain (58%), and CAM-ICU (72%). Reported availability of local protocols were: sedation (59%), ventilator weaning/SBT (59%), delirium (57%), mobilization (49%), pain (46%), and physical restraint (43%). ICUs reported they routinely practice: daily sedation/analgesia interruption (69%), physical restraints (66%), weaning opioids to prevent iatrogenic withdrawal (62%), daily spontaneous breathing trials (56%), and analgesia-first sedation (49%). Nearly 60% ICUs who experienced drug shortages (44/87) changed their sedation practices during the pandemic and perceived that C19 patients required higher amounts of sedatives, analgesics, neuromuscular blockade, and had a higher incidence of delirium.
Conclusions. There is international variation in the use of protocols, monitoring and medications for PAD. Clinicians experienced shortages of medications during the C19 pandemic and perceived that C19 patients required higher doses of sedatives, analgesics and paralytics.



Study Flow for the SANDMAN study: an observational study describing sedation, analgesia, and delirium strategies used in ICUs around the world.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000161

Introduction. Adrenergic beta-Antagonists(beta-blockers) are also widely prescribed to psychiatric patients to control adrenergic symptoms. These patients visit emergency department more frequently due to drug intoxication, and severe cardiovascular system abnormalities can be fatal to patients with poisoning. We analyze blood levels of beta-blockers and the clinical manifestations of patients, and want to predict the progression to severe complications at the beginning of the visit.

Methods. This study was conducted at the Regional Emergency Medical Center of a university hospital with about 60,000 patients visiting emergency centers annually. We analysed retrospective medical records in beta-blocker poisoning patients aged 18 years and older who visited the emergency department between 1 January 2016 and 31 May 2022.

Results. 200 patients were enrolled. Beta-blocker blood levels were significantly higher in patients with hypotension, bradycardia, and prolonged QT intervals, with median values of 247.0 (56.5: 333.8) ng/ml, 275.8(154.3:486.4) ng/ml, and 159.0 (33.9: 310.8) ng/ml, respectively. In the analysis of cardiovascular complication prediction rate with the ROC curve, the AUC value was 0.729, the cut-off value was 72.40 ng/ml (sensitivity, 0.667 and specificity, 0.819). In addition, the correlation coefficient between drug dose and blood concentration through medical history listening at the time of visit was 0.634, which was found to have a significantly higher relationship.

Conclusions. Because blood levels in patients with beta-blocker poisoning were significantly higher in patients with severe cardiovascular complications, consider performing a blood level test early in the emergency department visit. And, the amount of drugs found through listening to the medical history is highly correlated with blood levels, so they estimated to have taken more than 72 mg of beta-blockers need active treatment and intensive observation from an early stage.

Polymyxin B-immobilized membrane can scavenge damage associated molecular patterns and neutrophil extracellular traps in vitro

M. M. Islam[1], U. Salma[1], A. Okumura[2], E. Watanabe,[1], N. Takeyama[1]
[1]Emergency and Critical Care Medicine, Aichi Medical University, Nagakute, Aichi, Japan; [2]Pediatrics, Aichi Medical University, Nagakute, Aichi, Japan

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000164

Introduction. Although both damage-associated molecular patterns (DAMPs) and neutrophil extracellular traps (NETs) have physiological roles in regulating inflammation and immune response including antimicrobial defenses against infection, they also have various pathological potential [1]. We hypothesized that the removal of excessively released DAMPs and NETs from circulation would give benefits to the patients. Direct hemoperfusion with a cartridge containing polymyxin B (PMX)-immobilized membrane (Toray, Japan) is frequently practiced in the treatment of septic shock to remove endotoxin.
Objectives. This study aimed to evaluate the efficacy of PMX-immobilized membrane to adsorb DAMPs and a released-NETs components in vitro.
Methods. DAMPs (commercially available DNA, RNA, nucleosomes and histone) and a released-NET from activated neutrophils were added separately into each well (9.5 cm2) with or without PMX-immobilized membrane (2 cm x 2 cm each with a surface area of 4 cm2) and incubated up to 60 min with shaking at room temperature. To increase the dose of PMX, the surface area of PMX-immobilized membrane was increased by repeated exposure of the membrane to the DMAPs and NETs. Following incubation, the levels of DAMPs and NETs components were assayed. Amounts of DNA conjugated with myeloperoxidase (MPO), and cell-free DNA were assayed by sandwich ELISA and Qubit fluorometer as NET-components, respectively.
Results. DAMPs and NETs components levels were significantly dampened dependent on an area of membrane surface and incubation time after incubation with PMX-immobilized membrane (Table).

Data was expressed as Median (IQR) and analyzed using ANOVA.

Conclusions. Our in vitro experiments demonstrate that PMX-immobilized membrane can absorb DAMPs and a released-NET components efficiently. Our results open new doors for understanding the application of hemoperfusion with a cartridge containing PMX-immobilized membrane to selective removal of circulating DAMPs and NETs in patients with sepsis which may improve remote organ damage.

Corticosteroid use as a risk factor for superimposed nosocomial bloodstream infections in hospitalized patients with COVID-19

N. Sathaporn, B. Khwannimit[1]
[1]Prince of songkla university, hat yai, songkhla, thailand, Department of Internal Medicine, Faculty of Medicine, Hat Yai, Thailand
Correspondence: N. Sathaporn
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000166

Introduction. Corticosteroids are a component of the standard therapy for patients with coronavirus disease 2019 (COVID-19). In real-world practice, corticosteroid dose and treatment duration depend on the physician's pragmatics. Despite, various data from some studies investigating the risk factors for blood stream infection (BSI) in patients with COVID-19, there are limited data on corticosteroid doses. Therefore, this study aimed to evaluate the potential risk factors for nosocomial BSIs in hospitalized patients with COVID-19, including the exploration of corticosteroid dosage.
Methods. A retrospective cohort study of hospitalized adult patients with COVID-19 was conducted in a tertiary care hospital between February 2020 and January 2022. COVID-19 infection was diagnosed by a positive reverse transcription-polymerase chain reaction. Nosocomial BSIs were defined as the presence of microorganisms in one or more blood cultures at least 48 h after admission. We performed univariate and multivariate analyses of various parameters to identify risk factors for nosocomial bloodstream infection.
Results. Of 252 patients, most patients (81.4%) were admitted to the ICU. 19% had nosocomial BSI. The overall mortality rate was 27%. However, mortality in the nosocomial BSI group was significantly higher than that in the non-BSI group (62.5% vs. 18.6%, $p < 0.001$). Of the patients diagnosed with COVID-19 pneumonia, 97.9% were in the nosocomial BSI group, and 87.3% were in the non-BSI group. Corticosteroids were administered to all patients in the nosocomial BSI group. Meanwhile, 81.4% of the patients in the non-BSI group used corticosteroids. The median equivalent dexamethasone dose until the first episode of BSIs was 14.1 mg/day (interquartile range, 10.4–17.7). The median durations from corticosteroid administration to the first episode of BSIs were 11.5 days. The rate of receiving methylprednisolone was significantly higher in the nosocomial BSI group than in the non-BSI group (35.4% vs. 10.8%). The use of tocilizumab, baricitinib, and tofacitinib was not associated with nosocomial BSI. Forty-three patients (89.6%) experienced one episode of nosocomial BSI. The maximum number of episodes of nosocomial BSIs (five) occurred in one patient who underwent extracorporeal membrane oxygenation (ECMO); nonetheless, other patients (4 [8.3%]) experienced second episodes of nosocomial BSIs. Pneumonia (46.6%) was the most common source of infection, followed by primary BSI (20.7%), catheter-related BSI (10.3%), urinary tract infection (8.6%), intra-abdominal infection (8.6%), and skin and soft tissue infections (5.2%). Multivariate analysis revealed that male sex (odds ratio [OR] 3.18; 95% confidence interval [CI]: 1.60–7.33), receiving methylprednisolone (OR: 2.43; 95% CI: 1.24–7.31), receiving an equivalent dexamethasone dose of 6–12 mg (OR: 3.08; 95% CI: 2.08–26.94), and increased white blood cell count on admission (OR: 3.56; 95% CI: 1.05–1.17) were significant predictors of nosocomial BSIs.

Table 1 (000166) Different variables associated with nosocomial BSIs in hospitalized patients with COVID-19 in the multivariate analysis

Variables	OR (95% CI)	p-value
Male	3.18 (1.60–7.33)	0.001
Receiving methylprednisolone	2.43 (1.24–7.31)	0.015
Equivalent dexamethasone dose <6 mg/day 6–12 mg/day >12 mg/day	Reference 3.08 (2.08–26.94) 1.91 (0.97–14.96)	0.002 0.06
White blood cell count on admission × 103 cell/mm3 (± SD)	3.56 (1.05–1.17)	<0.001

Conclusions. Unmodified risk variables for nosocomial bloodstream infections included male sex and leukocytosis at admission. Using methylprednisolone and obtaining a cumulative dosage of dexamethasone were adjusted risk variables associated with superimposed nosocomial bloodstream infections in hospitalized patients with COVID-19.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000167

Introduction. Multiplex polymerase chain reaction (mPCR) assays have emerged as tools for rapid diagnosis. The aim of this study was to asses the concordance of a semi-quantitative mPCR wiith conventional microbiologica cultures (CMCs) in endotracheal aspirates (ETAs) among patients with suspected ventilator-associated pneumonia (VAP).
Methods. CMCs and mPCRs (Biofire FilmArray Pneumonia Panel plus, BioMérieux, France) were performed in parallell on the same ETA samples.
Results. A total of 32 samples from 27 patients were analysed. The median age of patients was years, the sex ratio (male/female) was 20/7, the median SAPSII score was 35.
Overall respectively 18 mPCRs and 21 CMCs were positive.
The most frequently identified bacteria on mPCRs were *Pseudomonas aeruginosa* (8), *Klebsiella aerogenes* (3), *Staphylococcus aureus* (3), *Enterobacter cloacae* (2). On CMCs results were as follow *Pseudomonas aeruginosa (6), Klebsiella aerogenes (2), Staphylococcus aureus (3), Enterobacter cloacae (1).*
mPCRs off-panel bacteria were detected in 8 cases *(Stenotrophomonas maltophilia* 3, *Achromobacter* 1, *Hafnia alvei* 2, *Citrobacter koseri* 1 *Acinetobacter radioresistens* 1).
Bacterial type
When both tests were positive, they were concordant for at least one bacterial type in 12 cases.
They were fully concordant in 9 cases.
In case of positive mPCRs and negative CMCs (n = 4), the discrepancy was linked to a previous recent infection with the same bacteria in 2 cases.
In 5 cases, CMCs retrieved a causative pathogen not included in the test panel.
Bacterial load
The number of bacteria copies/mL detected by mPCRs and CFU/mL by CMCs were compared.
Results were similar in 2 cases.
In 9 cases mPCRs results were higher than CMCs ones. Conversly CMCs never showed higher results.
Of note, in 3 cases positive but under the clinical significance thresholds (105 CFU/mL) CMCs showed 10^5 to 10^6 copies/mL on PCRs.
Conclusions. mPCR may be a useful tool for VAP diagnostic.
However, interpretation of the results must be made with caution, integrating microbiological and clinical issues.

Introduction. Maternal critical care (MCC) encompasses the care of parturients from the onset of deterioration to post-discharge follow-up. Maternal critical illness can present additional management challenges, and maternity admissions to the intensive care unit (ICU) have been increasing in recent years. While the timely detection of critical illness in the labor suite has been receiving increasing attention, less focus has been given to the preparedness of ICUs to respond to the needs of maternity patients admitted to the intensive care unit. Many staff in the ICU may have had no prior exposure to the labor suite, and it is unusual for critical care training programs to address obstetric considerations in any depth.
Objectives. Our survey aimed to determine whether ICUs are adequately equipped to care for maternity patients. We assessed four broad areas: (i) competencies: the availability of staff with maternity-specific competencies in ICUs; (ii) emergency preparedness: the extent to which ICUs are ready to respond to obstetric emergencies, including the appropriate teams, drugs and equipment; (iii) follow-up and support: the provision of psychological screening, support and patient follow-up; and (iv) leadership and quality improvement: the presence of service leadership, local guidelines and data collection for quality improvement purposes.
Methods. Between September 2021 and January 2022, we conducted an international cross-sectional online survey of European hospitals with maternity units from 26 countries in the WHO Europe Region representing over 2 500 000 deliveries annually.
Results. 81.9% of centers (928 of 1133) provided onsite critical care facilities to maternity patients. Over 90% of the centers offered daily specialist obstetric reviews. Dual-trained staff (midwifery and critical care accreditation) were available in 24.3% of units, while 16% had access to the continuous presence of a midwife when a maternity patient was admitted. 3.5% of ICUs did not have immediate access

touterotonic drugs, 7.5% to neonatal resuscitation equipment, 9.2% toa neonatal resuscitation team, and 11.4% to perimortem cesarean section equipment. Breastfeeding support was available in 82.2%, while physical contact between mother and baby was not possible in 29.5%. Screening for psychological trauma in maternity patients occurred in only 30.6%. Post-discharge follow-up was available in 33.1%. A named senior doctor who oversaw maternal critical care activities was available in 54.4%; 36.2% of units had an equivalent named senior nurse. Maternity-specific critical care policies were available in 71% of units. 62.5% collected data for quality improvement purposes, but only 41.2% submitted data on maternity patients to a national database. Detailed information is provided in Fig. 1.

Conclusions. Gaps exist in the provision for maternity patients admitted to European ICUs. Critical care facilities were not consistently available, and when they were available, they were often inadequately resourced, which could compromise patient safety and experience.

Figure 1 (abstract 000168) Maternal critical care resources available for maternity patients in the intensive care units

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000171

Introduction. Electromagnetic stimulation of the phrenic nerve can induce diaphragm contractions; until recently, there were no specific coils designed for targeted and prolonged non-invasive electromagnetic phrenic nerve stimulation (NEPNS) in critically patients. We previously demonstrated the absence of interference with other electronic devices with 100% intensity at 30 cm distance (1). The feasibility of NEPNS was demonstrated by inducing diaphragmatic contractions before surgery in lung-healthy, normal-weight patients to ventilate these patients in a dose-dependent manner, i.e., higher intensity produced higher tidal volume (2).

Objectives. We aimed to test feasibility of NEPNS in critically ill patients i.e., can the intervention be applied in the ICU setting. Secondary aim was to examine if NEPNS has an effect on diaphragm thickness.

Methods. This feasibility non-randomized controlled study (NCT05238753) aimed to enrol 30 patients within 36 h of intubation, who were expected to remain ventilated for at least 72 h. The intervention group should receive 15 min NEPNS sessions (A) twice, (B) three, or (C) five times per day, while the control group received standard of care. For the simulation, the STIMIT exclusive PMR35 Dual Coils (STIMIT AG, Biel, Switzerland) driven by a PowerMAG 100 clinical stimulator (Mag&More GmbH, Munich, Germany) were used. If feasible, NEPNS was used stand-alone to ventilate the patient (ventilator in continuous positive airway pressure (CPAP) mode without pressure support); if necessary to adequately ventilate the patient, pressure support was added. Primary outcome was feasibility, measured as (1) sessions performed according to protocol or by follow-up session the following day, (2) time to find the optimal stimulation point, and (3) tidal volume with stimulation only (i.e., no further ventilatory support) reaching 3–6 ml/kg IBW. Key secondary endpoint was expiratory diaphragm thickness measured with ultrasound from Day 1 to Day 10 (or extubation).

Results. The study was stopped prematurely because the CE certificate of the coils was revoked due to the new medical device regulations in the EU, i.e., a total of 11 patients (5 intervention group (A), 6 control) were enrolled in 2022. The intervention twice per day was executed in 87% and 92% of cases without and with a recovery session on the following day, respectively. Time to find stimulation point was 23 [12–62] seconds. Lung ultraprotective ventilation (3–6 ml/kg IBW) was achieved in 732/6356 (11%) of stimulations with stimulation only and 2511/6356 (40%) of stimulations with additional pressure support. The remaining 49% stimulations were either with spontaneous breathing or stimulated breaths outside 3–6 ml/kg IBW. The diaphragm thickness increased by NEPNS ($p = 0.034$, Fig. 1).

Conclusions. NEPNS was feasible in the ICU setting. NEPNS seems to prevent diaphragm atrophy during mechanical ventilation measured by expiratory diaphragm thickness.

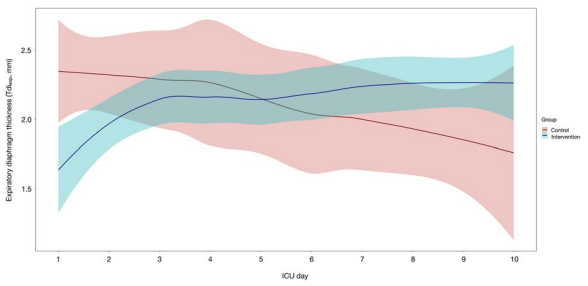

Figure 1 (abstract 000171) Trajectory of expiratory diaphragm thickness (Tdiexp, mm) measured by ultrasound over time (with 95% confidence interval) for intervention group (blue) and control (red). Intervention received non-invasive electromagnetic phrenic nerve

stimulation twice daily for 15 min which increased Tdiexp compared to controls as demonstrated in a mixed model analysis using Tdiexp from Day 1 to Day 10 (or till extubation). The intervention ($p = 0.034$), time ($p = 0.032$) and the interaction of time and group ($p = 0.004$) were significant. Delta Day 10 vs. Day 1 was significantly different (0.926 [0.485–1.063] in the intervention vs. − 0.731 [− 0.909 to − 0.565] in the control, $p = 0.036$)

A quality improvement project aimed at improving documentation of central venous catheter (CVC) and arterial line insertion within the intensive care unit (ICU) following implementation of a new trust-wide electronic noting system

J. Deane[1], L. Achiam[1], A. Myers[1], T. Samuels[1]
[1]Intensive Care Medicine, East Surrey Hospital, Redhill, United Kingdom
Correspondence: J. Deane
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000175

Introduction. Invasive catheterisation is associated with important complications including local and systemic infection. This can lead to increased mortality and higher health care costs (1). Accurate documentation of insertion and maintenance is essential in limiting catheter-associated infection and many centres now use an Electronic Health Record to improve record-keeping.
East Surrey Hospital has a busy 16 bed, mixed medical and surgical adult ICU. A comprehensive electronic notes system was introduced in 2022 to improve documentation. Prior to this, line insertion was documented by completing a separate electronic proforma which was copied into the patient's electronic notes.
Objectives. Our aim was to review the impact of using a fully electronic notes system on the documentation of central venous and arterial catheterisation and to explore ways to further promote accurate record keeping.
Methods. In this single centre study, an initial retrospective review was performed for a 2-week period (1/11/21–14/11/21) prior to electronic noting (pre-eSASH). Correct documentation of the following aspects of invasive catheterisation in ICU patients was recorded: indication (CVC only), clinician name, date inserted, type of line, patient and clinician preparation (CVC only), technique used, post-procedure care/complications. Comparable retrospective data were recorded for an early 'post-eSASH' cohort of patients (1/11/22–14/11/22).
Following these initial results, a poster was created and displayed locally, with a guide on how to correctly document lines alongside a QR code which users could scan to view a more detailed presentation on the line documentation process. The same dataset was then prospectively collected for patients admitted 1/2/23–14/2/23 (post-intervention).
Results. In the pre-eSASH cohort, a total of 23/29 (79.3%) CVCs and 10/15 (66.7%) arterial lines were correctly documented. These rates were much higher when compared with the post-eSASH cohort where 5/11 (45.5%) CVCs and 7/20 (35%) arterial lines were correctly documented. Following the intervention, a total of 10/26 (38.5%) CVCs and 13/26 (50%) arterial lines were correctly documented.
Conclusions. This survey suggests that the introduction of the new electronic notes system, eSASH, adversely affected rates of correct line documentation within the ICU (see Fig. 1). Rates of correctly documented arterial lines marginally improved following the intervention but there was minimal impact on CVC documentation. Overall, documentation appears to have significantly deteriorated following the implementation of eSASH even in spite of the intervention.
Documentation of invasive catheterisation must be improved and this may require systematic changes in the structure of the electronic system, such as simplifying the method and template for line insertion. This study is limited by small sample size and the retrospective nature of the initial phase. Further work will be done on education and reviewing the barriers to correct documentation.

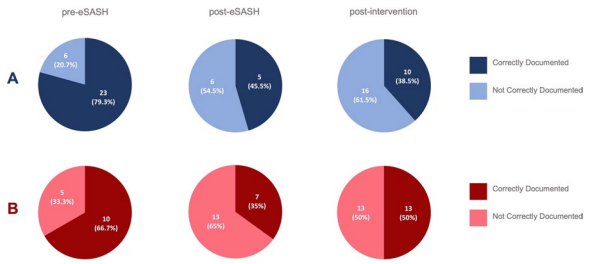

Figure 1 (abstract 000175) Pie Charts to show the number of correctly vs not correctly documented CVCs (A) and Arterial Lines (B) before and after implementation of eSASH and following our intervention. Percentages included in brackets (%)

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000178

Introduction. Monitoring vital functions is an essential part of intensive care: alarm systems identify deteriorating patients and can trigger life-saving alarm reactions. Previous research suggested that patient characteristics influence alarm loads, with higher alarm loads being observed in male patients [1]. At comparable disease severity, women are admitted to the intensive care unit (ICU) less frequently and experience higher mortality rates than men [2,3]. Whether differences in alarm loads between male and female patients translate into differences in alarm management has not been studied.

Objectives. We sought to assess the impact of patient sex on healthcare providers' reaction to ICU alarms.
Methods. Following IRB approval (Ethics vote no. EA1/127/18), this retrospective analysis included adult patients admitted to a German ICU between July 2019 and June 2021, who stayed at least 24 h, with annotated alarm data [3]. Blood pressure, heart rate, and oxygen saturation alarms were assessed in this study. Alarms were classified as actionable and non-actionable, with alarms triggering a medical intervention being defined as actionable. To account for age-related differences in alarm loads and actionable rates, we stratified patients by age (decade of life). Primary outcome was the average number of actionable alarms per sex per age group. The secondary outcome was the average number of alarms per sex per age group, independently of actionable rates. We compared both outcomes in terms of the patient's biological sex, as obtained from the medical record. Due to extremely high numbers of alarms per patient and in total, no hypothesis testing is applied. We present descriptive results.
Results. In our cohort of 976 patients, the total number of alarms was 1,226,079 with 18,077 monitored days. Female patients made up 40.3% of the cohort and were responsible for 36% of total alarms. Cohort sizes and monitoring days increased with age for both sexes (Fig. 1). The median number of alarms per monitored patient day was 93.3 [1st qt: 55.8, 3rd qt: 149.6]. In comparison, the female median of generated total alarms with 89.4 was lower than the male one with 96.1 alarms [female: 1st qt: 53.8, 3rd qt: 145.5; male: 1st qt: 56.5, 3rd qt: 152.4]. The average alarm actionable rate per patient was 12.8% [SD 10.0%]. Average actionable rates for the entire female patient cohort were lower [female: 12.6% mean, SD 9.5%; male: 13.0% mean, SD 9.8%]. When assessed individually, average actionable rates for alarm types for blood pressure [13.6% female; 14.1% male] and oxygen saturation alarms [13.7% female; 13.9% male] were higher than the average actionable rate for heart rate alarms [11.6% female; 10.4% male]. In an inter patient sex comparison, females had lower average actionable rates for blood pressure and oxygen saturation, but higher rates for heart rate alarms.
Conclusions. This study is the first to investigate the influence of patient sex on ICU providers' alarm reactions. In this descriptive analysis, we did not find large differences in actionable rates and alarm loads between female and male patients. Further research should focus on inter age group relationships—investigating the effects of alarm threshold settings and other pathophysiological factors, such as disease severity and patient comorbidities. This could pave the way towards more informed ICU alarm adjustments.

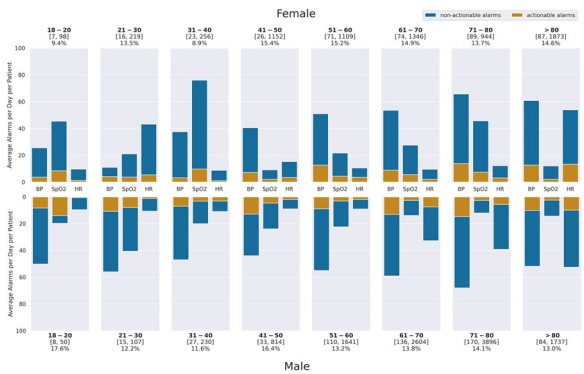

Figure 1 (abstract 000178) Distribution of actionable and non-actionable alarms in female versus male patients, stratified by life-decade. Alarm types: blood pressure (BP), oxygen saturation (SpO2), and heart rate (HR). Per age group and patient sex: [Number of patients, monitored days] and total actionable rate in percent (across all alarm types)

Introduction. Seraph-100 Microbind Affinity Blood Filter (ExThera Medical) is an extracorporeal hemoperfusion device designed to treat bloodstream infections. The filter membrane can bind bacterial and viral pathogens, increasing their elimination and reducing bacterial and viral blood titers. The device received an authorization for emergency use in critically ill patients with COVID-19 by the FDA. We aimed to summarize the efficacy and safety profile of the device in a consecutive sample of COVID-19 ICU patients.
Methods. Data was gathered from a sample of 26 consecutive COVID-19 patients that were admitted in the ICU of our hospital between November 2021 and February 2022. Eleven patients received treatment with Seraph-100 plus standard care. The control group was composed of subjects that received only standard care. Patients treated with Seraph received only a single hemoperfusion treatment. Clinical and analytical parameters, coinfections and mortality rates were compared between groups.
Results. We found no significant differences between groups regarding age, sex or comorbidities (Table 1). Treatment with Seraph was generally well tolerated. We observed no significant modifications of leukocyte cell count or C-reactive protein levels associated with

Seraph-100 treatment. In addition, no differences regarding in-hospital mortality (Table 1 and Graphic 1) or length of ICU stay were observed, although patients treated with Seraph suffered less frequently cases of Gram-positive bacteria associated pneumonia.

Conclusions. In this case series, hemoperfusion with Seraph-100 was not associated with improved survival or shorter ICU stay. However, these results may be due to the small sample size and high heterogeneity present in key clinical parameters, such as COVID-19 severity, development of other clinical complications or length of ICU stay at the time of administration of therapy, as well as the duration or dose of hemoperfusion. To adequately standardize the use of this innovative therapy in It is necessary to analyze the most appropriate timing and dose for each patient profile.

Exosomes derived from endothelial progenitor cells rescue Lipopolysaccharide-induced human brain microvascular endothelial cell injury via miR-126a-5p

Introduction. Sepsis is a potentially life-threatening complication of infection and one of the most intractable medical syndromes, accompanied by severe vascular endothelial injury,which is featured increased vascular permeability and the massive release of inflammatory mediators. During sepsis, endothelial cells (ECs) undergo multiple phenotypic and functional modifications, which are initially adaptive but eventually become harmful, leading to microvascular dysfunction. Thus, therapies that mitigate local inflammatory cytokine release could reduce the severity of ECs injury and improve patient outcomes. Endothelial progenitor cells (EPCs) are mobilized and migrate into the circulation from the bone marrow. A close association has been identified between the maintenance of endothelial structure and function by EPCs and their ability to differentiate and repair damaged endothelial tissue. EPCs mediate the process of re-endothelialization after vascular injury in multiple steps, including mobilization, chemotaxis, homing, proliferation, and differentiation. It has been shown that the process of endothelialization and angiogenesis after the endothelial injury is affected by EPCs. Our previous work found that EPCs from bone marrow transplantation promote neovascularization in the ischemic hind limbs of mice.

Exosomes are 30-150nm membrane vesicles recognized as a vehicle for modulating the function of recipient cells through the delivery of proteins, RNA, microRNAs, and other molecular constituents. They exchange their cargo with the endothelial cells of the target organ, opening new horizons for therapeutic application. Recent preclinical and clinical studies have shown that EPCs-EXOs have a beneficial therapeutic effect on various diseases, including cardiovascular diseases and kidney and lung disorders. However, there remains a research gap to fully understand the therapeutic potential of EPCs-Exos on the endothelium in sepsis. Based on that, a LPS induced septic model of Human Brain Microvascular Endothelial Cells (HB-ECs) was established to investigate the roles of EPCs-EXOs and miR-126 in sepsis-induced endothelium injury.

Objectives. EPCs play a crucial role in maintaining vascular homeostasis and facilitating vascular repair by releasing paracrine mediators such as exosomes, especially its bio-active molecules miRNAs. However, the effects of EPCs-EXOs on lipopolysaccharide(LPS)-induced endothelial cell injury are still unknown. To determine if EPCs-EXOs benefit LPS-induced endothelial cell injury and its underlying mechanism.

Methods. Methods: EPCs were isolated from peripheral blood in mice and identified by flow cytometry and immunocytochemistry. Exosomes extracted from EPCs were determined by transmission electron microscope and western blot. The HB-ECs were randomly

divided into five groups: control group (HB-ECs control), LPS group (HB-ECs + LPS), EPC group(HB-ECs + LPS + EPC),EPCs-EXOs group (HB-ECs + LPS + EPCs-EXOs), and GW4869 group (HB-ECs + LPS + EPC-EXOs + GW4869). GW4869, the exosome inhibitor, was added one hour before LPS treatment in the co-culture of HB-ECs and EPCs-EXOs. HB-ECs proliferation, cytokine secretion, apoptosis, tube forming, sprouting capacities, and miR-126a-5p expression were examined in each group at different coculture time.

Results. Compared to the control group, inflammation was induced in the LPS group by increasing cytokines and chemokines, including TNF-α, IL-6, and Caspase 3. EPCs-EXOs group show that EPCs-EXOs suppressed the increased secretion of LPS-induced cytokines at the 20th hour after coculture. The flow cytometry results showed that LPS significantly induced the apoptosis of HB-ECs. Still, it decreased after being co-cultured with EPCs or EPCs-EXOs, and the protective effect was antagonised by GW4869 significantly. In addition, microscopic image results showed that HB-ECs sprouting and tube formation were visible after 5 h of implantation. In contrast, LPS reduced tubule formation and budding, but EPCs or EPCs-Exo reversed this reduction. RT-PCR showed that LPS decreased the miR-126 RNA level, the EPCs-EXOs exhibited robust protective effects via reversing miR-126 RNA level.

Conclusions. Exosomes derived from EPCs in mice protect against LPS-induced HB-ECs injury, promote angiogenesis, antagonize apoptosis and inhibit inflammation in part due to the increased expression of miR-126a-5p.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000188

Introduction. Vitamin C has pleiotropic mechanisms of action that target multiple pathogenic pathways in sepsis. However, the effects of vitamin C on clinical outcomes of septic patients have been inconsistent among previous randomized trials [1, 2]. A recent randomized trial even showed a higher risk of death or persistent organ dysfunction in those who received vitamin C [3]. However, these trials may have been limited by delayed initiation and insufficient dosage of vitamin C.
Objectives. To assess the efficacy of early and high-dose intravenous vitamin C in a murine model of sepsis.
Methods. Sepsis was induced using the cecal ligation and puncture (CLP) model with fluid resuscitation and antibiotic therapy. Mice were randomized for treatment with intravenous vitamin C (45 mg/kg) or vehicle given 1 h after CLP in the early group and 6 h after CLP in the late group. The treatment continued every 12 h for 4 days for a total of 8 doses. To assess the synergistic effects of early and high-dose vitamin C, mice were additionally randomized for treatment with vitamin C (90 mg/kg) given 1 h after CLP in the early group. Serum inflammatory biomarker (interleukin-6 [IL-6]) was measured 24 h after CLP in the early group and 6 h after CLP in the late group. The Murine Sepsis Score (MSS) [4] was used to assess the severity of sepsis 24 h after CLP in both groups. Moreover, time-dependent IL-6 level was measured by collecting blood samples on 1, 6, 12, 24, 48, and 72 h after CLP in a separate model.
Results. In the late group, vitamin C did not increase survival compared to vehicle (median [IQR] survival time, 24 [18–78] h vs 108 [24–180] h; $p = 0.29$, log-rank test). In the early group, low-dose vitamin C did not increase survival compared to vehicle (median [IQR] survival time, 60 [24–180] h vs 72 [36–192] h; $p = 0.27$, log-rank test), while high-dose non-significantly increased survival compared to vehicle (median [IQR] survival time, 150 [36–192] h vs 72 [36–192] h; $p = 0.31$, log-rank test). In the late group, the mean (SEM) serum IL-6 level was non-significantly higher in the vitamin C-treated mice than in the vehicle-treated mice (49.1 [19.0] ng/ml vs 13.7 [4.6] ng/ml; $p = 0.09$, one-way ANOVA). The mean (SEM) serum IL-6 level was elevated after CLP in the early group, but this was not significantly decreased with low-dose or high-dose vitamin C (23.3 [6.5] ng/ml vs 28.6 [6.3] ng/ml vs 26.9 [7.0] ng/ml; $p = 0.84$, one-way ANOVA). Consistent findings were found for MSS in both groups. When only living mice were analyzed up to 72 h, the serum IL-6 levels peaked at 6 h after CLP and gradually decreased until 24 h ($p < 0.05$, one-way ANOVA with Tukey's multiple comparison test).
Conclusions. In our study, late intravenous vitamin C did not increase survival but showed a proinflammatory effect in CLP-induced sepsis. Conversely, early and high-dose vitamin C tended to increase survival. The IL-6 profile within 24 h of CLP should be further assessed in the early group.

Effect of ventilator ratio on day 7 after ventilator care on 90-day mortality in patients with ARDS: a single-center study in Korea

W. Yoo[1], K. Lee[2]
[1]pulmonary, national university, Busan, Republic of Korea; [2]Department of internal medicine, Pusan National University Hospital, Busan, South Korea, Republic of Korea
Correspondence: W. Yoo
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000191

Introduction. Ventilatory ratio (VR) is an index of impaired ventilation and has been reported as a prognostic factor in patients with acute respiratory distress syndrome (ARDS) requiring mechanical ventilation (MV). Few studies have investigated the effect of VR on mortality in ARDS patients requiring MV more than 7 days. The aim of our study was to investigate the relationship between VR on day 7 after MV and 90-day mortality.
Methods. Data from 131 patients (male, 67.9%, mean age 70.1 ± 11.0 years; 90-day mortality rate, 46.6%) who were hospitalized in a respiratory intensive care unit were retrospectively analyzed over 10 years. The relationships between VR with 90-day mortality were tested by logistic regression analysis.
Results. Of total enrolled patients, patients (n = 50) with VR ≥ 1.8 (cut-off level based on Youden's index) on day 7, 90-day mortality rate was significantly higher than dose of VR < 1.8 (64.0% vs 35.8%, p = 0.002). This cut-off level was associated with significantly higher 90-day mortality [odds ratio (OR), 2.873; 95% confidence interval [CI], 1.238–6.666; p = 0.014] based on multivariate logistic regression analysis. In patients without tracheostomy during hospital stay (n = 71), their 90-day mortality was significantly higher (57.7% vs 33.3%; p < 0.001) than those with tracheostomy. Also, their cut-off level of VR on day 7 was 2.2 (based on Youden's index), which was associated with higher 90-day mortality (OR 6.254, 95% CI 1.228–31.850; p = 0.027) based on multivariate analysis.
Conclusions. Higher VR on day 7 was associated with 90-day mortality in ARDS patients requiring MV more than 7 days. The cut-off level of VR was according to tracheostomy.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000196

Introduction. Hip fractures are one of the leading injuries in the elderly population all over the world. Although there are many current discussions about the use of intensive care to improve postoperative care of patients with hip fractures, data on this subject are limited. Postoperative follow-up is as important as preoperative follow-up of elderly patients with hip fractures who have more than one comorbidity.
Objectives. The mortality and morbidity of elderly patients with hip fractures can be reduced by careful preoperative preparation of elderly patients, not delaying the operation, follow-up in the postoperative intensive care unit (ICU) and transferring them to the service from the ICU in a short time. For this reason, we wanted to retrospectively evaluate the outcomes of patients with hip fractures followed in the postoperative intensive care unit at 30 days, 90 days and one year mortality.
Methods. Age, gender, admission diagnosis, comorbidities, length of stay in ICU, APACHE II scores, NIM, IMV, length of stay on mechanical ventilator of 68 patients with femur fracture followed in the intensive care unit, need for inotropic support, RRT and HD requirement, blood transfusion, presence of central venous catheter, arterial catheterization status, length of stay in the intensive care unit, 30, 90-day and 1-year mortality, day of the operation and anesthesia technique performed was recorded.
Results. The approximate mean age of 68 patients included in the study was 78.52 (min: 57, max: 97). The mortality profile of the elderly patients followed in the postoperative intensive care unit at 30 days, 90 days and 1 year was calculated and found to be 34.48%-41.38% and 24.14%. There is a statistically significant difference in terms of mortality status of the patient and age, APACHE II scores, ICU length of stay and hospital stay values.
Conclusions. Among the factors affecting mortality after hip fracture in studies; age, gender, type of fracture, pre-fracture activity level of the patient, ASA score, time until surgery and anesthesia method are counted. As a result; Apart from the systemic changes due to aging, this patient group, who has an additional disease that impairs their life functions, requires careful preoperative preparation starting with hospitalization, ensuring that their co-morbidities are under control as much as possible, reviewing their nutritional status, and post-operative short-term intensive care follow-up with morbidity and mortality.

Introduction. Although Covid-19`s main clinical features are related to respiratory disease, other organs are also affected directly by the virus. Neurological symptoms and syndromes are also found in the literature. Interestingly, many patients present a clinical dissociation between hypoxemia and the cardiovascular response; tachycardia or hypotension are not usually found in contrast to other severe infections. These characteristics features shall be related to the neurotropism of the virus.
Cardiovascular response to stress (such as hypoxemia) is mediated by the autonomic nervous system and heart rate variability (HRV) is an important part of it. It has been extensively studied that loss of variability is associated with poor outcomes in different diseases. HRV in Covid-19 is an actual research topic but its usefulness as a prognostic marker is yet to be defined.
Objectives. To analyse if HRV metrics could be used to identify, at admission in the ICU, those patients that were going to need mechanical ventilation during their stay.
Methods. We performed a prospective single-centre observational study. Adult patients admitted to the Hospital Clínico San Carlos ICU from February 2021 to December 2021 with confirmed SARS-CoV-2 disease but not under invasive mechanical ventilation were included. Exclusion criteria were previous history of diabetic neuropathy, history of neurologic autonomic disease, atrial fibrillation and recent (< 3 months) brain trauma.
Data was collected within 24 h from admission in spontaneous ventilation. Waveforms were continuously recorded at least for 10 min at 500 Hz during a stable sitting condition of the patient. We analyze EKG raw data, extracting RR intervals. Each recording was visually inspected, artifacts were deleted. R-R peak times were then export to R and analyze with the RHRV package. We interpolated the input data at 4 Hz.

The study protocol was approved by the local Ethics committee (CI 21/169.E).
HRV metrics were calculated as recommended by the Joint Task Force. For frequency domain metrics, we use wavelet based analysis. We also analyzed non-linear dinamics with Poincaré plots and detrended fluctuation analysis.
STATISTICAL ANALYSIS: a sample size of 21 patients was calculated. Variables were compared using non-parametrical tests. $p < 0.05$ was considered significant.
Results. 27 patients were analyzed, 55.5% of them required intubation. 73.3% of intubated patients were male and 3 patients (20%) had diabetes as a previous diagnosis. RAAS inhibitors were the more common treatments (53.3% vs 8.3%, p 0.019). Betablockers were not commonly used in these patients (6.7% in intubated patients). Intubated patients had a more rapid evolution to disease as they were admitted to the hospital more precociously (5 days vs 8 days, p 0.007) although the stay in the general ward previously to the ICU admission was the same (2 days, p 0.943). Heart rate variability, defined by time domain metrics, was similar between groups (SDNN 29.55 vs 32.4 ms, p 0.981; pNN50 0.32 vs 0.7, p 0.719 and rMSSD 12.35 vs 15.25, p 0.981). We found no statistical differences between intubated and non-intubated patients in frequency domain analysis: total power 339.08 vs 643.04 msec2 (p 0.456); normalized LF was lower (75 vs 83.67%, p 0.083) and normalized HF higher (25 vs 16.32%, p 0.083). Therefore, LF/HF ratio was lower in intubated patients, near statistical significance (3 vs 5.12, p 0.083). Nonlinear dynamics analysis also showed no differences. SD1 and SD2 derived from Poincaré plots were similar between groups (8.73 vs 10.79, p 0.981 and 41.05 vs 43.61, p 0.867; respectively). DFA alpha1 was lower in intubated patients (1.22 vs 1.33, p 0.548) but alpha2 was similar (1.11 vs 1.12, p 0.829).
Conclusions. At ICU admission, mechanical ventilation need cannot be predicted using HRV analysis in Covid-19 patients. Although not reaching statistical significance, LF/HF ratio was lower in afterwards intubated patients. Further research is needed in order to define if this finding is related to Covid-19 pathophysiology.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000202

Introduction. Sepsis and septic shock is a leading cause of mortality in the intensive care unit. Promising new therapies continue to be investigated for the management of septic shock. We tried to evaluate a novel Adsorban through a retrospective evaluation of patient's data in our centre. We used it as an adjuvant therapy in our patients with septic shock due to varied causes.
Objectives. In this study, we aimed to present the effect of Adsorbent therapy, which is still being discussed in the treatment of septic shock, on renal recovery and mortality with our results.
Methods. We retrospectively analysed data of Septic shock between 2022 to 2023 had received Adsorban (BioSkye MG350, China) as adjuvant therapy along with standard of care. Septic Shock and Septic Shock + Adsorba group were formed and their data were screned. We retrospectively analyzed patients admitted to ICU with sepsis between March 2022 and March 2023. Patients included in the study were diagnosed according to The Third International Consensus Definitions for Sepsis and Septic Shock (Sepsis-3). These therapy received continuous veno-venous hemodiafiltration (CVVHDF) for acute kidney injury and Adsorban Demographic data, procalcitonin and leukocyte levels before and after therapeutic cytokine removal and duration of Adsorban application were recorded.
Results. 2500 patients were screened in the last year. The data of 12 patients who received Adsorbent Treatment from 2500 patients were accessed. After the adsorbent treatment, the fever of the patients decreased and the need for antipyretic decreased. White blood cell and PCT values were found to be low in all patients who received adsorbent treatment. Decreases in the hourly vasopressor drug needed by the patients were detected, but it was not statistically significant. After CRRT, an increase in urine output was observed at the end of an average of 12 h, and creatinine values decreased after hours.
Conclusions. Adsorbent treatment with CRRT in patients with septic shock is thought to have a positive contribution in the treatment of septic shock. Since it was determined that this treatment was started too late in patients whose survival effect was not positive, it should be considered whether to start this treatment early. In addition, long-term discharge of patients from intensive care seems to be associated with comorbidities.

Cost effectiveness of extracorporeal carbon dioxide removal (ECCO2R) in a UK healthcare system

D. Roberts[1], O. Ethgen,[2], V. Sanjay[3]
[1]Medical Science, Baxter Healthcare, Newbury, France; [2]Economics, Serfan Innovation (Strategic Economic Research & F, Namur, Belgium; [3]Health economics, Baxter Healthcare, Oxford, United Kingdom
Correspondence: D. Roberts
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000203

Introduction. This study extends on the original research by Ethgen et al. (2) on the cost-effectiveness of ultra-protective lung ventilation (ULPV) strategies with extracorporeal carbon dioxide removal (ECCO2R) by applying cost analysis from a United Kingdom (UK) National Health Service (NHS) perspective.
Objectives. This economic evaluation complements existing clinical studies and value in facilitating ultra-lung protective ventilation (2).
Methods. The study utilised a decision-analytic model adapted for the UK NHS healthcare setting that tracks expected health states when ECCO2R with ULPV versus mechanical ventilation (MV) in patients with moderate ARDS in the ICU was used. Health outcomes were based on ventilation settings, duration of ventilation, length of stay in the Intensive Care Unit (ICU) and hospital, and complications associated with ECCO2R. (Table 1).
Results. Base case analysis (table 1) demonstrated ECCO2R-enabled ULPV is cost-effective compared to conventional MV by £1,133. Lifetime cost per Quality Adjusted Life Year (QALY) was £15,023 in the ECCO2R ULPV group, versus the £20,000 NICE QALY threshold. The analysis found this intervention aimed at enhancing ULPV adherence in ICU's would result in an additional 0.629 quality-adjusted life years (QALYs) per patient, with an incremental cost-effectiveness ratio (ICER) of £4,100 (– £7,664 to –£14,670) per QALY gained. Comparatively, the study found 3.086 QALYs for ULPV care and 2.457 QALYs for non-LPV care (table 1).
Sensitivity analysis showed in both short (60 days) and long terms (lifetime) that ventilated days (table 1) and the pressure support most impacted cost per QALY (Fig. 1.).
Discount rate for both cost and QALYs was kept constant at 3.5% (common practice).
Conclusions. While few studies assess cost-effectiveness of MV versus ULPV with ECCO2R (2,3), this study used numerous parameters informed by the LUNG SAFE study as the primary source (1). This international study provided data on 2377 ARDS patients, including baseline characteristics, MV settings, length of stay, and survival outcomes.
Limitations of the LUNG SAFE study to define the MV comparator in the analysis was plateau pressures were not monitored in 60% of ventilated ARDS patients, and a significant proportion of plateau pressure reached above 30 cm H2O. Influencing a possible overestimation of benefits associated with ECCO2R.
Despite these limitations, this study (1) still demonstrated the potential economic advantages of ULPV strategies with ECCO2R technology in managing ARDS patients within the UK NHS healthcare setting (table 1).
In conclusion, this study presents data that shows how ULPV ventilation with ECCO2R can benefit survival, provide fewer days in the ICU and hospital, and lower costs in a UK NHS. Further research is needed to explore the long-term cost-effectiveness of ECCO2R and other ULPV strategies in the management of ARDS.

Introduction. Mechanical ventilation (MV) can induce cytokine upregulation in both healthy and injured lungs due to alveolar cellular responses to stretch and decompartmentalization from cellular damage. (1) Cytokines include IL-1β and IL-6. (2) Granulocyte–macrophage colony-stimulating factor (GM-CSF) is a cytokine that plays a critical role in maintaining alveolar epithelium under homeostatic and pathologic conditions. (3) An external insult triggers GM-CSF to facilitate the epithelial wound-healing process, driving the repair processes. (3) GM-CSF also expresses elevated levels of IL1-β and IL-6. (3) We used transvenous diaphragm neurostimulation (TTDN) to reduce lung stretch during MV in a lung injury model and the resulting cytokine expression in lung tissue.
Methods. Lung injury was induced in deeply sedated pigs, ventilated using volume-control mode at 8 ml/kg, PEEP 5 cmH2O, with rate and FiO2 set to achieve normal blood gases. Injury was induced using oleic acid, delivered via the pulmonary artery until PaO2/FiO2 < 200. Animals were ventilated for 12 h post-injury. MV + TTDN100% group (n = 6) received TTDN synchronized to inspiration on every breath, targeting a reduction in ventilator pressure–time-product of 15–20%; MV group (n = 6) received volume-control ventilation only. At study end, lung tissue was sampled and homogenized. Cytokines were measured using porcine specific ELISA assays.
Results. Median (IQR) GM-CSF: 35 pg/ml (28–45) MV Dorsal; 20 pg/ml (5–41) MV Ventral, 1 pg/ml (0–8) MV + TTDN100% Dorsal, 0 pg/ml (0–18) MV + TTDN100% Ventral. IL-1β: 232 pg/ml (175–365) MV Dorsal, 611 pg/ml (227–973) MV Ventral, 331 pg/ml (188–465) MV + TTDN100% Dorsal, 359 pg/ml (201–765) MV + TTDN100% Ventral. IL-6: 18 pg/ml (14–59) MV Dorsal, 78 pg/ml (11–142) MV Ventral, 39 pg/ml (16–47) MV + TTDN100% Dorsal, 34 (9–54) pg/ml MV + TTDN100% Ventral.
Conclusions. TTDN resulted in lower cytokine expression in the ventral lung regions indicating a reduction in lung strain and ventilator-induced injury mitigation.

Prognostic factors in predicting longer hospital stay in patients with croup

J. Lee[1]
[1]Emergency Department, Chonnam National University Hospital, Gwangju, Republic of Korea
Correspondence: J. Lee
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000206

Introduction. Croup is a common respiratory inflammation of the trachea, larynx, and bronchi that can lead to inspiratory stridor and barking cough. For diagnosis and evaluation of severity for the croup, the Westley score based on clinical symptoms is most commonly used. Factors that determine this include stridor, retractions, cyanosis, level of consciousness, and air entry. Since the evaluation of these physiological factors is subjective, there are many limitations in scoring.
Methods. This retrospective observational study included patients with croup who visited our emergency department between January 2019 and December 2021. Croup is defined as acute obstructive laryngitis, J05.0 in the International Classification of Diseases 10th Revision, based on information entered by the pediatrician at discharge. The primary outcome was hospitalization for longer than a short stay.
Results. In total, 110 patients were included. The longer hospital stay rate was 41.8% (n = 46). In the multivariable analysis, oxygen demand (OR, 1.13; 95% CI, 1.02–1.25), sex (OR, 2.74; 95% CI, 1.08–6.96), and potassium level (OR, 5.13; 95% CI, 1.72–15.26) were independently associated with a longer hospitalization. The areas under the curve (AUCs) of potassium level, oxygen demand, and sex for admission were 0.697 (95% CI, 0.596–0.798), 0.631 (95% CI, 0.552–0.710), and 0.611 (95% CI, 0.522–0.701), respectively. The AUC value of the three-factor prognostic model was 0.771 (95% CI, 0.681–0.861), which was higher than potassium level, oxygen demand, and sex alone.
Conclusions. Potassium level, sex, and oxygen demand were independently associated with a longer hospital stay for croup. The combination of potassium level, sex, and oxygen demand demonstrated a fair predictive performance of the length of hospital stay.

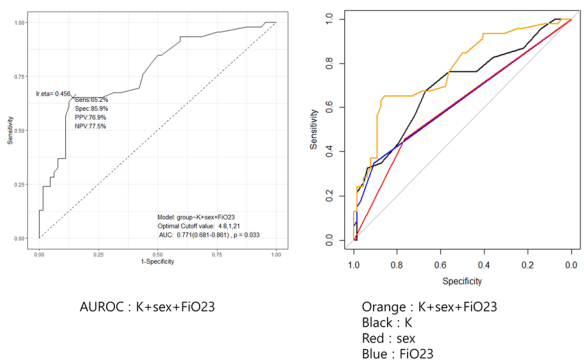

Figure 1 (abstract 000206) Receiver operating characteristics curve analyses of potassium, sex, and oxygen demand for predicting a longer hospital stay in patients with croup. The AUCs of potassium, sex, and oxygen demand were 0.697 (95% CI, 0.596–0.798), 0.631 (95% CI, 0.552–0.710), and 0.611 (95% CI, 0.522–0.701), respectively; AUC, area under the curve; CI, confidence intervals
Fig. 2 The receiver operating characteristics curve analysis of the three factors combined was 0.771 (95% CI, 0.681–0.861)

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000208

Introduction. Acute kidney injury (AKI) biomarkers, such as NGAL and L-FABP, have been reported to be useful for early AKI diagnosis and prognostic prediction in critically ill patients admitted to the ICU, postoperative patients following cardiovascular surgery, and patients with sepsis. Few studies have used AKI biomarkers to predict prognosis in patients with severe COVID-19, and there have been no reports examining both NGAL and L-FABP.
Objectives. To investigate whether urinary NGAL (uNGAL) and urinary L-FABP (uL-FABP) can predict AKI development, initiation of kidney replacement therapy (KRT), and prognosis of critically ill COVID-19 patients admitted to the ICU.
Methods. This was a single-center, retrospective cohort study including 357 critically ill COVID-19 patients admitted to our ICU between February 2020 and January 2023. A total of 287 patients were divided into two groups based on median values of uNGAL and uL-FABP levels measured at ICU admission. Levels of uNGAL ≤ 33.3 μg/gCr and > 33.3 μg/gCr were defined as the N–L and N–H groups, respectively. Levels of uL-FABP ≤ 59.7 μg/gCr and > 59.7 μg/gCr were defined as the L–L and L–H groups, respectively. Fisher's exact test was used to determine AKI development and initiation of KRT. The Logrank test was performed for 28-day mortality.
Results. Median age, BMI, P/F ratio, CRE, APACHE II score, and ICU stay were 68 years, 25.2, 159, 0.79 mg/dL, 11, and 8 days, respectively; 281 patients (78.7%) were male, 310 (86.8%) required mechanical ventilation, and 17 (4.8%) required ECMO. A total of 62 patients (21%) had CKD, 173 (48.4%) developed AKI (defined by KDIGO classification), 78 (21.8%), 49 (13.7%), and 46 patients (12.9%) were staged 1, 2, and 3, respectively, and 27 (7.6%) required KRT. The incidence of AKI was significantly higher in the N–H and L–H groups than in the N–L ($p < 0.01$) and L–L groups ($p < 0.01$), respectively. Initiation of KRT was significantly more frequent in the N–H group than in the N-L group ($p < 0.01$), but there was no significant difference between the L–L and L–H groups ($p = 0.08$). Rates of 28-day mortality were significantly higher in the N–H group than in the N–L group (Logrank $p < 0.01$), but there was no significant difference between the L–L and L–H groups (Logrank $p = 0.52$). The Kaplan–Meier curves are shown in Fig. 1 and 2.
Conclusions. While both uNGAL and uL-FABP are useful in predicting AKI development, uNGAL may be more useful than uL-FABP in predicting outcomes, such as requirement for KRT and 28-day mortality in patients with severe COVID-19. In critically ill COVID-19 patients

with hypercytokinemia and multiple organ failure, uNGAL, which is upregulated by inflammation associated with infection in addition to ischemia, may be more useful than uL-FABP, which is upregulated by oxidative stress and ischemia.

Pneumocystis jiroveci pneumonia associated with malnutrition in immunocompetent but malnourished children

J. Kang[1], H. Eunha[1], K. Younga[1]
[1]Pediatrics, Pusan National University Yangsan Hosptial, Yangsan, Republic of Korea
Correspondence: J. Kang
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000209

Introduction. Malnutrition is associated with opportunistic infections, and *Pneumocystis jiroveci* has been occasionally reported as one of the causative pathogens in malnourished patients. We herein report two cases of *Pneumocystis jiroveci* pneumonia (PCP) in immunocompetent but malnourished children.
Methods. Patient 1 was a 4-month-old girl with maple syrup urine disease, who had been fed low branched-chain amino acid formula and underwent intermittent peritoneal dialysis. She had a mild dry cough for a month, and a chest X-ray three weeks ago before presentation showed diffuse haziness on both lung field.
Patient 2 was a 5-month-old male born at 28 weeks of gestation. He was transferred to our hospital because of mechanical ventilator weaning failure, despite being treated for pneumonia for three weeks. He was found to have rickets after four months of feeding only hypoallergenic formula for suspected gastroesophageal reflux, which is known as "Neocate rickets".
Results. In both patients, *Pneumocystis jiroveci* was detected in sputum aspirates using Polymerase Chain Reaction tests. They required mechanical ventilator support due to hypoxemic respiratory failure caused by PCP, and could be weaned from mechanical ventilator after treatment with trimethoprim/sulfamethoxazole.
Conclusions. These cases suggest that PCP should be considered as an opportunistic infection in malnourished children who shows prolonged unexplained respiratory symptoms and radiologic abnormalities, regardless of their immune status.
A letter of consent has been received for identifiable patient(s) in this abstract. IRB has been approved.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000210

Introduction. Non-contrast CT (NCCT) imaging of the head is widely accepted in evaluating acute stroke. However,its sensitivity in identifying the ischemic regions is low. Current guidelines only recommend using NCCT to exclude hemorrhage [1]. To assess the extent of brain ischemia, CT perfusion (CTP) helps to evaluate the hemodynamic status of brain with quantified perfusion values. Several randomized controlled trials have also used CTP results to guide thrombodectomy [2]. Unfortunately, the advantages of CTP imaging in the assessment of patients, who have undergone cardiac surgery, are largely unknown.
Objectives. To investigate the association between CTP results and neurological outcomes, and to compare NCCT and CTP in terms of their correlation with clinical outcomes in patients with suspected ischemic cerebral conditions after cardiac surgery.
Methods. Data of patients undergoing cardiac surgery presenting with postoperative neurological symptoms were prospectively collected from June 2020 to July 2022. NCCT was used to exclude those with cerebral hemorrhage. Patients with suspected ischemic cerebral conditions examined by both NCCT and CTP were included. ASPECT score was calculated. Volume of CBF < 30%,volume of Tmax > 6.0 s and mismatch volume were determined based on CTP images to reflect ischemic core and penumbra. The primary outcome was the Modified Rankin Scale (mRS) on discharge from hospital. Secondary outcomes included in-hospital mortality, length of hospital and intensive care unit stay, and tracheotomy. The area under the receiver operating characteristic (AUROC) curve was used to evaluate the predictive power.
Results. 9134 patients were screened. Among them, 132 presented with postoperative neurological symptoms. 45 patients were included for the analysis. There was no statistically significant difference in mRs on discharge between patients with a positive initial NCCT result and those with a negative result (4.00 vs 3.00, P = 0.062). There was also no significant difference in all the secondary outcomes stratified by NCCT results. Patients with unfavorable neurological outcomes (mRs > 3) had significantly lower ASPECT score (P = 0.034), higher volume of ischemic core (P < 0.001) and penumbra (P < 0.002) (Table). The ASPECT score, volume of ischaemic core and penumbra correlated with the mRS on discharge. The AUROC of the ASPECT score, volume of ischemic core and penumbra in predicting unfavorable neurological outcomes were 0.679 (0.523–0.810), 0.792 (0.644–0.898) and 0.696 (0.541–0.824) respectively (Fig. 2).

	Overall	mRs < = 3	mRs > 3	p value
	45	22	23	
ASPECT	9.00 [8.00, 9.00]	9.00 [8.00, 10.00]	8.00 [7.50, 9.00]	0.034
Positive initial NCCT, n	20 (44.4)	7 (31.8)	13 (56.5)	0.136
Volume of CBF < 30%, ml	0.00 [0.00, 19.80]	0.00 [0.00, 0.00]	16.30 [0.00, 43.50]	< 0.001
Volume of Tmax > 6 s, ml	33.60 [0.00, 176.90]	0.00 [0.00, 67.12]	129.90 [6.90, 239.75]	0.020
Tracheostomy, n	16 (35.6)	4 (18.2)	12 (52.2)	0.029
LOHS, days	17.00 [14.00, 28.00]	15.00 [13.25, 24.75]	20.00 [14.50, 29.00]	0.387
LOICU, days	11.00 [7.00, 19.00]	8.00 [6.00, 11.75]	14.00 [9.00, 23.50]	0.038

Conclusions. NCCT result was not associated with the neurological outcome in patients with suspected ischemic cerebral conditions after cardiac surgery. Patients with unfavorable neurological outcomes presented significantly worse markers on CTP. Volume of ischemic core on CTP may be better to predict the neurological outcomes in patients with suspected ischemic cerebral conditions after cardiac surgery.

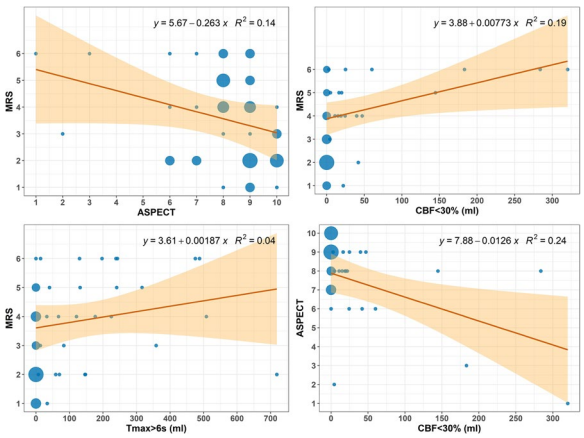

Figure 1 (abstract 000210) Relationship between NCCT and CTP variables

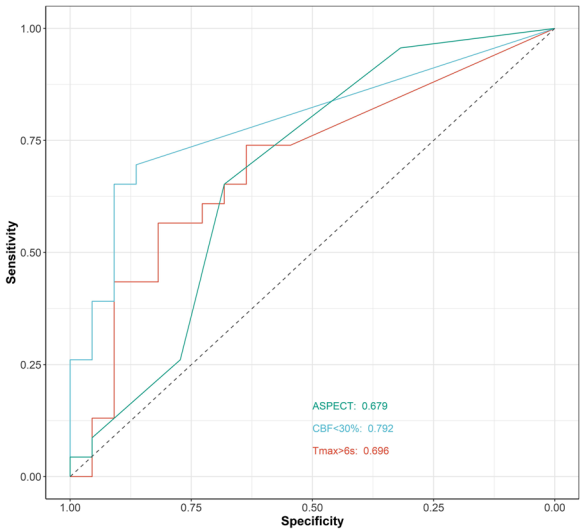

Figure 2 (abstract 000210) Receiver operating characteristic curves of 4 NCCT and CTP variables for poor neurological outcomes (mRs > 3)

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000214

Introduction. The Simplified Acute Physiology Score 3 (SAPS 3), and the Sequential Organ Failure Assessment (SOFA) score are models that predict the mortality rate of patients admitted to intensive care units. Because there are differences in the parameters used to calculate the scores of SAPS3 and SOFA, there may be differences in the expected prognosis of the two models for the same patient. We aimed to compare the in-hospital mortality prediction of SAPS3, Korean SAPS3, a first-level customization of SAPS3, and SOFA scores in sepsis patients. We also evaluated the predicting performance of the three scoring systems in pulmonary sepsis versus non-pulmonary sepsis.
Methods. This retrospective cohort study analysed the prospectively collected national database of the Korea Sepsis Association from September 2019 to December 2021. Adult patients who were diagnosed with sepsis based on the sepsis-3 definition were included. To compare the ability of three predictive models, calibration and discrimination were determined by the Hosmer–Lemeshow test and the area under the receiver operating characteristic (aROC) curve, respectively. In addition, comparison between models according to the site of infection was also performed (pulmonary sepsis patients vs. non-pulmonary sepsis patients).
Results. The study included 4,673 patients. The hospital mortality rate was 36.4%(1,703 patients). The 1748 patients with pulmonary sepsis had higher hospital mortality rates than the 2,925 patient with non-pulmonary sepsis (41.8% vs. 33.3%; $P < 0.001$). The SAPS 3 score was significantly higher for the pulmonary sepsis patients compared with non-pulmonary sepsis patients (74.0 vs. 70.0; $P < 0.001$). However, there was no significant difference in the SOFA score, which did not reflect the severity of patients with pulmonary sepsis relatively well (10.0 vs. 10.0; $P = 0.894$). The discriminative performance in all patients was fair with SAPS-3 and SOFA while lower with SOFA (aROC: 0.741 vs. 0.725; $P = 0.0159$). In the pulmonary sepsis patients, the discrimination of SOFA was poor, and significantly lower than that of the SAPS 3 and K-SAPS 3 (aROC: 0.686 vs. 0.719; $P < 0.001$). The general equation of SAPS3 and Korean SAPS3 showed good calibration in all analyses, while SOFA exhibited poor calibration in all patients ($\hat{C} = 20.11$, $P = 0.01$) and non-pulmonary sepsis patients. ($\hat{C} = 19.30$, $P = 0.023$). All prognostic models significantly overestimated the observed mortality ($SMR < 1.0$).
Conclusions. In patients with sepsis admitted to the ICU, SAPS3 was superior to the SOFA score in predicting prognosis. The regional customization of SAPS also improved the quality of prediction for patients with sepsis, and this tendency was more prominent in patients with pulmonary sepsis.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000215

Introduction. The Faculty of Intensive Care Medicine (FICM) and the Intensive Care Society specify standards of care for patients referred to ICU: documentation of a discussion with a consultant, time of assessment, and time of decision to admit (1). In addition, accepted patients should be admitted within 4 h of decision. Furthermore, documentation should include of Treatment Escalation Plan (TEP) detailing consideration of benefits and burdens of therapies. Most units have access to a local audit system, but this is limited to recording activity occurring within an ICU. Furthermore, identifying referrals and evaluating processes of care entails burdensome manual data collection. Therefore, FICM guidelines recommend that the ICU community should develop a methodology to review referrals and evaluate decision making processes.
Objectives. We aimed to establish an innovative, data-driven programme in order to develop the data infrastructure required to identify referrals to critical care across a region in Scotland (NHS Lothian) in order to support a data-driven quality improvement (QI) programme of work so that performance could be benchmarked against national standards. Here, we report the process to establish the infrastructure and initial baseline data for the QI programme.
Methods. We worked with local NHS informatics teams to use free text recognition tools to scan electronic health records (EHR) in order to automate the identification of ICU referrals. Structured and unstructured data fields were extracted from EHR and transferred on a weekly basis to automate collection of key data items. For patients subsequently admitted to ICU, additional data fields were extracted from the local ICU audit database. This was supplemented by manual case note review in a subset to extract a limited set of fields that could not be automated (e.g. documented patient-centred discussions for TEP; past medical history; organ dysfunction at the time of referral). We automated data wrangling and reporting using R statistical package(3) to import, code and clean routine data flows and report in a standardised format (Fig. 1).
Results. During the period 05/07/2022 to 22/01/2023, there were a total of 625 ICU referrals averaging 3 per day (Fig. 2). For the subset with manual data extraction (n = 107), 41% of referred patients were admitted to ICU. These patients were younger (mean age 53 vs 63), less frail (27% vs 33%) and had higher number of organ dysfunction (median 2 vs 1). Benchmarking performance against FICM standards, > 90% of referrals were seen within one hour, and > 75% were admitted within 4 h of decision-to-admit. (Fig. 3) Consultant involvement was documented in EHR in only 47% of referrals. In the group of patients for whom ICU was deemed not to be of overall benefit, TEP discussion was documented in 79%.
Conclusions. We have established a data-driven system to efficiently identify and report the key aspects of ICU referrals. Limitations include not identifying referrals in cases when the free-text recognition does not perform. Whilst manual extraction is currently required, we plan to automate collection of other fields through linkage to other routinely collected and administrative datasets available regionally. A programme of QI work is underway using this newly established data platform to efficiently measure processes to continuously drive improvement.

Introduction. Manual data abstraction from electronic health records (EHRs) is the golden standard of data collection for observational research, but it is time-consuming and requires extensive review by highly trained personnel. The COVID-19 pandemic gave rise to initiatives collecting multicentre data, including the ProVent-COVID collaboration using manual data abstraction and the COVID-Predict collaboration using automated data collection, both from similar patients receiving similar standard of care, presenting an opportunity to compare the fitness of use of both methods for observational research.
Objectives. We aimed to replicate the ProVent-COVID investigation of association of ventilatory dead space (Vd/Vt) with 28-day mortality using automatically extracted data from COVID-Predict to confirm or challenge their findings.
Methods. Data was obtained from the COVID-Predict Dutch Data Warehouse containing full-admission data from critically ill COVID-19 patients from 25 Dutch hospitals. The database contains 200 million data points from 3464 adult COVID-19 patients. Patients intubated for longer than 2 days were included. We analyzed ventilation parameters at the first hour of invasive ventilation and every 8 h thereafter for the first 4 days. Mean for each day was taken into analysis. Exposure variables were Harris-Benedict Vd/Vt fraction, direct estimation of Vd/Vt, end-tidal-to-arterial PaCO2 ratio and ventilatory ratio. The primary outcome was 28-day mortality. A multivariable generalized mixed-effects model with hospital as a random effect and fixed effects: age, gender, BMI, PaO2/FiO2, creatinine, hypertension, diabetes, use of ACE inhibitors or ARBs, vasopressor or inotropic support, fluid balance, pH, mean arterial pressure, heart rate, respiratory system compliance and PEEP were used in the base model, and in further models each ventilatory exposure variable was added to check for improvement in predictive accuracy.
Results. Final cohort consisted of 1515 patients, 1157 survivors and 358 non-survivors. Non-survivors were typically older, male, with higher BMI, more severe ARDS, and suffered more often from diabetes, immunosuppression, and higher baseline creatinine values. Vd/Vt calculated were consistently higher in non-survivors and increased subsequently (Fig. 1), but after adjustment for the base risk model (AUC 0.795), none of the markers of impaired ventilation measured at the start of ventilation or the following day was significantly associated with 28-day mortality (p = 0.096–0.787, AUC 0.793–0-813). The inclusion of these variables did not improve the AUC-ROC compared to the base model (Fig. 2).
Conclusions. Using automated data extraction from EHRs, we confirmed findings of ProVent-collaboration and found no association between Vd/Vt estimation and 28-day mortality when controlling for confounding factors. Concordance of our results adds credibility to the notion that automatically extracted data from EHRs may provide a high quality and reliable resource circumventing the need for manual data curation. Given the significant time and resource costs associated with manual data extraction, these findings could have significant implications for the development of more efficient and effective ways of extracting data from large datasets, even beyond the COVID-19 crisis, saving intensivists time and resources.

Introduction. Previous research has described differences in the provision of prehospital treatment for women who experience out-of-hospital cardiac arrest (OHCA). However, some studies have reported conflicting results regarding survival outcomes or in-hospital interventions between the sexes.
Objectives. The aim of this study was to investigate the association of gender with survival outcomes and in-hospital treatments, such as post-resuscitation care, in Japan.
Methods. This was a retrospective analysis of data from the Japanese Association for Acute Medicine (JAAM)-OHCA Registry, a multicenter nationwide prospective database in Japan in which 137 institutions providing emergency care participated. We included OHCA patients aged ≥ 18 years who presented with a shockable rhythm at the scene

between June 2014 and December 2020. The outcome measure was 30-day survival and in-hospital interventions. We compared the outcomes between gender groups using multivariable logistic regression.
Results. A total of 5926 adult OHCA patients were eligible for our analysis. Of these patients, 4270 were men and 1026 were women. The proportions of patients with 30-day survival outcomes were 39.5% (1685/4270) and 37.4% (384/1026) in the men and women groups, respectively [crude odds ratio 0.92, 95% confidence interval (CI) 0.80–1.06]. Although there was no significant difference, survival outcomes tended to be better in women than men in the multiple regression analysis [adjusted odds ratio (AOR) 1.38, 95% CI 0.82–2.33]. Furthermore, there was no significant difference between the sexes in terms of patients who received ECPR (AOR, 0.81; 95% CI, 0.49–1.33) or TTM (AOR, 0.99; 95% CI, 0.68–1.46).
Conclusions. After adjusting for prognostic factors, there was no difference in survival rates and in-hospital interventions between men and women.

Effect of rigorous fluid management using real-time monitoring of ECW ratio by bioelectrical impedance analysis in critically ill postoperative patients: A prospective, single-labelled, randomized controlled study

Y. J. Chung[1], K. Hyesung[1], G. R. Lee[1], E. Y. Kim[1]

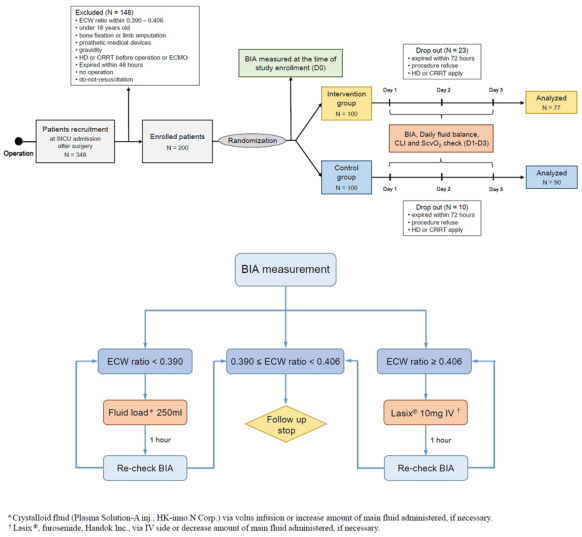
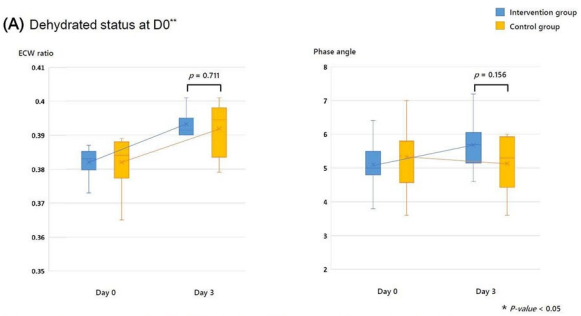
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000220

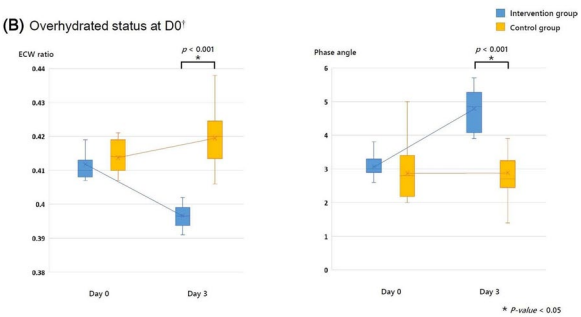
Introduction. Postoperative fluid management is known to influence outcomes of postoperative patients who are prone to hemodynamic instability. However, the national guidelines for proper postoperative fluid strategy have not been recommended yet. We have previously reported that the overhydration status with extracellular water (ECW) ratio above 0.390 could affect postoperative outcomes. Based on this, we aimed to determine whether aggressive fluid control using ECW ratio could improve clinical outcomes through a randomized controlled trial.
Methods. From November 2021 to December 2022, intensive care unit (ICU) patients admitted after surgery were randomly assigned to an intervention group or a control group whether postoperative fluid management was controlled via bioelectrical impedance analysis (BIA). Among patients in the intervention group, dehydrated patients received a bolus infusion with crystalloid fluid whereas diuretics were administrated to overhydrated patients until the value of ECW ratio fell within its normal setting range (0.390–0.406). Contrarily, BIA was performed once a day for the control group. Patients in the control group received liberal fluid treatment regardless of BIA results.
Results. Based on enrollment criteria, 77 patients of the intervention group and 90 patients of the control group were finally analyzed. There were no significant differences in demographic characteristics between the two groups. The length of hospitalization and 28-day mortality were significantly lower in the intervention group than in the control group. In multivariate analysis, the overhydrated status [odds ratio (OR): 2.731, 95% confidence interval (CI): 1.001–7.663, $p = 0.049$] and high CLI value at D0 (OR: 1.024, 95% CI: 1.008–1.039, $p = 0.002$) were risk factors of postoperative morbidities. Regarding the 28-day mortality, high CLI value at D0 (OR: 1.024, 95% CI: 1.001–1.047, $p = 0.037$) and liberal fluid strategy without BIA monitoring (OR: 10.979, 95% CI: 1.243–96.991, $p = 0.031$) were the significant predisposing factors.
Conclusions. Rigorous fluid treatment with volume control based on ECW ratio by BIA could improve postoperative morbidities and 28-day mortality of ICU patients. Real-time monitoring of ECW ratio will help establish optimal fluid treatment strategies for postoperative ICU patients who are prone to fluid imbalance.



*Crystalloid fluid (Plasma Solution-A inj., HK-inno.N Corp.) via volus infusion or increase amount of main fluid administered, if necessary.
†Lasix®, furosemide, Handok Inc., via IV side or decrease amount of main fluid administered, if necessary.



**Dehydration means as the case where the value of ECW ratio is under 0.390 measured at the time of study enrollment (D0).



†Overhydration means as the case where the value of ECW ratio is above 0.406 measured at the time of study enrollment (D0).

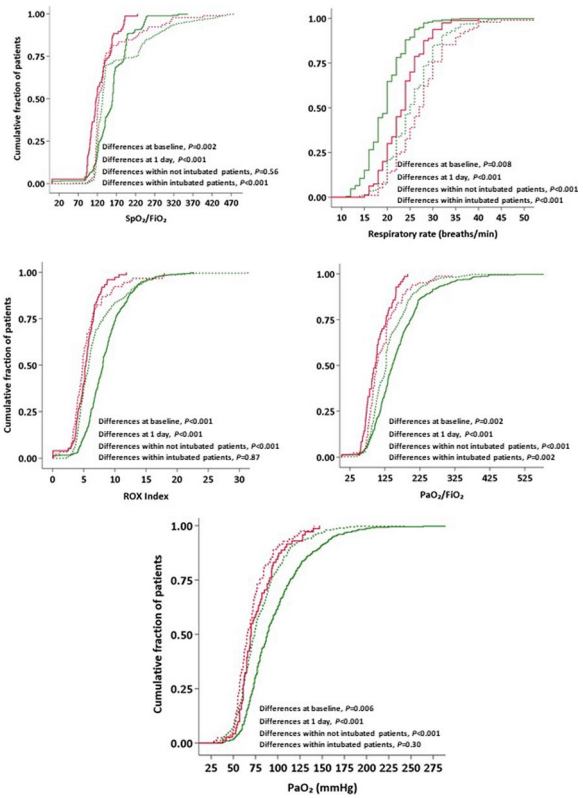
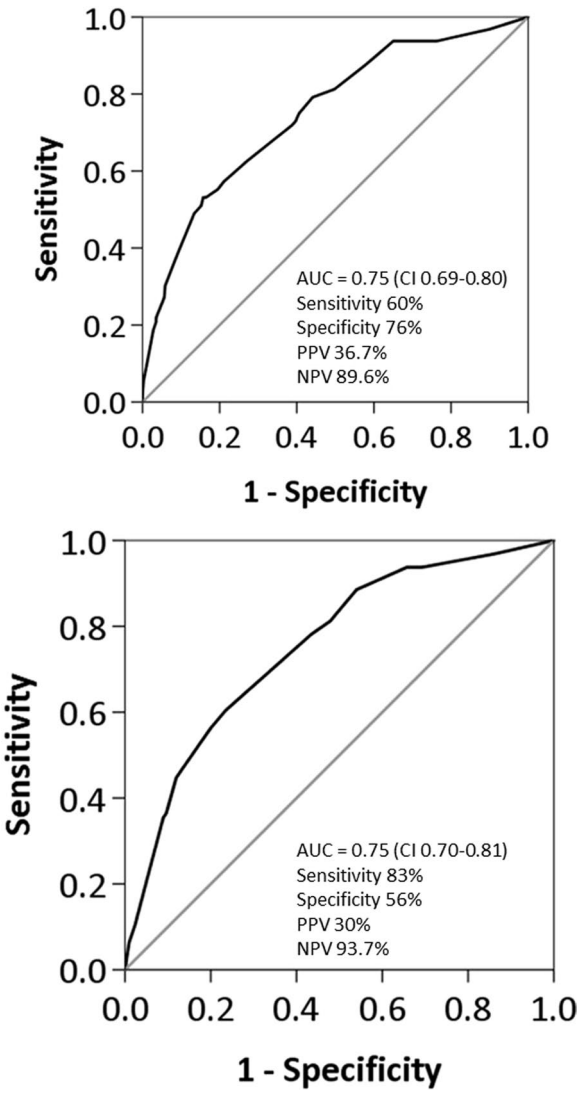
Introduction. During the SARS-CoV-2 pandemic, the awake prone position (APP) strategy has been implemented as a rescue therapy because of the overwhelming surge of cases and the shortage of invasive mechanical ventilation (IMV). APP may prevent IMV in spontaneously breathing, critically ill patients with acute hypoxemic respiratory failure. It is central to predicting which patient population will benefit from this technique in order to avoid delaying further actions.
Objectives. We aimed to determine whether 24 h test of awake prone positioning could identify patients needing tracheal intubation in the first 72 h after hospital admission.
Methods. A total of 523 consecutive adult patients admitted to the ICU under high-flow oxygen therapy (HFO) were eligible for participation with COVID–19 acute hypoxemic respiratory failure. Exclusion criteria were any contraindications to APP and acute hypercapnic respiratory failure.
Results. 522 patients were analyzed.
96 patients (18.4%) were intubated for invasive ventilation within 3 days hours after the start of awake-prone positioning.
Intubated patients were more tachypneic and hypoxemic (Figure 1). Otherwise, there were no differences between the two groups, neither concerning patient characteristics nor other ventilatory parameters and hemodynamic parameters (Table).
Baseline characteristics that had an independent association with intubation within 3 days were a baseline age > 61 years old, BMI ≥ 35 kg/m2, and respiratory rate ≥ 27 breaths/min. The AUC–ROC for the multivariable model using these baseline characteristics was 0.75 (95%CI 0.69 to 0.80) (Fig. 1A). Responses to awake prone positioning that had an independent association with intubation were failure to increase PaO2 > 16 mmHg, and failure to increase the ROX index > 1.64 (Fig. 1B).
Conclusions. In this cohort, one out of five patients needed intubation for invasive ventilation within 3 days after the first session of awake proning.
The effects of awake prone positioning on oxygenation and respiratory rate in patients with acute hypoxemic respiratory failure due to COVID-19 had moderate prognostic capacity for intubation within the first 72 h.



Cumulative frequency distribution of the study variables SpO2/FiO2, respiratory rate, ROX index, PaO2/FiO2 and respiratory rate.



(A) ROC curve for the multivariable model of baseline variables associated with intubation on day 3 and independent predictors of intubation on day 3, based on age > 61 years/old, respiratory rate, BMI ≥ 35 kg/m2and respiratory rate ≥ 27/min at baseline. (B) ROC curve for the multivariable model, based on age > 61 years/old, BMI ≥ 35 kg/m2, change in respiratory PaO2, and ROX index from after 1 day from supine to prone.

Table 1 (abstract) Demographic and clinical characteristics between intubated and non-intubated patients during the first day of prone position

Variable	No Intubation [N = 426]	Intubation [N = 96]	P
Age, years*	55 [45; 64]	63.5 [54.5; 69.5]	<0.001
Gender, female**	103 [24.2%]	28 [29.2%]	0.31

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000225.

Introduction. Ventilator liberation should be initiated as early as feasible and safe to limit the detrimental effects from prolonged mechanical ventilation and sedation [1,2]. However, though essential, choosing the right moment for weaning and extubation is still challenging. We hypothesized that electrical impedance tomography (EIT) could be a promising non-invasive lung imaging modality to support weaning decisions [3].
Objectives. The aim of this study was to describe 1) the detailed evolution of EIT parameters during a spontaneous breathing trial (SBT), and 2) the relation between EIT parameters and SBT success or failure.
Methods. Adult patients receiving invasive mechanical ventilation (more than 72 h) were eligible for inclusion. Continuous EIT monitoring was performed around a T-piece SBT. EIT parameters, (end-expiratory lung impedance (EELI), tidal impedance (dZ) and global inhomogeneity index (GI)), were computed on a breath-by-breath basis. Trends and between-group differences (SBT success vs. failure) were analyzed using linear mixed-effects models.
Results. Twenty-four patients were included (58% male; age: 62.0 ± 10.2 y, BMI: 26.7 ± 5.0 kg/m^2, 11,2 ± 6.1 days of ventilation). Figure 1A shows a significant drop in EELI after the start of the SBT, which did not recover to its baseline value after restarting mechanical ventilation. Other trends were a significant drop in dZ and a significant increase in the GI after the start of the SBT. These changes continued during the full length of the SBT, but (contrary to the EELI) restored to their baseline value after restarting mechanical ventilation.
Significant differences between patients with a successful (n = 19) and a failed (n = 5) SBT were found, with a higher GI in patients who failed the SBT. The distinction in GI between the two groups was present at all time points including the timepoint before initiation of the SBT (Fig. 1B).
Conclusions. Insight in physiological trends for the individual patient can be obtained with EIT during weaning from mechanical ventilation. De-recruitment during the SBT is common, observed by a drop in EELI without loss of tidal volume (dZ). An elevated GI might be a predictor for weaning failure, but this requires further study in a larger cohort.

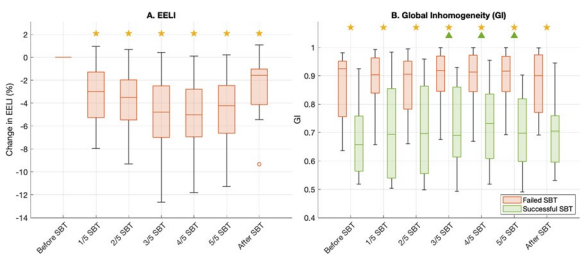

Figure 1 (abstract 000225) A. Detailed description of % change in EELI during the SBT. Parameters were extracted at 5 moments during the SBT and compared to the baseline value (before SBT). Yellow stars

indicate significant differences compared to the baseline value. B. GI index of patients with a failed and successful SBT. Yellow stars indicate significant differences between the two groups. The green triangles indicate a significant trend compared to baseline for the successful patients

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000226

Introduction. Survivors of critical illness are frequently left with a long-lasting disability. Moreover, delirium or acute confusional syndrome is a severe neuropsychiatric disorder associated with multiple complications and a worse short- and long-term prognosis. We hypothesised that patients who developed delirium during ICU stay, compared with patients who did not, would have worse health-related quality of life following a critical illness.
Methods. Prospective longitudinal observational and analytical study assessing perceived quality of life measured with the Barthel Index, the Clinical Frailty Scale, and the SF-36, comparing patients who developed delirium during ICU stay and patients who did not.
Results. In a cohort of 1462 patients, we selected controls for the 93 patients who developed delirium. Of 156 completed questionnaires (84,7%), we observed that (a) in each of the two groups of patients, the scores related to the physical aspect of quality of life tended to improve over time ($p < 0{,}001$), being consistently less favourable in the group of patients who developed delirium compared to the group of controls ($p < 0{,}001$); (b) the patients who developed delirium also presented lower scores on the SF-36 scale, these differences being statistically significant, and therefore evidencing a worse quality of life, with impact on both the psychological and social spheres ($p < 0{,}001$).
Conclusions. Patients who developed delirium had significantly lower scores two years after hospital discharge on the three used questionnaires, displaying a clear negative impact on the physical, psychological, and social dimensions. The study's results reinforce the need to support and strengthen the care of ICU survivors. Moreover, this study has contributed to the improvement of the Protocol for the prevention and early detection of post-intensive care syndrome, initiated in our hospital center in 2018.

The impact of macronutrient restriction in critically ill patients with and without relative hypophosphatemia: a secondary analysis of the EPaNIC RCT

C. Lauwers[1], L. Langouche[1], G. Van den Berghe[1], A. Wilmer[2], P. Wouters[1], J. Gunst[1], M. Casaer[1]
[1]Laboratory of Intensive Care Medicine, Academic Department Of Cellular And Molecular Medicine, KU Leuven, Leuven, Belgium; [2]Medical intensive care, KU Leuven, Leuven, Belgium
Correspondence: C. Lauwers
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000227

Introduction. Hypophosphatemia may be a hallmark of refeeding-related metabolic complications. In the refeeding syndrome trial (1), standard nutrition as compared to nutrient restriction increased mortality in patients who developed hypophosphatemia upon feeding, despite adequate phosphate and micronutrient provision. As such, a decline of phosphate upon feeding may signal a metabolism unfit for proper substrate oxidation and may predict potential harm by enhanced feeding.
Objectives. We aimed to assess the differential impact of early versus delayed administration of Parenteral Nutrition (PN) in patients whose phosphate levels declined early after intensive care unit (ICU) admission and in patients with stable phosphatemia.
Methods. This is a secondary analysis of the randomised controlled EPaNIC trial (2) that studied the impact of withholding PN (Late PN) versus early full feeding (Early PN) in critically ill patients during the first week in ICU (n = 4640). Relative hypophosphatemia (RHP) was defined as a decrease of > 0.16 mmol/l between the first and second ICU days. Patients with an available phosphate measurement on both days were included. The effect of Early versus Late PN on outcome in groups with and without RHP was assessed by adjusted logistic and Cox regression models. These analyses were repeated with an interaction term combining the feeding intervention and occurrence of RHP, and in propensity score-matched groups of RHP patients to correct for RHP occurring eventually more in one study arm.
Results. RHP occurred overall in 23.7% (834 out of the 3520 included patients) and was more frequent in patients on Late PN (26.3% n = 471) than Early PN (21.0% n = 363, $p = 0.0002$). Among patients with RHP, patients randomised to Late PN as compared to Early PN had a shorter ICU stay (4d vs 6d, $p < 0.0001$), a higher likelihood of an earlier alive ICU discharge (HR 1.26 (1.09–1.46)) and definite weaning from mechanical ventilation (MV)(HR 1.26(1.09–1.46)), a lower hospital mortality (12.1% vs 17.4%, $p = 0.03$), a lower rate of infections (26.1% vs 38.0%, $p = 0.0002$) and a shorter duration of kidney replacement therapy (KRT) (7.5d vs 15d, $p = 0.01$), which was not the case in the group with stable phosphatemia. For ICU stay, alive ICU discharge and definite weaning of MV, RHP significantly interacted with the randomised feeding intervention. In the matched subgroups (two groups

of 356 patients) of RHP patients, patients randomised to Late PN as compared to Early PN had a shorter ICU stay (3d vs 6d, $p < 0.0001$), a higher likelihood of an earlier alive ICU discharge (HR 1.77(1.50–2.08)) and definite weaning from MV (HR 1.54(1.31–1.80)), a lower ICU, hospital and 90-day mortality (5.6% vs 10.1%, 11.5% vs 17.1%, 11.1% vs 16.7%, resp., p = 0.03 for all), a lower rate of infections (21.4% vs 38.8%, $p < 0.0001$) and a shorter duration of KRT (8d vs 16d, $p = 0.005$).
Conclusions. Patients with RHP randomised to Late PN as compared to Early PN experienced better outcomes. Monitoring phosphate levels and reducing macronutrient intake in patients developing RHP may improve outcome.

Introduction. Reinforcement learning (RL) is a machine learning technique uniquely effective at sequential decision making [1], which makes it potentially relevant to intensive care unit (ICU) treatment challenges. We set out to systematically review, assess level-of-readiness and meta-analyze the effect of RL on outcomes for critically ill patients.
Methods. A systematic search was performed in 5 relevant databases from inception to March 25th 2022, with subsequent citation tracking. Journal articles that used any reinforcement learning technique in an ICU population and reported on patient health related outcomes were included for full analysis. Conference papers were included for level-of-readiness assessment only [2]. Descriptive statistics, characteristics of the models, outcome compared to clinician's policy and level-of-readiness were collected. RL-health risk of bias and applicability assessment was performed.
Results. A total of 1033 articles were screened, of which 18 journal articles and 20 of conference papers were included (Fig. 1) [3]. Thirty of the included articles were prototyping or modelling articles and six were validation articles (Fig. 2). Applications of RL in the ICU in the included articles were related to sepsis treatment with vasopressors and intra-venous fluids, heparin dosin, dosing of propofol and fentanyl, blood glucose control, ventilator setting optimization, all medication dosing, insulin dosing and antibiotic treatment. All articles reported RL-algorithms to outperform clinical decision making by intensive care professionals in retrospective data with off-policy evaluation. The modelling techniques for the state-space, action-space, reward function, RL model training and evaluation varied widely. The risk of bias was high in all articles, mainly due to the evaluation procedure. A meta-analysis on outcomes relevant to critically ill patients proved unfeasible given the heterogeneity of clinical focus and reporting amongst studies.
Conclusions. In this first systematic review on the application of RL in intensive care medicine we found no studies that demonstrated improved patient outcomes from RL-based technologies. All studies reported that RL-agent policies outperformed clinician policies, but such assessments were all based on retrospective off-policy evaluation.

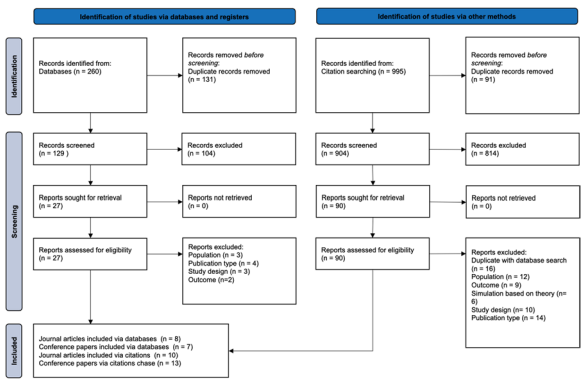

Figure 1 (abstract 000228) Flowchart of article inclusion

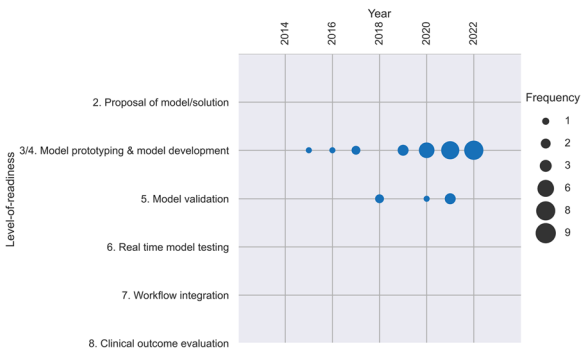

Figure 2 (abstract 000228) Level-of-readiness over time

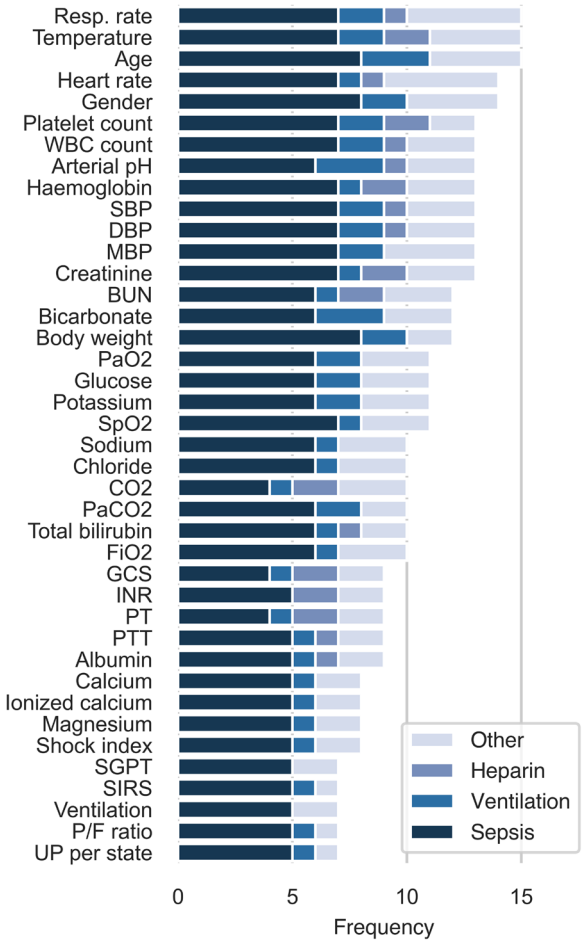

Figure 3 (abstract 000228) Frequency of included variables for state-space per application
Resp., respiratory; SpO2, oxygen saturation pulse oximetry; MBP, mean blood pressure; SBP, systolic blood pressure; DBP, diastolic blood pressure; WBC, white blood cell; BUN, blood urea nitrogen; PaO2, partial pressure of oxygen; PaCO2, partial pressure of carbon dioxide; GCS, Glasgow coma scale; INR, international normalized ratio; PT, prothrombin time; FiO2, inspired oxygen fraction; CO2, carbon dioxide; PTT, partial thromboplastin time; SGPT, serum glutamic pyruvic transaminase; P/F, PaO2/FiO2 Ratio; SIRS, Systemic Inflammatory Response Syndrome; UP, urine product.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000229

Introduction. A high anticholinergic burden (ACB) occurs after exposure to certain medications, including antimuscarinics, antihistamines and selected antipsychotics. In older people (>65 years), a high ACB could lead to falls, confusion, delirium and dementia. A subdural haematoma (SDH) presentation to a Neurointensive Care Unit (NICU) in >65 years is devastating as it is associated with a high risk of death and loss of independent living (1). Our aim was to explore the prevalence of medications with anticholinergic effects among older inpatients with a SDH presentations in NICU admission in a tertiary referral teaching hospital.
Objectives. To explore the prevalence of ACB in older patients admitted to NICU with diagnosis of SDH on admission; establish any changes/exposure to medications with anticholinergic effects and whether these were documented on discharge.
Methods. Retrospective cohort review of older patients admitted to NICU during 2021–2022 with a diagnosis of SDH was conducted. ACB was estimated using a validated tool (the Anticholinergic Effect on Cognition (AEC) scale) with significant exposure defined as at least one medicine with an AEC score ≥ 2 or total AEC score > 3 (2).
Results. Of 59 older patients admitted to NICU with a SDH, 50 (84.7%) had a pharmacy-verified medication history and thus were suitable for inclusion. The median [IQR] age was 74 [69–79] years and 34 (68%) admitted with a traumatic SDH. 13 of 50 (26%) had documentation of anticholinergic medications on NICU admission; 9 of 50 (18%) had a significant AEC score. Ten patients (20%) died during admission (9 taking no medications with an AEC score > 0). The median hospital stay was 28 [6–38] days. Of the 13 patients taking AEC medicines before hospitalisation, half had at least one anticholinergic medicine discontinued during admission, however only one discharge summary had documentation of either anticholinergic medicine presence or changes to these medications.
Conclusions. Approximately a quarter of older patients admitted with SDH were taking medications with anticholinergic properties; 18% had a significant AEC score that may have contributed to their NICU admission. AEC medications were frequently stopped during admission although documentation of this to community healthcare teams was poor. Future research should focus on a larger dataset series with linear regression analysis to assess relative risk of significant AEC score in this devastating condition.

When are alarms most relevant: a temporal analysis of alarm relevance in the intensive care setting

M. Prendke[1], A. R. Flint[1], K. Rubarth[1], F. Balzer[1], A. S. Poncette[1]
[1]Institute of Medical Informatics, Charité-Universitätsmedizin Berlin, Berlin, Germany

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000230

Introduction. Alarm fatigue, the desensitization to too many, often irrelevant alarms, is highly common on modern ICUs and endangers patient safety [1]. To counteract alarm fatigue and alleviate alarm load, it is crucial to be aware of irrelevant and therefore avoidable alarms. It has been shown that the number of alarms is influenced by time of day, being highest in the morning and declining throughout the day and that many avoidable technical alarms worsen the alarm load [2]. For a better understanding of avoidable alarms relevance-annotated alarm data is necessary [3]. If the alarm relevance for certain time intervals is known, medical staff can act accordingly, e.g., adjusting alarm thresholds and alarm pauses.
Objectives. Investigate the temporal perspective of alarm relevance, analyzing patterns during the course of a day as well as on different weekdays.
Methods. Following IRB approval (Ethics vote no. EA1/127/18), retrospective analysis of annotated alarm data [4] from 07–09/2022 (one 21-bed ICU, 92 days, 210 patients, 175,804 alarms). An alarm is annotated as actionable and considered relevant if followed by related medical intervention. Metrics: Mean number (M), standard deviation (SD) of alarms per minute (I) and per weekday (II) in the ICU investigated. Positive predictive value (PPV) as the probability of alarm being actionable. Binomial generalized linear mixed-effects models with shift (I) and day of the week (II) as predictors, patient id as random effect, rate of actionable alarms as response to analyze differences in alarm relevance between shifts (I) and weekdays (II) by Odds Ratios (OR) with 95% Wald-Confidence Intervals (CI). Due to exploratory nature of study, we abstain from using Bonferroni correction of significance level.
Results. The number of alarms decreases during the day, while PPV increases. The two curves seem reversely related (Fig. 1). Mean PPV per shift is 0.115 (SD = 0.042) for morning, 0.140 (SD = 0.047) for afternoon and 0.150 (SD = 0.061) for night shift. There was a significant difference in alarm relevance between morning and night shift (OR: 1.559, CI [1.204, 2.020], p = 0.001), while the difference between morning and afternoon (OR: 1.278, CI [0.961, 1.700], p = 0.091) as well as between afternoon and night shift (OR: 1.217, CI [0.914, 1.621], p = 0.179) were not statistically significant. The mean number of alarms increases during the workweek and decreases from Friday through the weekend. PPV is highest at beginning of the week (maximum on Mon M = 0.155, SD = 0.049), decreases in the second half of the week starting on Thursday (minimum on Saturday M = 1.121, SD = 0.041) and is on average lower on the weekend (PPV M = 0.123, SD = 0.037) than during the week (PPV M = 0.137, SD = 0.46) (Fig. 2). The difference in alarm relevance between weekend and workweek is significant (OR: 1.848, CI [1.365, 2.501], p < 0.001).
Conclusions. This research confirms the known pattern of declining alarm load during the day [2] for relevant as well as irrelevant alarms. From a temporal perspective, alarm relevance is reversely related to the total number of alarms. This can be explained by more irrelevant alarms when patients are more active, staff are interacting with the patient or manipulating equipment. Data interpretation is limited by data being collected in a routine clinical setting, including e.g., stress, handover situations, which influence alarm occurrence and management. Further research is needed to confirm this study's findings depending on alarm-issuing device, alarm type, set alarm threshold and patient characteristics.

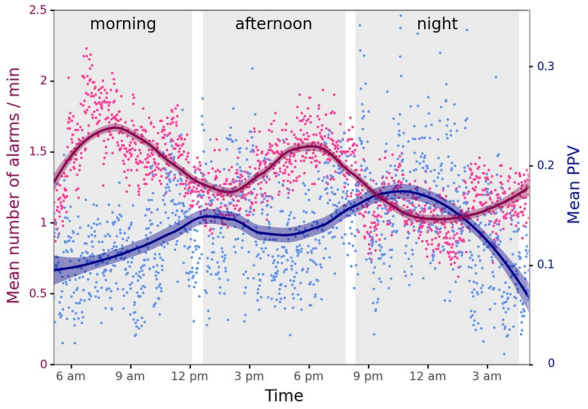

Figure 1 (abstract 000230) Mean number of alarms (pink) and PPV (blue) per each one-minute time interval of a 24 h day. The grey bars visualize the morning, afternoon, and night shits, while the white spaces inbetween represent handover periods. The lines are calculated by a LOESS smoothing function, the less intensely colored band width shows the respective 99% CI

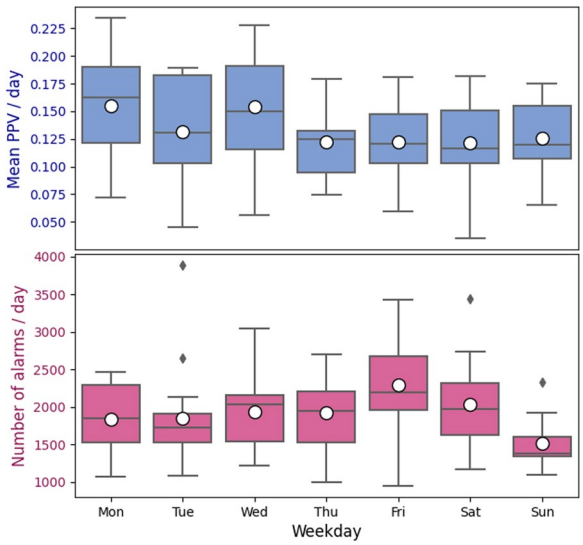

Figure 2 (abstract 000230) Distribution of number of alarms (pink) and PPV (blue) per weekday as boxplots. Arithmetic mean of values for each weekday as white dot in box. The investigated time interval does not include national holidays

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000232

Introduction. The prevalence of potentially inappropriate medications (PIMs) in older adults is a pervasive public health concern. Admission to an intensive care unit (ICU) affords an opportunity to review and reduce prescribing harm.
Objectives. The objective of this study was to evaluate the deprescribing practices of PIMs in an ICU setting.
Methods. We evaluated deprescribing practices of PIMs following admission to ICU. A retrospective chart review was conducted on patients who were 60 years or older, hospitalized between June 1, 2013 and June 1, 2015, at a tertiary hospital in Hamilton, Ontario. Medications listed in the 2015 Beer's Criteria and opioids without a cancer diagnosis were marked as PIMs. Discharge records were used to identify PIMs that were deprescribed.
Results. Seventy-two patients with a mean age of 72.3 and an average of 2.6 co-morbidities were included in the study. The majority of patients admitted and discharged from ICU (88.8% and 81.9%, respectively) were found to be taking at least one PIM. Of the total medications at ICU admission, 30.6% were identified as PIMs, and half of these (50.5%) were successfully deprescribed. The mean number of PIMs prescribed at ICU admission was 2.64, which decreased to 1.92 at ICU discharge ($p = 0.01$). The most frequently deprescribed PIMs were opioids (26%), antipsychotics (26%), anti-hypertensives (17%), and NSAIDs (17%). The number of patients with zero PIMs increased from 11.1% to 18% at ICU discharge and 37.5% at hospital discharge. Overall, 31.2% of the study population were successfully deprescribed all PIMs by time of discharge from hospital.
Conclusions. The results of this study highlight the prevalence of PIMs among older adults admitted to the ICU and the potential benefits of deprescribing practices in this setting. The high sucess rate of PIMs deprescribed per patient subsequent to their ICU stay underscores the opportunity this setting presents to healthcare professionals to initiate deprescribing and improve medication use and outcomes for this particularly vulnerable patient population.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000263

Introduction. The intensive care unit (ICU) environment is by nature a highly stressful one for all who navigate the space. Patients are often gravely unwell; relatives and friends encounter noisy and often chaotic conditions; staff work with a consistent need to function at their best both as individuals and as part of a closely articulated team. Aligned to their inevitable high acuity, poor patient outcomes may add to the hostility of the specialty for healthcare providers. Little research has examined the impact of this environment on clinicians, and how they manage these stressors.
Objectives. This study aimed to explore the coping strategies employed by experienced Intensivists and the things that moderated their response positively to the stressors within the ICU environment. It also aimed to identify support pathways available.
Methods. Experienced Intensivists from seven centres in three countries were interviewed in this prospective qualitative study. In a semi-scripted iterative interview, participants were asked how they managed their emotions in the ICU. Audio-recordings were transcribed, and thematically analysed, and emerging themes and subthemes are described.
Results. Participants reported a wide range of strategies, including normalising and contextualising the stressful event; compartmentalising stressors; separating work and home life; and having a level of acceptance that things do not always go in the way they are anticipated. Most endorsed the utility of professional support, but few disclosed accessing such services personally, which may reflect a perceived stigma attached to doing so. Many described a sense of responsibility for the wellbeing of other staff. Factors that mitigated stressors included positive and mutual respectful relationships with colleagues, patients and their families; and taking away new knowledge from episodes involving poor patient outcome.
Conclusions. Intensivists described several ways that they managed and mitigated the effect of ICU environmental stressors. They perceived a level of stigma in seeking professional help for themself. They also expressed a need to provide support to other team members within the ICU, however acknowledged limited training to do so.

Constructing the persona of the intensivist: a qualitative study

D. Dennis[1], R. Khanna[2], C. Knott[3], A. Calhoun[4], P. Vernon Van Heerden[5]
[1]Departments of Intensive Care and Physiotherapy, Sir Charles Gairdner Hospital, Perth, Australia; [2]Phoenix Australia, Australian National Centre of Excellence in Posttraumatic Mental Health, Melbourne, Australia; [3]Department of Intensive Care, Bendigo Health; Monash Rural Health; Monash University; Austin Health; University of Melbourne, Melbourne, Australia; [4]Department of Pediatrics, Division of Critical Care, and Norton Children's Medical Group, University of Louisville, Louisville, United States of America; [5]Department of anesthesiology, critical care and pain medicine, Hadassah Medical Center, The Hebrew University of Jerusalem, Jerusalem, Israel
Correspondence: D. Dennis
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000237

Introduction. Intensivists are a distinctive subset of the medical profession who work within a persistently high-acuity high-stakes environment that defines an intensive care unit. They require a unique set of clinical and human skills, and an understanding of these attributes may be useful for both the people they work with as well as those considering future specialisation in the field.
Objectives. The aim of this study was to explore the self-perceived characteristics of Intensivists and in doing so, define and assemble the 'Intensivist persona' that might provide useful insight for the entire healthcare team.
Methods. This prospective qualitative study involved face-to-face interviews with 42 Intensivists in Australia, Israel and the USA who each had more than four year's clinical experience at a Consultant level. Participants were asked to describe typical personality traits of 'flourishing' Intensivists. They were also asked how they thought Intensivists were viewed by other healthcare providers external to the intensive care specialty. Interviews were audio recorded and transcribed; data were coded within a thematic framework using NVivo software. Authors then agreed upon and constructed personas of the contemporary Intensivist that reflected these themes.
Results. Seven personas were built according to how Intensivists saw themselves. These were the 'Fixer'; the 'Retriever'; the 'Diplomat'; the 'Negotiator'; the 'Pragmatist'; the 'Neurotic'; and the 'Duck'. A further three personas were created relating to how they perceived they were viewed by others. These were the 'Superhero'; the 'Naysayer'; and the 'Dictator'.
Conclusions. This study describes the personality traits of modern-day Intensivists as perceived by a subset of the group. These may or may not match the perceptions of other healthcare professional's perceptions but add to a better understanding of how intensivists see themselves.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000238

Introduction. As a healthcare professional, reflection upon one's own idiosyncrasies, behaviours, and attitudes that moderate performance and endurance is important. In synergy, the experiences of others also offer opportunities to gain insight and understanding. This study analysed the views of veteran intensive care medicine specialist doctors (Intensivists) as valued peer mentors on several issues affecting their day-to-day performance, mental wellbeing and burnout within the intensive care medicine specialty.
Objectives. The aim was to distil the anecdotes of experienced Intensivists into some pragmatic advice for doctors intending to work in the speciality in the future.
Methods. This was a prospective qualitative study involving face-to-face interview with Intensivists who had a minimum of 4 years of experience working at a consultant level at one of seven urban tertiary hospitals (Australian, n = 3; Israeli, n = 1, United States of America, n = 3). Participants were asked as to the advice they would give if they could step back in time to mentor a younger version of themselves. Data was audio-recorded, transcribed and coded thematically. Verbatim quotations are presented to support coding choices.
Results. Forty-two participants (Australian, n = 15; Israeli, n = 6, United States of America, n = 21) contributed to the dataset. The themes of advice that emerged were that it was better to have systems and processes in place to prevent certain events from happening; death and adverse events were inevitable; and that there should be a level of preparedness in terms of developing personal strategies and networks to manage these traumas.

Conclusions. The collated wisdom of expert Intensivists might guide the Intensivists of the future to improve practice.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000239

Introduction. Prediction of good neurological outcome after cardiac arrest is tantamount to the prediction of a patient's quality of life upon return of spontaneous circulation (ROSC), yet research on time and cost-efficient neuroprognositication tests is insufficient.
Objectives. The aim of the study was to evaluate the utility of clinical examinations performed after ROSC in predicting good neurological outcomes in out-of-hospital cardiac arrest (OHCA) patients treated with targeted temperature management (TTM).
Methods. This retrospective study included OHCA patients treated with TTM from 2009 to 2021. Initial clinical examination findings related to the Glasgow Coma Scale (GCS) motor score, pupillary light reflex (PLR), corneal reflex (CR) and breathing above the set ventilator rate were assessed immediately after ROSC and before the initiation of TTM. The primary outcome was good neurologic outcome at 6 months after cardiac arrest.
Results. Of 350 patients included in the analysis, 119 (34%) experienced a good neurologic outcome at 6 months after cardiac arrest. Among the parameters of the initial clinical examinations, specificity was the highest for the GCS motor score, and sensitivity was the highest for breathing above the set ventilator rate. A GCS motor score of > 2 had a sensitivity of 42.0% (95% CI 33.0–51.4) and a specificity of 96.5% (95% CI 93.3–98.5). Breathing above the set ventilator rate had a sensitivity of 84.0% (95% CI 76.2–90.1) and a specificity of 69.7% (95% CI 63.3–75.6). As the number of positive responses increased, the proportion of patients with good outcomes increased. Consequently, 87.0% of patients for whom all four examinations were positive experienced good outcomes.
Conclusions. The initial clinical examinations predicted good neurological outcomes with a sensitivity of 42.0–84.0% and a specificity of 69.7–96.5%. When more examinations with positive results are achieved, a good neurologic outcome can be expected.

Table 1 (abstract 000239) Demographic characteristics of subjects according to neurologic outcome

	Good n=119	Poor n=231	*p*-value
Age, median (IQR)	50 (39–61)	59 (46–72)	< 0.001
Male, n (%)	91 (76.5)	162 (70.1)	0.257
Comorbidities

Introduction. Shear wave elastography (SWE) has the potential to non-invasively measure intrinsic myocardial stiffness, based on the propagation speed of shear waves traveling through the myocardium after valve closure. However, recent work has shown that shear wave propagation speed (SWS) is related to the myocardial operational stiffness, which is defined by the slope of the end-diastolic stress–strain relationship (EDSSR) at the operating volume/pressure. Therefore, operational stiffness can be altered by both changes in intrinsic myocardial stiffness and myocardial loading conditions.
Objectives. We aimed to investigate whether SWE can detect differences in operational stiffness induced by alterations in myocardial loading during mechanical ventilation, and whether this technique could also detect changes in intrinsic stiffness in ischemic cardiomyopathy (ICM).
Methods. We assessed SWS in 8 sedated and mechanically ventilated sheep: 5 healthy controls and 3 sheep with ICM after at least 16 weeks following left coronary artery ligation. Left ventricular parasternal long-axis views were acquired with a state-of-the-art ultrasound scanner with high frame rate technology (> 1100 Hz). SWS after mitral valve closure was measured in the basal septum during an inspiratory hold at 30 cmH2O and 15 cmH2O and expiratory hold at 0 cmH2O (atmospheric pressure) to change myocardial loading conditions in a non-invasive manner. We used linear regression to assess the trend of the SWS during ventilation manoeuvres per animal and repeated measures ANOVA and Student's T-test to assess differences between groups.
Results. In all sheep, SWS declined with higher inspiratory pressures ($p = 0.0025$, Fig. 1), consistent with a reduction in left ventricular preload resulting in a shift towards a flatter part on the EDSSR. SWS during expiratory hold at atmospheric pressure was significantly lower in the control group vs. the ICM group (mean $\pm$ SE 5.3 ± 0.6 vs. 8.6 ± 1.1 m/s; $p = 0.03$). Furthermore, the change in SWS with higher inspiratory pressures was larger in the ICM group vs. the control group (slope of the regression line -0.18 vs. -0.07 m/s/cmH2O; $p = 0.03$). These observations suggest loading changes on a steeper part of the EDSSR in the ICM group.
Conclusions. In conclusion, our results suggest that SWE is able to detect differences in operational stiffness due to altered myocardial loading conditions induced by mechanical ventilation. Secondly, SWE appears to differentiate healthy controls from sheep with ICM based on the magnitude of the SWS during expiratory hold at atmospheric pressure, but also on the magnitude of the SWS change during loading alterations with higher inspiratory pressures. Further work should assess whether SWE combined with respiratory hold manoeuvres could contribute to differentiate intrinsic stiffening from altered loading conditions, and to exploit its full potential as a non-invasive bedside method for the assessment of operational stiffness in the mechanically ventilated critical care patient.

Introduction. Drug delivery directly into the lung via nebulisation has the potential to reduce systemic side effects, and to focus the therapeutic effect within the lung. With this, the environmental contamination associated with aerosolisation (drug and infectious agents) needs to be determined, particularly whether this is influenced by oxygen delivery devices. Experimental and laboratory-based studies have provided information on the distribution of fugitive and exhaled aerosols in controlled settings. However, real world data on fugitive medical and patient derived aerosol particle distribution is sparse.
Objectives. In this study, we examined the aerosol particle distribution of fugitive medical and patient derived aerosols in the bed spaces of patients undergoing the management of COVID-19 pneumonia. These patients were participating in a randomised inhaled heparin study.
Methods. Patients randomised in the 'Can Nebulised HepArin Reduce acuTE lung injury in Patients with SARSCoV-2 Requiring Mechanical Ventilation in Ireland' (CHARTER) Trial, a randomised controlled study on the effect of nebulised unfractionated heparin in ICU patients with SARS- CoV-2 requiring advanced respiratory support, were enrolled in this study. An optical particle sizer (OPS 3300, TSI, Inc., USA) was placed on a metal tray and an inflow hose was attached from the sampling port to the nurses station at the patients bed space. Measurements were taken at one-minute intervals for a period of 24 h. Data on particle mass concentration (µg/m3) was analysed using GraphPad Prism (USA).
Results. A total of 20 separate periods of air sampling collection was recorded on 12 patients, of which n = 14 were randomised to the heparin treatment and n = 6 to standard respiratory care. All patients underwent advanced respiratory support with n = 10 managed with high flow nasal cannula oxygen (HFNO), n = 7 managed with non-invasive ventilation (NIV) and n = 3 managed with invasive mechanical ventilation (IMV).
Peak particle mass concentration during nebulisation with heparin was significantly higher for patients managed with HFNO than patients undergoing NIV or IMV (34.4 ± 5.0 vs. 6.9 ± 14.0 vs. 1.6 ± 1.4ug/m3, p = 0.01, Fig. 1). Average peak particle mass concentration for 24h period was higher for patient undergoing HFNO compared to NIV and IMV. (31.4 ± 24.3 vs. 6.2 ± 10.8 vs. 4.0 ± 2.9ug/m3, p = 0.02). There was no difference in average peak particle concentration over a 24h period in those receiving aerosolized heparin vs no heparin (39.9 ± 34.7 vs 14.8 ± 10.7ug/m3, p = 0.1) or during period of heparin nebulisation compared to non-heparin nebulisation (34.3 ± 44.8 vs 20.7 ± 7.7ug/m3, p = 0.7).
Conclusions. Patients who received HFNO generated larger quantities of fugitive medical and patient derived bio-aerosols than patients who received IMV and NIV. However, there was no statistically significant difference in the mass concentration levels between patients who did and didn't receive heparin.

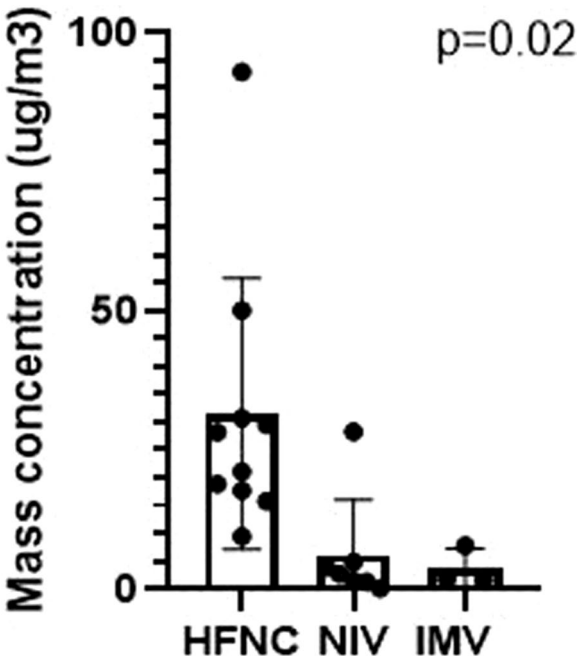

Figure 1 (abstract 000241) Peak mass concentration detected during heparin nebulisation for patients undergoing heparin nebulisation with high flow nasal oxygen (HFNO), non-invasive ventilation (NIV) and invasive mechanical ventilation (IMV)

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000242

Introduction. Rhabdomyolysis (RM) is a common postoperative complication of type A aortic dissection (TAAD) and is primarily diagnosed by creatine kinase (CK) levels. However, controversy remains regarding which biomarker may be more appropriate to diagnose RM and reflects clinical outcomes. Compared with CK, serum myoglobin has a shorter half-life, making it an early marker of RM [1]. Previously, in traumatic RM, serum myoglobin was a more sensitive and specific test than serum CK, for predicting acute kidney injury (AKI) [2]. The clinical value of serum myoglobin in assessing patients with TAAD developing RM after surgery is unclear.
Objectives. This study aimed at assessing whether myoglobin would be superior in the diagnosis of postoperative RM in patients with TAAD.
Methods. For TAAD patients undergoing surgical repair, CK, muscle-type CK (CKMM), and myoglobin were recorded for the first three days postoperatively. Renal function parameters were followed up until death or discharge. The primary endpoint was a composite outcome comprising of death and persistent AKI (meeting AKI criteria but not completely resolved by discharge). The relationship among RM parameters were assessed using linear regression. The impact of different diagnostic thresholds on risk stratification and clinical decision making was investigated using receiver operator characteristic (ROC) and decision curve analysis (DCA).
Results. Of the 373 patients in the study cohort, 40 died and 104 met the composite outcome. CKMM (R2 = 1.00) was much more closely correlated with CK than with myoglobin (R2 = 0.29) (Fig. 1). The density distribution of myoglobin varied more markedly in patients with different outcomes (Fig. 2). Myoglobin (AUROC: 0.755 and 0.841), but not CKMM (AUROC: 0.652 and 0.0.746), was more accurate than CK (AUROC: 0.653 and 0.751) in predicting the composite outcome and death (Fig. 3). A threshold of 1500 ng/ml for myoglobin (approximately equals to 2000 IU/L of CK) had a sensitivity of 65(54–75) and specificity of 77(70–83) for the composite outcome, and a sensitivity of 85(69–95) and specificity of 71(65–77) for death. In addition, DCA showed that higher clinical net benefits can be achieved with myoglobin-based interventions.
Conclusions. The use of myoglobin as a diagnostic parameter for post-operative RM in patients with TAAD could better reflect the severity of the patient and provide greater clinical net benefit.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000245

Introduction. Trauma causes a state of hypercoagulability, and its presence is common early in the injury course. D-dimer (DD) easily measured and considered a good screening tool of coagulation activation. Its increase amount in plasma is a reflection of the extent of coagulation and fibrinolysis activation and hence are elevated in hypercoagulable states. Hence, in trauma, measuring DD levels may be helpful in providing useful prognostic information in absence of overt haemorrhagic manifestations. So, our study will try to find prospectively whether D-dimer levels at the point of admission can be a predictor to the outcome of patients with trauma.

Methods. This prospective observational study involved 105 adult patients of age group 18-60yrs coming to trauma emergency within 24 h of injury and blood samples collected within this period. The primary outcome was to assess whether D-dimer levels at the time of admission in hospital predicts outcome in these patients. Association of D-dimer levels with injury severity score (ISS), with blunt or penetrating trauma, time duration from injury to admission, and its contribution to hospital stay were secondary outcomes. Value of D Dimer above 250 ng/ml were considered elevated. For ease of statistical analysis, patients were be divided into two groups—ISS score less then 16 and ISS score more or equal to 16. Patients demographic variables were noted. We also recorded the time from injury to time of admission and divided the patients into two groups-patient reaching emergency within 6 h of injury and those reaching emergency more than 6 h but less then 24 h of injury.

Results. The D-dimer level at admission was significantly high in patient who died then those who were discharged [1316.28 (384.5,3331.18) vs 498.03 (140,693) , p-0.041]. There was a significant difference in d-dimer levels between blunt and penetrating trauma [1280 (565,3377) vs 162(82,526), p-0.001] (Fig. 1). 5 patients with ISS < 16 and 6 patients with ISS > 16 died in the study period. Plotting a ROC of D-dimer values, a cut-off value of 1793.35 was calculated (sensitivity-0.72; specificity-0.4) and on its basis hospital stay was compared. There was no statistically significant difference [8 (4,17) vs 10 (5,19); p-0.396].

Conclusions. In our study, we found that admission levels of d-dimer was significantly more in patient who died then who were discharged from the hospital. Patient with blunt trauma had significantly higher d-dimer values then penetrating trauma victims. Injury severity score, time from injury, and hospital stay had no significant relation with d-dimer values. D-dimer values at admission can be a useful screening tool in trauma patients to predict outcome.

Table1: Shows D-dimer levels among death and discharge patients, in relations to ISS, type of injury, time to injury and hospital stay.

D-dimer levels	Median (Q_1, Q_3)	p-value
Outcome		
Death (n-11)	1316.28 (384.5,3331.18)	0.041
Discharge (n-94)	498.03 (140,693)	
Injury severity score (ISS)		
<16 (n-71)	1001 (304,2337)	0.105
>16 (n-34)	1438 (458,10936)

Introduction. A large proportion of patients infected with SARS-CoV-2 virus, complaint of symptoms even 12 weeks after the acute phase of the infection. Shortness of breath and weakness are reported to be the most common. Risk factors and the pathogenic mechanism and are not well understood. Follow-up and management of post-COVID-19 patients requires a multidisciplinary approach. Their assessment and monitoring is of vital importance for recognizing and addressing symptoms and improving the patients' quality of life.
Objectives. The purpose of this study is to assess muscular strength and respiratory function 1 to 6 months after COVID-19 infection in patients with mild, moderate, severe, or critical illness.
Methods. In this prospective cohort study, patients with laboratory-confirmed COVID-19 were enrolled and evaluated 1 to 6 months after the disease during the period June 2022 to December 2022. Demographic data, past medical history, vaccination status, duration of illness, chest imaging and post-COVID-19 symptoms were recorded. Respiratory function was evaluated using spirometry and muscular strength by using hand dynamometer.
Results. A total of 250 patients, who recovered from COVID-19, were included. The patients had a mean ± SD age of 50.4 ± 16.3 years and 137 (54.8%) were women. In the first month of the evaluation, most patients (84.4%) reported post-COVID-19 symptoms. More critically ill patients reported dyspnea (3rd month 100 vs. 48% vs, $p = 0.037$) and fatigue (6th month 100 vs. 70%, $p = 0.04$) compared to patients with severe disease. The observed/predicted ratios of FEV1 ($p = 0.006$), FVC ($p = 0.001$) and MMEF25-75% ($p = 0.05$), were significantly lower the 1st month in patients with critical illness (Fig. 1A). Patients with moderate to critical disease severity ($p = 0.014$), as well as patients who needed to be hospitalized in a COVID-19 medical ward or Intensive care unit ($p < 0.001$), had significantly higher risk rates of obstructive or restrictive lung disease. Hand grip strength was found significantly reduced in patients with comorbidities ($p = 0.001$) and in patients reporting post-COVID symptoms at 6 months after illness ($p = 0.047$) (Fig. 1B).
Conclusions. Impairment in respiratory function and muscular weakness are frequently found in patients infected with the SARS-CoV-2 virus, related to the severity of illness and the presence of comorbidities. Further research is needed on the long-term consequences of post-COVID-19 syndrome, as well as on the management of these patients, with the aim of improving their quality of life.

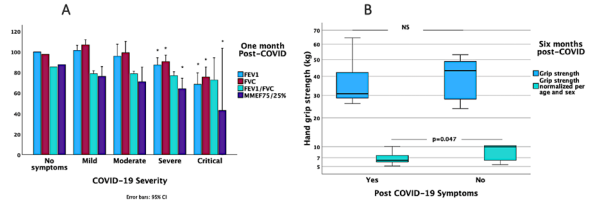

Figure 1 (abstract 000246) **A.** Lower FEV1, FVC, and MMEF25-75% the 1st post-COVID month in patients with critical illness; **B.** Decreased hand-grip strength 6 months after COVID-19 disease in patients reporting post-COVID symptoms

Introduction. Body temperature is a vital sign that is routinely measured, and fever is used as a means to evaluate infection. Therefore, patients with high fever sepsis are recognized and treated promptly, but sepsis patients with low body temperature or normal body temperature experience delayed recognition and treatment of sepsis. The early treatment of sepsis patients is associated with improved outcomes, and Rapid Response System(RRS) can provide optimal treatment for sepsis in general ward. Although studies on sepsis bundle compliance and mortality according to body temperature are often performed in emergency departments, there is little published data on sepsis based on the temperature of patients in the general ward.
Objectives. To investigate the difference in sepsis bundle compliance and 28-day mortality rates according to body temperature of patients with sepsis in general wards identified through a rapid response system.
Methods. A retrospective observational study of 1083 patients with sepsis in general wards identified through the rapid response system from July 2018 to December 2022 performed at a tertiary care hospital in South Korea. The patients were divided into three groups based on their body temperature at the time of RRS activation(i.e., hypothermia [< 36 °C] vs normothermia [36–38 °C] vs hyperthermia [> 38 °C]).
Results. We analyzed 1,083 sepsis patients by dividing them into three groups based on their body temperature (17 cases of hypothermia, 624 cases of normothermia, and 442 cases of hyperthermia). The rate of total 1-h sepsis bundle compliance was significantly difference each temperature group (64.7% in hypothermia vs. 49.5% in normothermia vs. 60.4% in hyperthermia, $p = 0.010$). Also the rate of compliance with overall sepsis bundle including lactate re-measurement was significantly difference each temperature group (64.7% vs. 49.5% vs. 60.4%, $p = 0.001$), and blood culture rate was significantly difference each temperature group (94.1% vs. 85.9% vs. 92.8%, $p = 0.002$). The 28-day mortality rates in the hypothermia, normothermia, and hyperthermia groups were 29.4%, 32.4%, and 16.5%, respectively ($p < 0.001$).
Conclusions. Sepsis patient with normothermia in general wards identified through the rapid response system was significantly lower compliance with the sepsis bundle and higher 28-day mortality rates than other body temperature group.

Toward general-purpose ICU predictive model: without task-specific feature selection and infinite observation windows

Introduction. To build predictive machine learning (ML) models using Electronic Healthcare Record (EHR) data from ICU, clinicians should choose relevant features and the observation window specifically for the target task. However, when building a general-purpose model, repeating this process for every task is hardly scalable. One potential solution is to put the entire events of a patient and let the model process them comprehensively. This solution, however, is infeasible with the current technology, because the modern machine learning algorithm (i.e. Transformer [1]) requires computations that increase quadratically by the number of input events.

Objectives. We propose a novel machine learning approach that can handle, theoretically, an infinite amount of events. This method has three key features: 1) it does not require task-specific feature selection, 2) it can handle an infinite observation window, and 3) it can make predictions for multiple tasks simultaneously.

Methods. Our key idea is to treat the EHR as free text [2] and automatically select task-related events (Fig. 1). We start by representing all EHR events as linearized text and individually encode them with a pretrained neural text encoder. Then, the retriever module learns which events are important for each task and selects the top-k most significant events automatically. This eliminates the need for manual task-specific feature selection and determining the observation window. Finally, the aggregator module, built with Transformer layers, makes multi-task predictions.

Results. A total of 68,118 ICU stays of adult patients (n = 49,168) was collected from the MIMIC-IV dataset [3]. The performance was evaluated for nine clinical tasks related to administrative outputs and sepsis-related lab values. For all tasks, our method achieved an average AUROC of 0.91 (0.70–0.99 for each task), indicating that this successfully addressed all the tasks simultaneously. Notably, in the ongoing experiment on eICU database [4], our method could handle the longest case where a patient had 284,282 events without requiring feature selection or a fixed observation window. The fact that our model automatically selects important events means, conversely, that the selected events are crucial. For instance, our model frequently selected "Lactic Acid" and "Pulse Oxymetry Alarm" events, which indirectly demonstrates the model has learned clinical knowledge.

Conclusions. The general-purpose ICU prediction model must not rely on task-specific preprocessing or task-specific models, and we provide a practical solution to this challenge. However, the current evaluation of our model is limited to a small number of tasks, and some of these are of limited clinical importance. To increase the clinical impact of our system, we plan to expand to incorporate a vast array of clinical tasks, such as sepsis and AKI.

Introduction. Inspiratory muscle training (IMT) consists of a resistive inspiratory maneuver through a pressure device comprising a unidirectional valve that hinders inspiration. IMT was found to significantly increase inspiratory muscle strength in adults undergoing invasive Mechanical ventilation (MV). Despite, we observe an important heterogeneity of IMT protocols, and it is unclear if it reduces MV duration. Furthermore, inspiratory muscles endurance is scantly evaluated while the assessment of this function may be fundamental for a successful weaning. In this multicentric controlled randomized parallel trial, we compared the effects of three different IMT protocols (CADER, MARTIN, and EDRIC) on inspiratory muscle strength and endurance in difficult to wean patients in two intensive care units (ICU).
Methods. 92 subjects presenting difficult weaning (after first spontaneous breathing trial failure or extubation failure) were randomized in 3 groups to perform one of the three different IMT protocols twice daily. The primary outcome was the Maximal Inspiratory Pressure (MIP) increase in each group during weaning. Secondary outcomes were Pressure peak increase (Ppk), as endurance marker, weaning duration, and safety.
Results. During the weaning process, the observed increase of MIP was 12.2 ± 11.2 cmH2O in EDRIC group, 5.3 ± 15.5 cmH2O in CADER group, and 6.8 ± 15.1 cmH2O in MARTIN group. There was a non-statistically significant difference between EDRIC group and CADER group (mean adjusted difference: − 6,65 [− 14,35; 1,04], p = 0.052), neither between EDRIC group and MARTIN group (mean adjusted difference: − 3,67 [− 11,52; 4,18], p = 0.289).
No significant difference in Ppk increase were observed between the three groups. Over 356 IMT sessions, only 3 serious adverse events were considered possibly related to the study. All events were spontaneously reversible bradycardia.
Conclusions. Independently of IMT protocol applied, MIP and Ppk seemed to improve in our cohort of difficult to wean patients. Ppk could be a helpful tool to assess diaphragm function exhaustively. EDRIC group showed a slightly higher efficacity.

Introduction. Electrical Impedance Tomography (EIT) is a non-invasive imaging technique that uses changes in electrical conductivity to create images of the lungs. The utility of Electrical Impedance Tomography (EIT)-guided Positive End-Expiratory Pressure (PEEP) titration in improving outcomes in with Acute Respiratory Distress Syndrome (ARDS) patients in comparison to traditional PEEP titration methods.
Methods. Extensive electronic database screening was done until 1st April 2023. Randomized Controlled Trials (RCT) evaluating the impact of the EIT-guided PEEP titration were included in this meta-analysis.
Results. Our search retrieved six RCTs with a total of 475 patients. No significant difference in P/F ratio [MD = − 6.35;95%CI − 19.32 to − 6.6; I2 = 0%], driving pressure requirement [MD = − 0.29;95%CI − 0.84 to 0.25; I2 = 0%], PEEP optimization [MD = 0.05;95%CI − 0.46 to 0.56; I2 = 87%], and successful weaning [OR = 1.35; 95% CI 0.8–2.2, I2 = 51%] with the application of EIT-guided PEEP titration.
Conclusions.: EIT-guided PEEP titration is a novel alternative, further well designed studies are needed for substantiating it's utility.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000257

Introduction. Epinephrine has been used for increasing coronary perfusion pressure during advanced life support (ALS) and promoting short-term survival (1, 2). A 3–5 min dosing interval of epinephrine during resuscitation is recommended in recent cardiopulmonary resuscitation (CPR) guidelines, but the recommendations lack scientific evidence. This study was aim to verify the effect of epinephrine on augmenting blood pressures and effect duration of epinephrine during ALS.
Methods. This is a secondary analysis study using data from a previously published study with swine cardiac arrest model (3). In the study, the epinephrine dose was fixed as 1 mg and the first dose of epinephrine was administered after no flow time of 2 min and low flow time of 8 min and then administered every 4 min. We defined 4 cycles of the dosing interval because a previous study was terminated at 26 min after induction of ventricular fibrillation. Augmented blood pressures and corresponding timeline were derived. Trend of augmented blood pressures following cycles and effect duration of epinephrine were also collected.
Results. Total 180 cycles were analyzed. The augmented blood pressures were the highest in the 1st cycle and gradually decreased as the cycles repeated. However, the effect duration of epinephrine was not different as the cycles repeated. Time achieving maximum blood pressures was about 90 s after epinephrine administration and it was not accordant with timing of defibrillation.
Conclusions. Augmented blood pressures after epinephrine administration during ALS was gradually decreased as the CPR cycles repeated. However, the effect duration of epinephrine during CPR was not different. Modification of epinephrine dosing interval might promote probability of successful defibrillation.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000258

Introduction. Automatic chest compression device (ACCD) can promote high quality of cardiopulmonary resuscitation (CPR) and it spreads worldwide recently. Early application of automated external defibrillator (AED) along with high quality CPR is crucial for favorable outcomes in patients with cardiac arrest. We developed an automated CPR apparatus (A-CPR) that combines ACCD and AED in a device and evaluated the performance of the A-CPR through a pilot animal experiment.
Methods. 11 pigs (5 in A-CPR group and 6 in ACCD CPR and AED [C-CPR] group) were enrolled in the study. After 2 min of observation without any treatment after ventricular fibrillation (VF) induction, CPR with 30:2 compression/ventilation ratio was performed for 6 min, mimicking basic life support (BLS). A-CPR or C-CPR was applied immediately after BLS and resuscitation including chest compression and defibrillation was performed following voice prompt from A-CPR device or AED. Hemodynamic parameters including aortic pressure, right atrial pressure, coronary perfusion pressure (CPP), carotid blood flow (CBF), and end-tidal carbon dioxide (ETCO2) were monitored during resuscitation. Time variables including time to start rhythm analysis, time to charge, time to defibrillate, and time to subsequent chest compression were also measured.
Results. There were no differences in baseline characteristics except PaCO2 (39 [35–40] in A-CPR vs 33 [31–36] in C-CPR, $p = 0.034$). There were no differences in hemodynamic parameters between groups. Time to charge (28.9 ± 5.6 s in A-CPR group vs 47.2 ± 12.4 s in C-CPR group), time to defibrillate (29.1 ± 7.2 s in A-CPR group vs 50.5 ± 12.3 s in C-CPR group) and time to subsequent chest compression (32.4 ± 6.3 s in A-CPR group vs 56.3 ± 10.7 s in C-CPR group) were shorter in A-CPR group than C-CPR group ($p = 0.015$, 0.034 and 0.02 respectively).
Conclusions. A-CPR can provide effective chest compressions and defibrillation, resulting in shortening the time to defibrillate.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000259

Introduction. The COVID pandemic represented a major global health emergency. Patients may require prolonged mechanical ventilation and eventually a tracheostomy. The ideal tracheostomy timing remains yet to be defined. Most studies about this topic are observational and therefore vulnerable to several biases, such as immortal-time bias.
Objectives. We aimed to evaluate whether tracheostomy timing in patients who required prolonged mechanical ventilation was related to outcomes by using an emulated target trial framework.
Methods. We emulated a hypothetical target trial in which Covid-19 infected patients who required mechanical ventilation (MV) for more than ten days would be randomly assigned to an early tracheostomy (< 21 days) or delayed tracheostomy strategy, which included patients who had a late tracheostomy (> 21 days) and those who were not submitted to a tracheostomy. We used the data from a cohort of patients admitted at Hospital das Clinicas from University of Sao Paulo. In this target trial, we would exclude patients likely to be extubated in the following 72 h and also patients likely to die in the upcoming week. The primary outcome was hospital mortality; ICU and hospital length of stay were secondary outcomes. A secondary analysis was performed evaluating the patients who received a late tracheostomy or no procedure.
Results. Between March to July of 2020, 618 were mechanically ventilated for > 10 days, of which 325 patients were included in the study after exclusions: 73 underwent early tracheostomy and 252 received a delayed tracheostomy approach. The adjusted odds ratio (ORadj) of early tracheostomy for hospital mortality was 1.21 (95%CI, 0.69–2.14, $p = 0.502$). The adjusted mean difference (MDadj) for ICU length-of-stay was 3.9 (95%CI, 0.4–7.4, $p = 0.03$) days higher, and for hospital length-of-stay it was 7.2 (95%CI, 2.1–12.2, $p = 0.007$) days higher for early tracheostomy compared to a delayed tracheostomy approach. When separating patients who underwent late tracheostomy vs. those who did not undergo tracheostomy, there was no difference in hospital mortality, but ICU LOS was higher for those who actually underwent late tracheostomy compared to those who were not tracheostomized (MDadj = 15.6, 95%CI 12.1–19.2, $p < 0.001$) and it was also higher for those who underwent early tracheostomy compared to those who were not tracheostomized (MDadj = 7.6, 95%CI 4.2–11.0, $p < 0.001$).
Conclusions. This emulated trial analysis did not observe an association between early tracheostomy and better outcomes in critically ill Covid-19 patients. Studies assessing treatment timing in critical care should avoid naive approaches that exclude patients who could have been included in a trial.

Table 1 (abstract 000259) .

	Delayed approach n = 252	Early tracheostomy n = 73

Catheter localization by transthoracic echocardiography during Peripherally Inserted Central Catheter: a real-time method to rule out the misplacement

Y. C. Jung[1], S. Man-Shik[1], K. Min-Woong[1]
[1]Cardiovascular and Thoracic Surgery, Chungnam National University Hospital, Daejeon, Republic of Korea
Correspondence: Y.C. Jung
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000260

Introduction. Catheter misplacement after a peripherally inserted central catheter (PICC) is annoying. If the catheter is found to be in an aberrant position after the procedure, the practitioner and patient should be prepared for re-insertion. A precise one-time PICC is crucial because patients who undergo PICC are mostly elderly or frail due to advanced disease. In addition, many patients may have poor peripheral access to the available central veins.
PICC placement can be achieved at the bedside without ultrasound or fluoroscopic guidance [1, 2]. However, there are concerns regarding the safety and success of PICC. If blind PICC placement is unsuccessful due to failure to advance the catheter or aberrant positioning, an imaging guidance approach is required for accurate PICC placement [3]. The wide use of real-time imaging techniques during procedures such as fluoroscopy or the C-armares widely usedbyr practitioners who perform PICC. Fluoroscopy is a valuable imaging tool that can provide a functional and anatomic assessment of patients in real time, as well as radiation exposure to patients and medical staff [4]. Adverse reactions can occur when contrast agents are used in fluoroscopic procedures [5]. Transthoracic echocardiography(TTE) is a reliable tool for detecting catheter misplacement and optimizing catheter tip positioning during central venous catheter insertion [6]. In an environment where ultrasound is prepared, echocardiography can be easily performed when PICC placement. Through this, it is possible to check whether the catheter is correctly located on the right side of the heart. If so, I thought it could clearly prevent the catheter from heading to the opposite arm or neck during PICC. We planned to perform PICC at bedside by this manner.
Objectives. To evaluate the feasibility of catheter detection in the right cardiac cavity using TTE during PICC.
Methods. We conducted a single-center prospective observational study (January 2022-March 2023). All consecutive patients who underwent PICC by TTE were included in this study. Puncture was performed using the landmark method or under ultrasound guidance. TTE was performed during the procedure to monitor the arrival of the catheter in the right cardiac cavity (Fig. 1). Catheter misplacement was defined as an aberrant position on a periprocedural or postprocedural chest X-ray. (CXR) The primary endpoint was the prediction of catheter misplacement based on catheter detection in the right atrial cavity. The secondary endpoint was optimization of catheter tip placement in the superior vena cava–right atrium (SVC–RA) junction at the CXR.
Results. In total, 110 patients were included. Ten patients were excluded due to poor echogenicity. One hundred patients underwent PICC using TTE. The catheter was visualized in the Rt cardiac cavity in 90 cases (Fig. 2). In 10 cases, the catheter was not seen in the right cardiac cavities and CXR showed catheter misplacement in 7 cases. Eight patients with catheter misplacement underwent the same method as the other arm. Therefore, there were a total of 108 procedures. In two patients, PICC failed due to anatomic reasons (Fig. 3). Catheter misplacement was detected by TTE with a sensitivity of 97% (CI 90–99%), a specificity of 90% (CI 55–99%), a positive predictive value of 99%, and a negative predictive value of 75%. Likelihood ratios were LR + 9.69 (CI 1.5–62.3) and LR− 0.03 (CI 0.01–0.1).
Conclusions. TTE is a reliable and feasible diagnostic tool for detecting catheter misplacement and optimizing catheter tip positioning during PICC placement**.**

Patient and public involvement in clinical ICU research: learnings from the FICUS study

R. Naef[1], L. Verweij[1], C. De Biasio[2], T. Zurbrügg[2], T. Brühlhart[2], M. Filipovic[3], M. M. Jeitziner[4], J. Safford[2], Ficus Study Group[5]

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000262

Introduction. Involving patients, family members and the public in clinical research helps ensure that research is relevant to those it seeks to serve, namely the healthcare services users. Recognising these potential benefits of patient and public involvement is increasingly mandated by funders. Participatory user-researcher collaborations seem likely to improve enrolment of trial participants, thus improving data quality and results obtained (Crocker et al., 2018). Practical guidance and experiences with user-researcher collaboration in the context of ICU research is, however, scant (Burns et al., 2017; Greenhalgh et al., 2019).
Objectives. We report on the approach, activities, and experiences with a user-researcher collaboration in the context of a multi-centre study investigating a nurse-led, interprofessionally delivered Family support intervention in Intensive Care UnitS (FICUS) (Naef et al., 2022).
Methods. A FICUS user group was established with a patient expert, three family members and one patient with lived experience of ICU care. The user group started work with the research team during the funding application stage of the study. The FICUS study is currently halfway into recruitment. The Critical Outcome of Research Engagement (CORE) (Dillon et al., 2017) guided the definition of the user-researcher collaboration and the development of co-production strategies across the entire research process.
Results. After funding for the study was secured, the FICUS user group structured their collaboration by defining aims, roles and responsibilities within the project, and compensation. Each user could make choices about their contribution as a listener, co-thinker, advisor, partner, or decision-maker (Smits et al., 2020) in relation to specific research activities: to co-produce study recruitment materials and instructions (e.g. video, flyers, study information pack, guidance on recruitment for clinicians), to support intervention delivery (e.g. training of study personnel), to participate in research team meetings and study group activities, to contribute to communication and dissemination (e.g. quarterly newsletter, protocol publication) and to represent their user perspective and expertise as co-researcher (e.g. presentations at symposia).
Conclusions. Establishing relationships and trust, clarifying roles and mutual expectations, and creating choice in level of contributions has enabled a productive user-researcher collaboration and mutual learning within the FICUS study in the first three years. A group of patient experts and service users have become a valued and essential part of the FICUS study group. Formal evaluation will be needed to examine the experience with and benefit of user-researcher collaborations on participation rates, data quality, translation of findings into policy, and mutual learnings.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000264

Introduction. Extubation failure after surgery may be associated with worse outcomes.1 To prevent or treat post-extubation respiratory failure, different forms of non-invasive respiratory support (NRS), including conventional oxygen therapy (COT), high-flow nasal oxygen (HFNO), continuous positive airway pressure (CPAP), and noninvasive ventilation (NIV), have been proposed.1
Objectives. The aim of this systematic review and network meta-analysis is assessing the effect of NRS application on the rate of re-intubation.
Methods. The review protocol was registered in PROSPERO (CRD42022377859). Medline, Embase, Scopus, CENTRAL, and Web of Science were searched from inception until March 19, 2023. All studies meeting the following criteria were included: participants were adult patients extubated after surgery; the intervention and comparison were any NRS modality; the primary outcome was re-intubation, whereas intensive care unit (ICU) and hospital mortality and length of stay, time to re-intubation, and the incidence of nosocomial pneumonia and patient discomfort were secondary outcomes; study design was randomized controlled trials (RCTs) or non-randomized controlled studies.
The risk of bias was evaluated with the Risk of Bias (RoB) 2 and the Risk Of Bias In Non-randomized Studies of Interventions (ROBINS-I) assessment tools.2 Meta-analyses were performed using a random-effects model, the inverse variance method for continuous outcomes, and the Mantel–Haenszel method for dichotomous outcomes.2 Statistical heterogeneity was assessed using the chi-squared test and I2 statistic. Two-sided p-values < 0.05 were considered significant.
Results. Twenty-seven RCTs (9028 patients) and five non-RCTs (2193 patients) were included (Fig. 1). Supra-diaphragmatic surgery was studied in 21 studies, while 11 studies investigated infra-diaphragmatic or mixed surgery. Twenty-three studies (72%) were performed in the ICU. NRS was employed as prophylaxis in 19 studies (59%) and therapy in 11 (34%). Most studies (11, 34%) tested the comparison between COT and HFNO, 9 (28%) between COT and NIV, and 9 (28%) between COT and CPAP.
Among RCTs, six studies were considered at low risk of bias, 16 studies arose some concerns, and five studies were considered at high risk of bias. Among non-RCTs, two studies were considered at serious and three at critical risk of bias.
As compared with COT, NIV (OR 0.50, 95% CI 0.28–0.88, p = 0.02, I2 = 62%) reduced the incidence of re-intubation (Fig. 2) and was associated with lower ICU (OR 0.39, 95% CI 0.17–0.90, p = 0.03, I2 = 0%) and hospital mortality (OR 0.51, 95% CI 0.34–0.77, p = 0.001, I2 = 0%). NIV and CPAP were associated with shorter ICU length of stay, CPAP with shorter hospital length of stay, and NIV with lower risk of nosocomial pneumonia. Among-group differences in discomfort were not significant.
Conclusions. NIV reduced the risk of re-intubation and mortality, as compared with COT, in adult patient extubated after surgical procedures.

Introduction. Unnecessary antibiotic treatment in ICU patients can lead to an increase in side effects, antibiotic resistance, and higher costs. Early termination of antibiotics may lead to clinical deterioration or a restart of antibiotics. Using machine learning models, we aim to predict whether therapeutic antibiotics can be safely stopped in intensive care patients.

Methods. We retrospectively collected data on all adult ICU patients that were treated with antibiotics in two tertiary academic hospitals in the Netherlands. We removed all antibiotic records marked as prophylaxis and reconstructed antibiotic courses. Our primary outcome was restarting of therapeutic antibiotics within 72 h and no readmission or death within 72 h after termination. We included monitor data, laboratory data, selective decontamination strategy, and culture results as predictors. We trained logistic regression, random forest and XGBoost models to predict restarting antibiotics.
Results. A total of 10,087 patients were included, with 10,643 hospital admissions and 11,439 ICU admissions between October 2015 and December 2021, with a total of 10,982 therapeutic antibiotic series. The primary outcome of restarting therapeutic antibiotics occurred in 2,504 (16.2%) of antibiotic courses. Of these, the same antibiotic was restarted in 567 cases (36.1%), and the same therapeutic subgroup according to the Anatomical Therapeutic Chemical (ATC) was restarted in 1,713 cases (68.4%).
Conclusions. Antibiotics are frequently restarted with the exact same antibiotic, indicating potential for improvement. Advanced analytics such as machine learning models could potentially identify patients for whom antibiotics will be restarted while also identifying patients for whom antibiotics can safely be terminated. Further research will use logistic regression, random forest, and XGBoost to attempt to classify these groups. Furthermore, performance may be improved through the use of soft predictors such as delirium observation scales, the use of antipsychotics and sedatives, or increased gastric retention.

Correspondence: S. Zhang
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000268

Introduction. Approximately one-third of hospitalized COVID-19 patients develop acute respiratory distress syndrome (ARDS). An alveolar fibroproliferative response (FPR) during hospitalization may induce long-term pulmonary fibrotic lesions in patients who recovered from COVID-19-related ARDS. Chest computed tomography (CT) and lung function test (PFT) are used to identify the signs of pulmonary fibrosis. N-terminal of procollagen III (NT-PCP-III) is a validated biomarker for an activated FPR in ARDS.
Objectives. We aimed to 1) assess pulmonary fibrotic injury in COVID-19 ARDS patients at 3 and 12 months after hospital discharge; 2) evaluate the association between dynamic changes in alveolar FPR during hospitalization and long-term outcomes as well as 90 day mortality in these patients.
Methods. In this prospective observational cohort study, bronchoalveolar lavage (BAL) and blood samples were collected from COVID-19 ARDS patients admitted to the ICU of two academic hospitals for the measurement of 17 pulmonary fibrosis biomarkers, including NT-PCP-III. Pulmonary function and chest CT were assessed at 3 and 12 months after hospital discharge. Forced vital capacity (FVC), diffusing capacity of the lungs for carbon monoxide (DLCO) and ground-glass opacities (GGO) percentage on CT images from the first and second follow-up visits were compared using a paired Wilcoxon test. Joint modeling was performed to assess the association between longitudinal changes in the biomarkers and mortality at day 90 after intubation. The relationship between alveolar biomarker concentrations and clinical outcomes was analyzed using linear mixed models and logistical regression models for consecutive and dichotomous independent variables, respectively.
Results. One hundred and fifty-four COVID-19 ARDS patients with 284 BAL samples were analyzed, ninety-two (59.7%) patients died within 90 days after intubation and 54 (35.1%) survivors completed the follow-up procedure. FVC and DLCO were impaired at the first follow-up and improved significantly at one year after hospital discharge ($p = 0.03$ and $p = 0.004$, respectively) (Fig. 1). A longitudinal increase in NT-PCP-III, along with other pulmonary fibrosis markers, was associated with increased 90-day mortality (HR 2.89, 95% CI: 2.55 to 3.28; $p < 0.001$). No significant association was found between the alveolar FPR during hospitalization and signs of pulmonary fibrosis assessed by pulmonary function test or chest CT images within one-year follow-up.
Conclusions. In COVID-19-related ARDS patients, the alveolar FPR during hospitalization was associated with higher mortality, but not with the presence of long-term fibrotic lung sequelae within survivors.

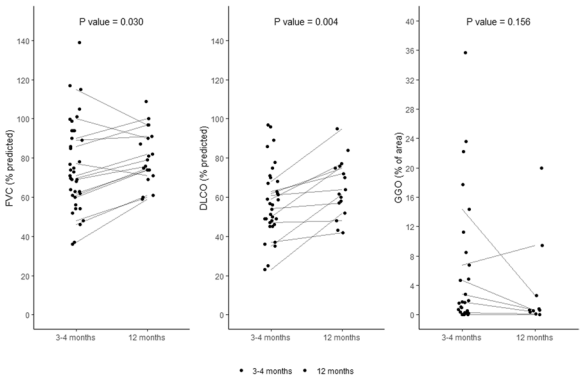

Figure 1 (abstract 000268) Comparison of lung function and CT image between the two follow-up visits. (Left) The changes of FVC % predicted value, (Middle) the changes of DLCO % predicted value, (Right) the percentage changes of GGO in the whole lung

A novel eye-tracking platform for the continuous and automatic diagnosis of delirium in ICU

A. Al-Hindawi[1]
[1]Intensive Care Unit, Chelsea and Westminster Hospital, London, United Kingdom
Correspondence: A. Al-Hindawi
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000269

Introduction. Delirium is associated with increased mortality, morbidity, and long-term cognitive dysfunction [1,2]. Yet, no objective marker has been developed to automate the diagnosis and current standards rely on a manual, laborious, assessment of consciousness and attention, e.g., the Confusion Assessment Method in ICU (CAM-ICU) [3]. Visual in-attention has been hypothesized to be diagnostic for delirium, however, no suitable eye-tracking platform exists [4].

Objectives.

1. To develop and deploy an eye-tracking platform suitable for use in ICU to classify delirium from eye movements
2. To develop a cognitive architecture that explains the data using established neuro-computational paradigms

Methods. Empiric requirements led to the development of a novel platform that uses specialized neural networks for the regression of eye movements in a calibration-free, non-invasive manner [5–7].
Following ethical and governance approvals, a multi-centre feasibility study was conducted. ICU patients recruited into the study underwent daily recording of eye movements for 10 min with concurrent measurement of CAM-ICU.
The data gathered were then used to train classification models to predict the conditional probability of delirium. Classification accuracy was assessed by discrimination performance using Receiver Operator Characteristics and Precision-Recall Curves alongside their summary statistics (Area under the ROC (AUROC) and mean Average Precision (mAP)).
For explainability, a novel architecture composed of multiple competing forward models of the visual processing hierarchy was built. Statistical significance was performed with an α of 0.05.
Results. A total of 210 recordings were made from 42 patients using the platform (Fig. 1a). Two models were trained (Fig. 1b); the eye-movements-only model achieved good discrimination performance (AUROC 0.67, mAP 0.68) whilst the second model, which took into consideration what the patient was looking at, further increased performance metrics (AUROC 0.76, mAP 0.81) (Fig. 2).
The novel competing forward models architecture (Fig. 1c) was able to recall internal cognitive states. Using data gathered from the study, the architecture demonstrated that patients with delirium are visually inattentive throughout the visual processing hierarchy ($p = 0.044$, χ^2, $df = 4$). This finding is in keeping with the network disconnectivity hypothesis but in an automatic, non-invasive manner.
Conclusions. A novel eye-tracking platform was developed, validated, and deployed across two hospitals which could objectively and automatically diagnose delirium. Neuro-computational models of the visual processing hierarchy demonstrate that delirium is punctuated by visual inattention throughout the visual processing hierarchy.

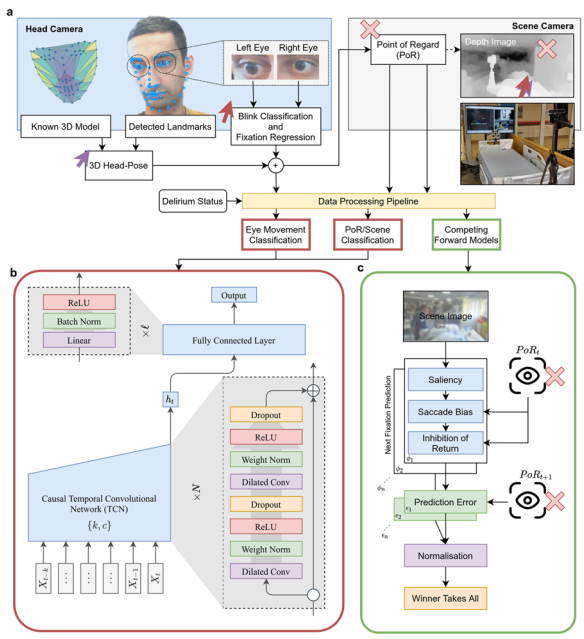

Figure 1 (abstract 000269) Data acquisition, processing, and model overview. a demonstrates the duties of the head-camera and the scene-camera pictorially. **(A)** The head-camera locates the patient's head using a face-detector followed by the extraction of pre-specified landmarks and the calculation of the 3D head-pose. The eye patches are also extracted which are used for blink classification and fixation regression. The gaze-vector, in combination with the 3D Head-Pose are then used to find the PoR of the patient from the scene-camera. Inset picture showing the setup of the cameras around a bed-space. **(B)** demonstrates the architecture for delirium classification using Temporal Convolutional Networks (TCNs). Time-series inputs are encoded to a fixed-sized vector using a TCN where a set of fully connected layers are used to convert the encoded vector to the probability of delirium. Xt represents the input at time point t, ht represents the hidden latent fixed vector size that encodes previous time points. **(C)** demonstrates the proposed competing forward models architecture for explaining viewing behaviour; the architecture is composed of three modules, the first module predicts the next fixation in a probabilistic manner (φn), the next performs prediction error measurement of each forward model (en), and the final module performs softmax normalisation. The forward models then compete for assignment in a Winner Takes All (WTA) scheme

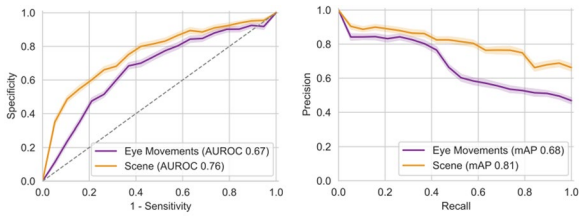

(a) Receiver Operating Characteristic Curve (b) Precision-Recall Curve

Figure 2 (abstract 000269) Performance of the models for the binary classification task of diagnosing delirium comparing an eye-movements only model against a scene model. The eye movements model classifies delirium based on time-series eye movement data, namely the horizontal and vertical eye angles of each fixation. Whereas the scene model contains time-series gaze-scene intersection data. Both classification models use the architecture in Fig. 2. Eye movements alone have good discriminatory performance for the diagnosis of delirium but are improved upon once scene information is added

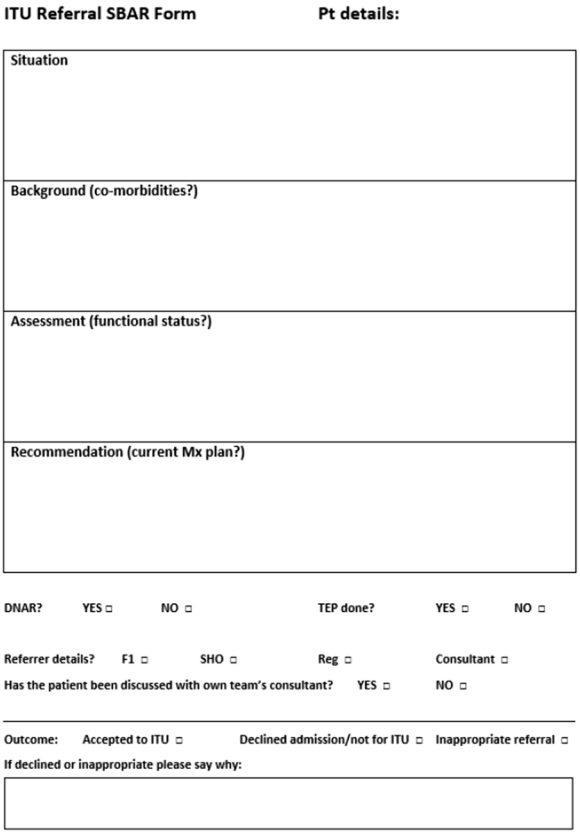
Reducing the number of inappropriate referrals to intensive care using a novel referral form—a quality improvement project

A. Agrawal[1]
[1]Intensive Care, Queen Elizabeth The Queen Mother Hospital, London, United Kingdom
Correspondence: A. Agrawal
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000270

Introduction. The intensive treatment unit (ITU) provides a specialist service within the hospital however with a limited number of beds available, there is often a large demand for the spaces. We found in our intensive care department that there were a large proportion of referrals to ITU compared to the number of patients actually accepted for admission. There was no record being kept of the referrals which were coming in to the department. Our two fold QIP focussed on creating a referral form to keep documentation of all the referrals made to ITU. Secondly, we audited the inappropriate referrals and then put in interventions to improve this. The role of trainees in ITU was reduced significantly by multiple bleeps which were often due to inappropriate referrals.
Objectives. The first aim was to create a standardised documentation of referrals to ITU within our local centre so they can be audited in the future. Our second aim was to reduce the number of inappropriate referrals to ITU to create greater efficiency within the department and improve flow in the hospital.
Methods. We first created a referral form (picture 1) which we wanted to be sustainable so was created using the SBAR handover tool as the format, which is commonly used in the intensive care medicine setting (Shahid & Thomas, 2018). This was used by the doctor in ITU who was accepting referrals to document the referral. This was used to categorise the type of referral which we then analysed over the period of 3 months. Inappropriate referrals were further classified into categories to create themes of inappropriate referrals. This led to development of teaching for medical and surgical specialties during their departmental teaching half days.
Results. Across the first data collection period we found each month there were 50–60% inappropriate referrals made to ITU. The main themes which emerged as the reasons for inappropriate referrals were inappropriate escalation status and patients who were referred without a clear organ support indication. Following departmental teaching for medical and surgical specialities, we saw a reduction in the number of inappropriate referrals to on average 40% per month during the re-audit period.
Conclusions. This QIP provides sustainable change in terms of increasing efficiency within the department as the referral form is a tool which aids the doctor receiving referrals in ITU, instead of adding to their workload. One of the main issues was objective decision making around which referrals were considered inappropriate. This also raises the issue of a lack of guidelines around admissions to ITU (Metcalfe et al., 2000). There was also a category of patients who were refused admission to ITU despite being appropriate referrals, mainly due to capacity within the unit. Further development of the project can aim to look at mortality within the appropriately referred patients who were refused admission to ITU.
The impact of this QIP on the trainees within ITU was reduction in the number of inappropriate referrals which meant during unsociable hours when resources are limited, more time can be spent on the patients within the unit. Patients were also escalated within their parent team appropriately before being referred to intensive care. This provided more effective and thorough specialty care for patients.



Picture 1 (abstract 000270) Referral form for ITU

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000275

Introduction. In the intensive care unit (ICU), physicians encounter a large amount of data, various alarms and noises. Previous studies have shown that vital signs deteriorated several hours before critical events,

but too much data can rather distract physicians from instantly recognizing the deterioration of the patients. By stratifying patients into different risk categories and detecting patients at risk of physiological derangements earlier, mortality prediction models help physicians redistribute the limited resources, recognize patients at risk, and correct the deterioration properly. In this study, we developed a deep-learning based real-time prediction model for mortality within 24 h in critically ill patients by utilizing only the variables easily extractable from electronic health records in most clinical settings.

Methods. The study protocol was reviewed and approved by the Institutional Review Board (IRB No. 2111-140-1275) of Seoul National University Hospital (SNUH), and the IRB waived the requirement for informed consent. The internal cohort consisted of patients who were admitted to one of six ICUs at SNUH between May, 2007, and October, 2021. We extracted binary mortality information from the time of patient death during the ICU stay and a panel of 27 critical candidate features which were selected by clinical experts, and easily collectible from the electronic medical recording systems. Candidate features consisted of 10 vital signs, 16 laboratory variables, and age.

To develop a machine learning model predicting the mortality risk score within 24 h in real-time, we employed a model ensemble approach to improve the effectiveness of our prediction model. Several individual models with different architectures were trained using SNUH dataset. Various combinations of models were compared and the best-performing ensemble model was selected as our final model.

The performance of model was assessed in two main domains: its predictive accuracy using the area under receiver operating characteristic curves (AUROC) and the ability to reduce alarm counts at the same sensitivity level using the mean alarm count per day (MACPD). Internal validation was conducted using SNUH dataset. We also performed external validation using Medical Information Mart for Intensive Care (MIMIC-III) and eICU Collaborative Research Database (eICU-CRD).

Results. During the study period, 61,954 patients were included and mortality occurred in 1,830 (2.95%). 147,187 event vital signs and 8,922,443 normal vital signs were analyzed. Our model showed better performance compared to the conventional models in the internal validation, with AUROC of 0.96 (95% CI 0.968–0.970) (Fig. 1).

Considering that the highest AUROC of mortality prediction among conventional models was 0.856 (95% CI 0.853–0.859) of national early warning system (NEWS), our model significantly improved the predictive ability for mortality within 24 h ($p < 0.001$). Though the performance was slightly decreased in the external validations, AUROCs were still higher compared to conventional models (0.895 (95% CI 0.894–0.896) vs. 0.793 (0.794–0.796) in MIMIC-III, and 0.901 (0.901–0.092) vs. 0.789 (0.788–0.790) in eICU-CRD, compared to NEWS, both $p < 0.001$) (Fig. 1). With sensitivity of 0.8, our model reduced MACPD from 10,960 counts in NEWS $\geq$ 4, to 978 counts (8.92%) in internal dataset. By our model MACPD was also reduced to 23.8% (11,429 in NEWS $\geq$ 4 and 2715 in our model, with sensitivity of 0.715) in MIMIC-III and, to 18.9% (11,804 in NEWS $\geq$ 4 and 2226 in our model, with sensitivity of 0.729) in eICU-CRD.

Conclusions. We developed a real-time and explainable ensemble model to predict mortality within 24 h for critically ill patients from a dataset of single center in Korea with more than 60,000 adult patients of 5 different ICUs. External validation was also done and performance was maintained in popular and open external dataset—MIMIC-III and eICU-CRD dataset. However, the results should be confirmed in a prospective study, before application as a decision-support tool at a real practice.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000278

Introduction. In hospital cardiac arrest is an event that has a significant impact on patient safety, and recently developed deep learning based early warning scoring (DEWS) has been shown to be an effective warning system. In our hospital operating a 'weekday only' rapid response team (RRT) with minimal manpower, cardiac arrest was 2.3 per 1,000 hospitalizations with high false alarms in general wards in 2022.

Objectives. We investigated whether deep learning-based warning score (DEWS) would be effective to predict of cardiac arrest and to reduce false alarms.

Methods. DEWS analyzed six parameters of age, sex, SBP/DBP, heart rate, respiratory rate, and body temperature and used the already validated DeepCARSTM (VUNO Med, South Korea) product. Inpatients in the general ward, excluding patients aged 15 years or younger and admitted to the intensive care unit (ICU), emergency department, operating and delivery room, were compared with modified early warning score (MEWS) for analysis. From January 1, 2023, to January 31, 2023, major adverse events (MAEs) such as cardiac arrest, unexpected ICU transfer, do-not-resuscitation, hospital death were retrospectively analyzed.

Results. During the study period, a total of 56,155 inputted vital signs were analyzed as predictive data, and a total of 2,243 patients were hospitalized. There were 2.22 cardiac arrests per 1,000 admissions and 26 unexpected ICU admissions. AUROC was 0.832 ($p < 0.01$) in DEWS compared to 0.732 in MEWS, and the sensitivity was 38.8% under the same condition of 98% specificity, which was higher than MEWS with 22.6%. False positive alarms decreased by 43% in DCARS from 1,760 cases to 1,001 cases. MEWS has a low correlation with score distribution, but true positives increase as DEWS increases.
Conclusions. In DEWS, higher prediction rate and false positive alarm can be reduced, so it can be applied in RRT operated with minimal manpower.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000282

Introduction. AHA/ASA clinical practice guidelines recommend lowering systolic blood pressure to < 160 mmHg to reduce the risk of rebleeding, however the evidence is scant and we do not know the effect on other complications or in the prognosis.
Objectives. To assess the effect of systolic blood pressure on the first medical contact, according to the cut-off point of 160 mmHg, on clinical course and outcome in patients with aneurysmal subarachnoid haemorrhage (aSAH).
Methods. Prospective cohort study that included all SAH admitted to our ICU from March 2017 to May 2021. Based on the blood pressure, patients were divided into high blood pressure (HBP) (BP ≥ 160 mmHg) and non-HPB (BP < 160 mmHg). Demographic, clinical, and outcome variables were collected. Statistical analysis was performed with STATA 14.0.
Results. 121 patients were included, 77% women, with a mean age of 58 years (48.11–63.31). 41.3% were previously hypertensive and 33% received treatment. 41.3% presented HBP on admission. The differences between the HBP and non-HBP groups are described in Table 1.

Table 1 (abstract 000282) Demographic and clinical variables and complications in both groups

	No HBP (SBP < 160) 71 (58,7)	**HBP (SBP ≥ 160) 50 (41,3)**	**p**
Sex (male)	22 (30,98)	22(44)	0,143
Age (years)	53,78 ± 12,23	61,5 ± 13,53	**0,001**
Previous HBP	20 (28,57)	30 (60)	**0,000**
Previous antihypertensive treatment	17 (24,28)	23 (46)	**0,011**
Scales			
SAPS 3	50,6 ± 15,53	53,86 ± 13,99	0,239
HH 4 or 5	22 (31)	17 (34)	0,72
Fischer 4	33 (47)	26 (53)	0,55
Complications			
Vasospasm	20 (28,98)	3 (6,52)	**0,003**
Ischemia	20 (28,98)	5 (10,86)	**0,021**
Rebleeding	6 (8,57)	5 (10,86)	0,679
Hydrocephalus	24 (34,28)	12 (26,08)	0,35
Troponins peak (ng/l)	112,9 ± 216,2	103 ± 265,1	0,826
Pro-BNP peak (pg/ml)	1213,4 ± 1722,5	874,13 ± 969,4	0,241

Data is displayed as mean and standard deviation or numbers and percentages.
Mortality was 28.9%, with no significant differences between both groups. Ordinal regression analysis adjusted for age and Hunt-Hess 4–5 showed no relationship with GOSE at 6 or 12 months.
Conclusions. HBP presented after SAH is more common in patients with premorbid hypertension, despite treatment. There are no differences in the presence of rebleeding, in mortality or long-term prognosis between groups, but patients without HBP presented more vasospasm and ischemia.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000285

Introduction. Extracorporeal membrane oxygenation (ECMO) has been developed to mainly provide continuous extracorporeal respiration and circulation for patients with severe cardiopulmonary failure. In the COVID-19 pandemic, ECMO has been extensively utilized to maintain the lives of patients with severe and critical COVID-19. It remains crucial to review the ECMO utilization and clarify its potential indications.
Objectives. This study aims to determine the clinical outcome after the ECMO practice and then perform preliminary economic evaluation.
Methods. We investigated the ECMO utilization in a certain region of China in 2022 and then followed-up the outcomes. Cost-effectiveness was estimated using the decision tree-Markov model, assuming a time period of 12 consecutive months.
Results. Number of ECMO practice increased by 109.2% in this region, particularly in designated hospitals and tertiary hospitals. Unfortunately, 36.0% of the COVID-19 patients died within the 30 days following the ECMO practice, regardless of on-ECMO / off-ECMO status, and 11.4% died in the following 2–8 months. In contrast, 52.5% remained alive. We further reviewed these patients' medical conditions at the point of ECMO. Subsequently, 17.7% of those dead and 25.5% of those alive might not be applicable to the ECMO indications. Moreover, we performed the economic evaluation. Compared with no ECMO practice, incremental QALY was estimated to be 0.6 quality-adjusted life years (QALY) in the following 12 months and increased to 1.65 QALY when those patients were redefined according to the ECMO indications. In addition, incremental cost-effectiveness ratio (ICER) was estimated to be USD 24200 per QALY that was approximately two times of local per capita GDP.
Conclusions. Extensive ECMO utilization might be cost-effective in the COVID-19 treatment; however, it primarily depends on the patients' medical conditions. ECMO indications should be further clarified to ensure the appropriate utilization and avoid potential abuse in future practice.

Advanced hemodynamic monitoring in patients with extracorporeal membrane oxygenation: femoral vs. jugular indicator injection for transpulmonary thermodilution with PiCCO®-device

S. Kopp[1], J. Windschmitt[1], T. Münzel[1], L. Hobohm[1], I. Sagoschen[1], J. Wild[1]
[1]Department of Cardiology, University Medical Center Mainz, Mainz, Germany
Correspondence: S. Kopp
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000286

Introduction. The use of venovenous extracorporeal membrane oxygenation (vv-ECMO) in acute lung failure increased in Germany from 2007 to 2018 by 236 percent (825 to 2,768 cases per year) [1]. An optimized advanced hemodynamic monitoring is crucial to guide treatment. The PiCCO® system, based on transpulmonary thermodilution (TPTD), is a frequently applied method in critical care and often used for this purpose.
Objectives. Our study aimed to investigate whether the site of injection-emoral vs. jugular-influences the comparability and validity of TPTD-derived measurements with the PiCCO®-device. Although several studies on managing advanced hemodynamic monitoring in patients with extracorporeal support systems were published [2–4], this topic has not been aimed yet. Therefore, we examined the site of indicator injection in the same patient with ongoing vv-ECMO therapy.
Methods. In a retrospective analysis of patients treated with vv-ECMO**,** we correlated extracorporeal blood flow (ECBF) with TPTD-derived measurements from jugular or femoral injections (n = 28). We analyzed the deviation of the measurements for extravascular lung water index (EVLWI), global end-diastolic volume index (GEDVI), intrathoracic blood volume (ITBVI) cardiac function index (CFI) as well as underlying mean transit time (MTt) and downslope time (DSt) depending on the current ECBF.
Results. Measurements from femoral indicator injection yielded significantly higher indexes for EVLWI (factor of 1.6, p = 0.0003), ITBVI (factor of 2.7, p < 0.0001), and GEDVI (factor of 2.5, p < 0.0001), than from jugular injection. The measurements with the femoral indicator injection revealed longer calculated times for MTt and DSt. The MTt was 1.5 times (p < 0.0001) and the DSt 1.3 times (p = 0.0031) as long as in the corresponding measurements with jugular injection (Fig. 1). A linear correlation was found between the ECBF level and the femoro-jugular deviation (Fig. 2). The correlation between the TPTD measurements of the jugular and femoral indicator injections with the underlying ECBF of the respective measurements was investigated. For this purpose, the correlation between the cardiac index (CI) measured with the femoral indicator injection and the sum of the CI of the jugular indicator injection and the ECBF indexed to the body surface area was demonstrated (p = 0.0035 and R2 = 0.3397, Fig. 3).
Conclusions. Femoral indicator injection leads to overestimating the parameters compared to jugular injection due to longer MTt and DSt. A linear correlation can be shown between the CI of the different injection sites, considering the ECBF indexed to the BSA. We can therefore postulate that the level of the ECBF also contributes the overestimation of the femoral parameters. Further studies are needed to investigate the interaction of ECBF, patient's cardiac output determined by other diagnostic methods, and the temperature change due to the device itself on the results of TPTD as well as the influence of the injection site.

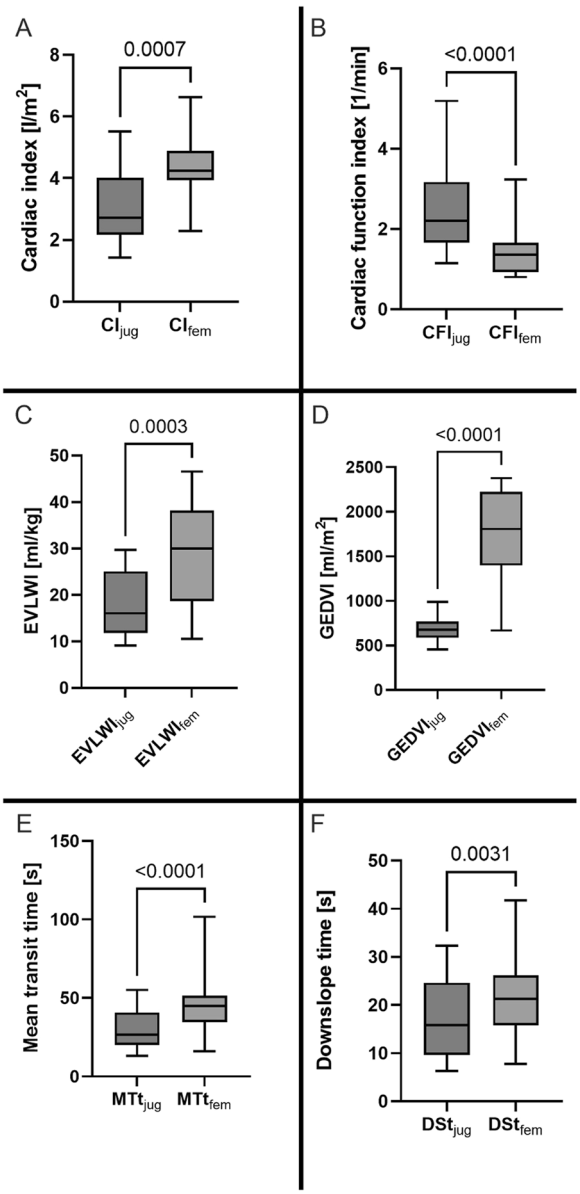

Figure 1 (abstract 000286) Comparison of TPTD-derived parameters from jugular vs. femoral indicator injection
A Cardiac index (CI, n = 23), **B** Cardiac function index (CFI, n = 21), **C** Extravascular lung water index (EVLWI, n = 21), **D** Global end-diastolic volume index (GEDVI, n = 21), **E** Mean transit time (MTt, n = 20), **F** Downslope time (DSt, n = 20); Paired t-tests, data are reported as mean, whiskers encompass the 95% confidence interval, p-values are shown above the brackets.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000287

Introduction. The introduction of artificial intelligence (AI) applications in the intensive care unit (ICU) has been scarce [1]. The vast majority of the developed AI models remain in the validation phase due to a lack of bedside testing and a lack of involvement of intensivists [1, 2]. Meanwhile, the potential impact of the use of these AI systems at the bedside remains unclear.
Objectives. The aim of this study is to gain insights into the potential clinical impact of an AI-driven decision support tool for the prediction of elevated intracranial hypertension in patients with severe traumatic brain injury (TBI). The model predicts extremely elevated intracranial pressure (ICP), defined as ICP above 30 mmHg for more than 10 min, with a forewarning of 30 min [3, 4]. Clinicians' reactions to this AI-driven tool were evaluated through a survey.
Methods. Our survey was distributed between January and March 2023 amongst the members of several international intensive care medicine societies. The target group was clinicians who regularly manage TBI patients. The survey was developed based on a literature review and in collaboration with clinical experts. The clinical response to a hypothetical AI-driven alert with an 80% probability of an event of extremely elevated ICP and a 30-min forewarning was assessed. Clinicians were asked to indicate which diagnostic or therapeutic intervention they would plan. Interventions were then grouped into Tiers according to the SIBICC guidelines [5].
Results. A total of 167 clinicians completed the survey. Most respondents were from Europe (73%), were intensivists in an ICU (89%), worked in a hospital with a specialised neuro ICU (54%) and had a protocol in place for the treatment of elevated ICP in TBI patients (60%). When presented with the hypothetical alert, 84% of respondents would plan additional diagnostic (12%) or therapeutic interventions (Tier 1 (23%), Tier 2 (35%), and Tier 3 (9%)) see Fig. 1. As shown in Fig. 2, most respondents agreed that an AI-driven decision support tool for ICP prediction in patients with TBI would help clinical staff in the treatment of TBI (83% agree, 12% neither agree nor disagree, and 5% disagree). Contrasting opinions were recorded on whether it will improve patient outcomes (51% agree, 45% neither agree nor disagree, and 4% disagree). Lastly, respondents were unsure whether there is currently enough evidence to implement such AI-driven tools in their clinical practice (19% agree, 43% neither agree nor disagree, and 38% disagree).
Conclusions. In conclusion, our survey results show that the majority of respondents would react to an AI-driven alert of intracranial hypertension in a hypothetical TBI case. Although this is a hypothetical clinical scenario that may not reflect future use at the bedside, these results show a generally open attitude from ICU clinicians toward the implementation of such an AI-driven tool in TBI patients with ICP monitoring.

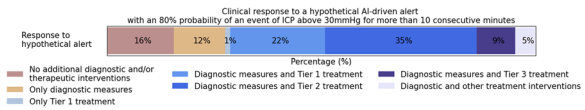

Figure 1 (abstract 000287) Clinical response of clinicians (Nresponses = 167) to a hypothetical traumatic brain injury (TBI) case. The scenario depicts a patient with isolated severe TBI with a stable intracranial pressure (ICP) (between 18–20 mmHg) and cerebral perfusion pressure (between 60–70 mmHg) for the past 24 h. The clinician is provided with a hypothetical artificial intelligence (AI) driven alert that, with an 80% probability, an event of intracranial hypertension (ICP > 30 mmHg for longer than ten consecutive minutes) will occur within 30 min. The percentage of respondents that would not act to the alert or would plan diagnostic and/or therapeutic interventions are reported in the horizontally stacked bar plot in a colour-coded way. The percentage of respondents that would take therapeutic actions were grouped in Tiers according to the SIBICC guidelines [5], also reported in colour-coded shades of blue

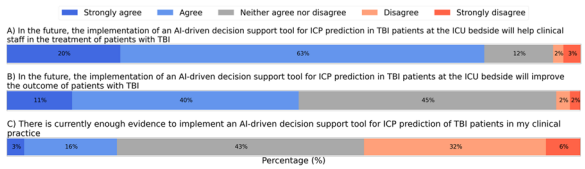

Figure 2 (abstract 000287) Clinicians' opinion on the implementation of an artificial intelligence (AI) driven decision support tool for intracranial pressure (ICP) prediction in patients with traumatic brain injury (TBI) in the intensive care unit (ICU) (Nresponses = 167). Panel A) shows the clinicians' opinion on the added benefit of AI-driven ICP predictions on the treatment of patients with TBI. Panel B) shows the clinicians' opinion on the impact of AI-driven ICP predictions on patients' outcomes. Panel C) shows the clinicians' opinion on the available evidence for the implementation of AI-driven ICP predictions in the ICU

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000288

Introduction. The capillary refill time (CRT) is used for clinical monitoring during septic shock. However, whether CRT is influenced by macrohaemodynamic variables, such as cardiac output and vasomotor tone, is unclear, and the effects on CRT of volume expansion and norepinephrine remain uncertain.
Objectives. In septic shock patients, we investigated the determinants of the CRT and its changes during volume expansion or modification of norepinephrine infusion rate.
Methods. In patients with septic shock, cardiac index (CI, transpulmonary thermodilution), arterial pressure and five CRT measurements were recorded before and after volume expansion (500 mL saline) and before and after modification of norepinephrine infusion rate. CRT was measured in a standardised way (standardised pressure applied on the fingertip under standardized light, computer-assisted measurement of skin colour changes). Determinants of the initial value and changes of CRT (in percent change from baseline) were explored.
Results. We enrolled 69 patients with septic shock (lactate 2.7 [2.0–4.5] mmol/L, norepinephrine dose 0.43 [0.14–0.75] µg/kg/min), 33 receiving volume expansion and 36 in whom the norepinephrine dose was changed. The least significant change of CRT was 23%. In the 17 patients (51%) with fluid responsiveness (increase in CI ≥ 15% with volume expansion), CI increased from 2.34 [1.69–3.06] to 3.17 [2.28–4.03] L/min/m^2 ($p < 0.001$). Among them, CRT decreased ≥ 23% in 9 (53%) patients and changed by less than 23% in the other ones (Fig. 1A). In the 16 patients (49%) in whom CI changed < 15% with volume expansion, CRT decreased ≥ 23% in two (13%) patients and remained unchanged in the other ones (Fig. 1B). In the 28 (78%) patients in whom mean arterial pressure (MAP) increased ≥ 15% during norepinephrine changes, MAP increased from 64 (60–70) to 86 (80–103) mmHg and CRT decreased > 23% in 11 patients (Fig. 2A) and remained unchanged in the other ones (Fig. 2B).
At multivariate analysis, the absolute value of CRT at baseline was associated only with arterial lactate at baseline. Still at multivariate analysis, the fluid- and norepinephrine-induced changes in CRT were associated only with the initial value of CRT, but not with the change of the investigated macrohemodynamic variables (CI, MAP, diastolic arterial pressure, heart rate, central venous pressure).
Conclusions. In patients with septic shock, the absolute value of CRT is related to arterial lactate but not to macrohaemodynamic variables. Fluid- and norepinephrine-induced changes of CRT are not straightforwardly associated with changes of macrohaemodynamic variables. The precision of CRT measured in a standardized way is poor.

Introduction. Acute respiratory distress syndrome (ARDS) is a heterogeneous condition developed in patients with an acute critically-ill disease. Subphenotypes of ARDS related to baseline inflammatory status, lung morphology, and respiratory physiology have been shown to provide prognostic and predictive information (1,2). Most analyses lacked the integration of dynamic changes over time. We, therefore, aimed to identify ARDS subphenotypes using data of the first 72hs, building the longitudinal trajectories for SOFA and compliance of the respiratory system (Crs), and assessing the association with 90-day mortality.
Methods. Multicenter, observational, and prospective/retrospective study of patients admitted to 60 Spanish ICUs due to COVID-19 infection (3). We analyzed data of patients with complete clinical, physiological, and biological data on days 1 and 3. Associations between subphenotypes of early, dynamic changes in SOFA and Crs and 90-day mortality were evaluated using a multivariate joint latent class model for longitudinal and time-to-event data.
Results. Using data from 816 patients, four classes provided the best fit (Fig. 1–2). Twenty-eight percent of patients were grouped in class 1 (n = 232), 5% in class 2 (n = 37), 6% in class 3 (n = 47), and 61% in class 4 (n = 500). The highest mortality risk was observed in patients with persistent higher SOFA scores and persistently low Crs (class 1). The lowest mortality risk was observed in those patients improving SOFA scores regardless of Crs (class 4). Patients in class 4 were younger, and have fewer comorbidities. Patients in classes 2 and 3 had similar SOFA trajectories but different Crs compliance trajectories and had an intermediate risk for death. No differences in the acute phase reactants on day 1, such as CRP or ferritin, were found between classes.
Conclusions. Persistently high SOFA scores, indicative of persistent multi-organ failure drive the risk for mortality in patients with COVID-19-related ARDS. Irrespective of baseline SOFA, trajectories of resolving organ failure, with decreasing SOFA scores, are associated with the lowest mortality risk.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000290

Introduction. Fluid balance can be crucial in the management of the critically ill patient, and is achieved by subtracting the recorded fluid output from input or by measuring changes in body weight. The latter can be difficult on a critically ill patient, as the input can be well known, the output, though, can be challenging to calculate, as it's affected by factors such as severity of illness, possible organ failure, etc. As hospital beds offer the ability to weigh patients in the ICU, what seems to remain unanswered is whether weight measurement is the most accurate way to monitor changes.
Objectives. The objective of this study was to investigate body weight measurements' accuracy in adult critically unwell patients who were also tested positive to COVID-19 and to assess the accuracy of conventionally recorded fluid balance charting methods to reflect any changes monitored in body weight.
Methods. This observational study was conducted at the 3rd ICU of G. Papanikolaou Hospital (Greece). During a 6 month period, (December 2022 to February 2023), 50 patients who were admitted at the unit were randomly selected to participate in the study. All participants were bed-weighed at 6 am for 2 consecutive days, in order to acquire at least 3 consecutive weight measurements. Fluid balance charts were reviewed for any calculation discrepancies. Data collected was analyzed with the use of IBM Statistics SPSS.
Results. Median value of patient age was 74 (IQR = 11) and 32 of them were male(64%). Median Apache Score was 23 (IQR = 15) and mean temperature was 36.4 oC (SD = 0.54). Documentation and calculation errors were noted and corrected at a percentage of 40%, equal to 20 out of 50 cases, ranging from − 1150 ml to + 3350 ml. Distribution of the adjusted fluid balance differences and body weight differences is presented in Figs. 1 and 2. We compared mean values of fluid balance and weight differences using Wilcoxon rank-sum test as we dealt with non-parametrically paired data. Fluid Balance was found to be higher when manually recorded at a mean difference of 877ml (conf. interval: 764 ml, 956 ml) with a statistical significance at $p < 0.005$. Spearman's rank correlation coefficients has also showed that an increase in Apache score may be related to higher differences between the calculated fluid balance and scale weight ($r = 0.73$). Similar positive results were noted with temperature and the needs in vasopressors and weight differences (positive correlation).
Conclusions. Fluid Balance monitoring can be time consuming and susceptible to calculating errors. Variations were observed between the calculated fluid balance by the nursing staff and the adjusted fluid balance, and also with the weight measurements on the bed scales. Assuming that body weight measurements offer a better representation of the body's fluid status, further investigation is required to establish its accuracy.

Introduction. The COVID-19 infection is still recognized as a serious threat to public health and healthcare systems. Numerous predictive models have been investigated in this context to support clinical decision-making, forecast admission to the Intensive Care Unit (ICU) and final outcome.
Objectives. In this study, we evaluated an automated machine learning (ML) platform, in forecasting the mortality of critically ill COVID-19 patients in the ICU, and compared it with a binary logistic regression (LR) analysis.
Methods. We retrospectively analyzed demographics, and routine blood biomarkers from consecutive Covid-19 patients admitted to the intensive care unit (ICU) of a public tertiary hospital, during a 17-month period, in order to build a prognostic model relative to the outcome. We used the the Google Vertex AI auto ML package and compared its performance in forecasting ICU mortality, with a traditional binary LR model.
Data preprocessing
We only use the first seven measurements after admission for each monitored biomarker. In case of missing values in any of the attributes taken into consideration in this study, we replace them by calculating the average of the existing measurements that correspond to this attribute in the dataset.
Model Building
There were two classes of patients in the classification problem we had to solve: patients who were discharged alive from the ICU and patients who died. The Google Vertex AI platform was utilized for our experiments. By using AutoML, researchers can develop comprehensive and precise predictive models. Traditional ML model development is time- and resource-intensive because it takes a long time to construct and compare the performance of many models. In AutoML experiments, scaling and normalization techniques are automatically applied to all data by default. Our research paper's objective is to present a straightforward procedure that can be explained to and even used by non-technical experts, so we kept all the default parameters and avoided applying custom settings at any point. For the logistic regression analysis, we used the generalized linear model in R programming language. We trained both models using a tenfold cross-validation (CV) procedure to avoid overfitting in our analysis.
Model Evaluation
The performance metrics used to evaluate the autoML model are the Precision-Recall Area under Curve (PR AUC), the Receiver Operating Characteristic Area Under Curve (ROC AUC), the F1 score, the Log loss, the Precision, and the Recall. For the logistic regression model ROC, sensitivity and specificity, were assessed.
Results. Totally, 373 patients (140 female, 233 male) with COVID-19 pneumonia were included in the study. Among them, 102 (27.34%) died in the ICU. Non-survivors were older (mean [SD] age 70 yr [11.6 yr] vs 64.4 yr [13.5 yr]) and slightly more likely to be female (28.6% vs 26.6%). A summary of two performance metrics (ROC AUC, Sensitivity) of the AutoML and LR modells is shown in Table 1, and PR curve graph in Fig. 1

Table 1 (abstract 000291) Comparison of performance metrics

	ROC AUC	SENSITIVITY
AutoML	0.955	0.906
LR	0.695	0.156

Conclusions. A growing number of disciplines now rely on ML, which has recently seen significant success. As the complexity of these tasks is frequently beyond the capabilities of non-ML experts, the demand for ready-to-use automated techniques has increased. The performance of an automated model built by Google Cloud Vertex AI package, in forecasting Covid-19 ICU mortality, surpasses the performance of a manually constructed LR statistical model. Our study highlights the empowerment given by the new techniques for fast, contextualized, feedback but also for the need for medical professionals and healthcare systems to invest in the integration of such tools.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000293

Introduction. High flow nasal oxygen (HFNO) can be an effective treatment to prevent endotracheal intubation for SARS-CoV-2 positive patients suffering from hypoxemic respiratory failure (1). Timely escalation of therapy is essential, as both delayed or too early intubation

are potentially harmful (2). A model that can predict HFNO failure at HFNO initiation may thus be helpful to guide clinical decision making.
Objectives. To develop and internal validate a prediction model for HFNO failure in hospitalized hypoxemic patients with COVID-19.
Methods. Data originating from a prospective observational multicenter cohort study (NL-9067), performed from December 2020 until July 2021, was used for the development of this prediction model. Patient inclusion criteria were ≥ 18 years, with a positive SARS-CoV-2 PCR, hospitalized and who started HFNO because of hypoxemia (O2 saturation < 92% and/or breathing frequency > 30 x/min) despite oxygen therapy of at least 6 L O2 per minute. Patients were excluded if there were reasons for direct intubation, intolerance for HFNO, contraindications for HFNO and/or intubation-restrictions. The primary outcome was HFNO failure, defined as endotracheal intubation. Missing data were imputed 50 times using multiple imputation and model results were pooled after estimation. For the model estimation, a logistic regression on pre-selected variables was used, where selection was based on input from clinical experts and literature. Apparent discrimination and calibration were assessed. Internal validation to evaluate stability of the model and correct for optimism was performed using bootstrapping. A p-value of < 0.05 was considered significant.
Results. A total of 608 patients (331 not-intubated, 277 intubated) were included for this analysis. Table 1 presents variables that were statistically significant predictors of HFNO failure, as well as other used non-significant variables based on literature and clinical rationale. As preliminary performance results, the apparent model discrimination C-statistic was 0.78 [95% Confidence Interval 0.74–0.81]. The apparent calibration plot had an intercept of 0.024 and a slope of 1.028 (Fig. 1). For internal validation, bootstrapping of the dataset was performed 100 times. The optimism-corrected C-statistic was 0.761 and the calibration intercept was -0.007 with a slope of 0.906.

Table 1 (abstract 000293) Multivariable logistic regression. *denotes the variables that were statistically significant predictors for HFNO failure. FiO2 (estimated fraction of inspired oxygen) was divided into three categories (1: > 0.21–0.40, 2: > 0.50–0.60, 3: ≥ 0.66

Variable	Odds Ratio (95% Confidence Interval)	P-value
* Age	1.021 (1.002–1.040)	0.033
Body Mass Index: Spline 1 & 2	1.086 (0.990–1.192) & 0.923 (0.817–1.043)	0.080 & 0.197
Charlson Comorbidity Index: 1 vs. 0 & 2 vs. 0	0.918 (0.590–1.428) & 0.889 (0.519–1.523)	0.704 & 0.667
* Days ill since symptom onset until HFNO initiation	0.931 (0.885–0.979)	0.005
C-reactive protein	1.000 (0.997–1.002)	0.891
Lymphocyte count	0.968 (0.869–1.079)	0.559
* Thrombocyte count	0.995 (0.993–0.997)	< 0.001
* Urea	1.053 (1.011–1.097)	0.013
* Respiratory rate before start HFNO	1.052 (1.023–1.082)	< 0.001
* O2 saturation before start HFNO	0.887 (0.841–0.936)	< 0.001
* FiO2 before start HFNO: Category 2 vs. 1 & 3 vs. 1	3.088 (1.734–5.501) & 5.362 (3.414–8.420)	< 0.001 & < 0.001

Conclusions. This novel preliminary developed model to predict HFNO failure for hospitalized hypoxemic patients with COVID-19 performed well, showing good apparent discrimination and excellent calibration. Model performance remained comparable after internal validation. Translation into clinical practice will require additional testing, such as external validation, decision curve analysis and comparison to other known prediction models.

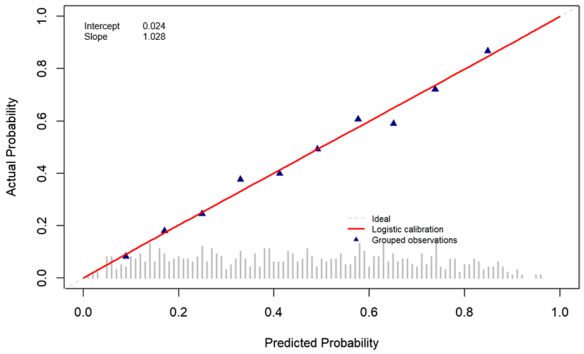

Figure 1 (abstract 000293) Apparent calibration plot

Responding to patient voice: implementing a recovery clinical nurse specialist role

Z. van Willigen[1]
[1]Therapy Services, University Hospital Southampton, Southampton, United Kingdom
Correspondence: Z. van Willigen
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000294

Introduction. Post Intensive Care Syndrome (PICS) encompasses the complex range of impairments (physical, cognitive and psychosocial) that can affect the recovery of survivors of intensive care (ICU) for months or even years after hospital discharge (1).
Funding for intensive care recovery services are widely reported as inadequate (2). In 2021 we won a Q community award and initially used part of this funding to deliver rehabilitation classes (EMPOWER) for survivors of critical illness in our own trust.
While we saw positive outcomes for patients who attended the classes (results published elsewhere), there was a climate of opinion from participants that much of the education and expectations around recovery after critical illness could have been addressed much earlier, while the patients were still in hospital (Fig. 1).
Objectives. So, in direct response our patients' voice, we decided to use the remaining fund to pilot an ICU Recovery Clinical Nurse Specialist (CNS) role for 6 months. The main objectives of this role were:
1. Collect length of stay data to evaluate if role could reduce bed days.
2. Assess and map the needs of our patients after ICU admission
3. Provide step-down ward multi-disciplinary team (MDT) education

Methods. Development of Recovery CNS Role
15 h a week were funded for an experienced ICU nurse to be seconded into the CNS role. The CNS integrated with ward MDTs and supported them to care for patients with a range of PICS symptoms. Patients were enabled to better engage with therapy teams. An information pack was created and given to patients. Basic psychological grounding-techniques were used along with reassurance and explanations about their ICU admission. By exploring predicted recovery trajectories, patients and families a realistic measure of what to expect and prepare for post-discharge.
Data collection. Patients ventilated for > 48h on ICU were visited on the ward by the CNS after ICU discharge. Mean and median length of stay (LOS), PICUPS (Post Intensive Care Unit Presentation Screen) and IPAT (Intensive Care Psychological Assessment Tool) data were collected.
Results. 46 patients were visited by the recovery CNS at least once. Of the 46, 21 were surgical patients and these were chosen for comparison due to the availability of baseline data. The results are presented in Table 1.
40 patients completed an IPAT score. Our data demonstrates that there is no correlation between number of days on ICU and psychological risk in our patient group: 65% were screened as being 'at risk' (Fig. 2).
The PICUPS (0 = greatest dependency and 5 = least dependency) was completed for 45 of the patients visited. The scores are also shown in Fig. 2 and show that for our group the highest dependency was for medical stability and nutritional needs.
Figure 3 describes a scenario where ward staff were not adequately trained in caring for a patient after an ICU admission. The visit by the CNS addressed these training needs.

Table 1 (abstract 000294) .

	No of Patients	Mean LOS	Median LOS
Baseline Nov 21—April 22	39	24	13
CNS Visits Nov 22—April 23	21	10.2	7

Conclusions. A recovery CNS role can reduce ward length of stay after an ICU admission. Additionally, it meets national recommendations, provides valuable education to ward teams and improves patient and family experience following critical illness. The role of the CNS in collecting data to map the needs of our patients provides vital information to prioritise limited resources to those most at risk of PICS.

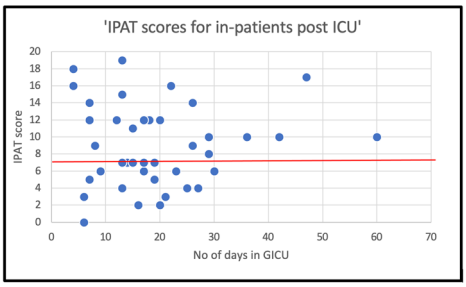
"...it is not as simple as admitting to ICU, treating, saving, reacting to the immediate threat to life. By doing so you give yourselves a responsibility for what comes next...

...I went to sleep, and woke up a long time later with a different body, with different needs and abilities...

...There is a requirement for specialist care, for a joined up and holistic treatment programme, for ongoing access to services to support physical and mental recovery. This should be an integral part of Intensive Care Treatment, it should not be an add-on...

...This care and treatment plan should be in place during step down in hospital and long after discharge home and it should be overseen and facilitated by an experienced practitioner who has a thorough understanding of all the complicated facets of ICU recovery."

Figure 1 (abstract 000294) .



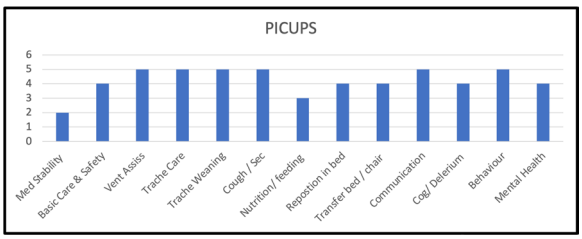


Figure 2 (abstract 000294) .

Tracheostomy-site dressing left unassessed

On visiting a long-term ICU patient on a ward, the CNS found him close to discharge but with a trache-site dressing on that had not been changed or reviewed for days. Many of the ward nurses had never cared for tracheostomy wounds. The CNS was able to support the ward staff to re-dress it and reassured the patient that all looked good. The sutures were due for removal the following day but this information was lost within ICU notes and not communicated. Informed staff and avoided the patient going home with them still in-situ.

2 weeks later at home, the patient had concerns about the wound. The wife was able to contact the CNS and send images which were identified as over-granulation. The patient was referred to the tracheostomy practitioners who cauterised with silver nitrate. This avoided GP / practice nurse visits, allowed timely treatment of the over-granulation, and provided instant reassurance to patient and his wife.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000295

Introduction. Studies have associated mechanical ventilation (MV) and acute respiratory distress syndrome (ARDS) with neuroinflammation.1–3 Neuroinflammation might be triggered by inflammatory proteins crossing over the blood–brain barrier (BBB), or by inflammatory proteins released by microglia cells 3,4. Hippocampal neuronal overactivation has been linked to an increased release of inflammatory proteins during MV.5,6 Granulocyte-monocyte colony-stimulating factor (GM-CSF) is a protein that regulates and controls inflammation.7 Also, GM-CSF can freely cross over the BBB.7 S100bis often used as a surrogate marker for BBB leakage or dysfunction 8,9. Diaphragm neurostimulation has been shown to mitigate neuroinflammation in preclinical models 2,3.
Objectives. This study focused on investigating whether diaphragm neurostimulation in association with MV would result in different tissue and serum concentrations of GM-CSF compared to the MV alone.
Methods. Juvenile pigs (4–5 months, 50–87 kg) underwent protective MV (volume control, PEEP 5 cmH2O, tidal volume 8 ml/kg) for 12 h, with moderate ARDS (PaO2/FiO2 between 100 and 200). ARDS was induced by injecting oleic acid into the pulmonary artery. Subjects were assigned to three groups (n = 6 per group): lung injury with MV only (MV), lung injury with MV and with TTDN every other breath (MV + TTDN50%), and lung injury with MV and with TTDN every breath (MV + TTDN100%). Diaphragm neurostimulation was delivered according to methods published previously. After the study, the hippocampus was harvested, homogenized and marked with an enzyme-linked immunoassay (ELISA) to measure the GM-CSF tissue concentration. Blood samples were also collected to measure the serum concentration of GM-CSF and S100b at the study end. The Kruskal–Wallis test was used for statistical analyses. Data expressed as the median interquartile range in pg/ml. P-values < 0.05 are considered statistically significant.
Results. GM-CSF concentrations in the hippocampus and in the serum were respectively 15 (9–28) and 0 (0–7), and for the MV group, 16 (10–20) and 0 (0–86) for the MV + 50%TTDN group, and 2 (0–8) and 12 (5–23) and for the MV + TTDN100% group, with $p < 0.0001$ and $p = 0.0475$ (see Table). S100b serum concentrations were respectively, 256 (158–430) for the MV group, 160 (155–342) for the MV + TTDN50% group, and 215 (210–398) for the MV + TTDN100% group, $p = 0.4512$.
Conclusions. In a preclinical model, 12 h of moderate ARDS leads to greater hippocampal concentration of GM-CSF and lower serum concentration of GM-CSF compared to the MV + TTDN100% group. The difference between hippocampal and serum concentrations of GM-CSF might provide a clue about the neuroprotective effect of diaphragm neurostimulation, and about how neuroinflammation is triggered in this preclinical moderate ARDS model. S100b serum concentrations are not significantly different between the groups indicating that all groups had similar BBB functions at study end.

Markers (end of study)	Concentration (pg/ml) Median (IQR)			p-value (Kruskal-Wallis test)	p-value (Dunn's multiple comparison test)	
	MV (n=6)	MV+TTDN50% (n=6)	MV+TTDN100% (n=6)			
GM-CSF Hippocampus	15 (9-28)	16 (10-20)	2 (0-8)	<0.0001	MV vs. MV+TTDN50%	ns
					MV vs. MV+TTDN100%	0.0199
					MV+TTDN50% vs. MV+TTDN100%	0.0375
GM-CSF Serum	0.0 (0-7)	0 (0-86)	12 (5-23)	0.0475	MV vs. MV+TTDN50%	ns
					MV vs. MV+TTDN100%	0.0479
					MV+TTDN50% vs. MV+TTDN100%	ns
S100β Serum	256 (158-431)	160 (155-342)	215 (210-398)	0.4512	n/a

Greater serum concentration of S100β at hospital admission is associated with increased risk of developing delirium during hospitalization

T. Bassi[1], E. Rohrs[2], M. Nicholas[3], S. Reynolds[2]

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000296

Introduction. Hospitalized patients often develop delirium during hospitalization 1,2. Blood–brain barrier (BBB) dysfunction has been associated with an increased risk of developing delirium during hospitalization 3,4. S100b is a biomarker that has been associated with BBB leakage and dysfunction. The focus of our study was to investigate existing literature to determine whether, at hospital admission, serum concentration of a biomarker for BBB dysfunction, S100b, was associated with the likelihood of developing delirium during hospitalization.
Objectives. We conducted a systematic review and meta-analysis to investigate whether, at hospital admission, serum concentration of a biomarker for BBB dysfunction, S100b, was associated with the likelihood of developing delirium during hospitalization.
Methods. Our meta-analysis followed the Preferred Reporting Items for Systematic Review and Meta-Analysis (PRISMA) protocol. Independent extraction with multiple reviewers' consensus was used to determine the studies included. The weight and heterogeneity of the manuscripts were calculated using inverse covariance with a random-effects model. The inclusion criteria were articles in English that investigated links between serum concentration of S100b at hospital admission and delirium during hospitalization. Exclusion criteria were single case reports, case series, comments, editorials, letters to the editor, articles that were clearly not relevant to the review objective, and articles concerning pediatrics.
Results. After excluding duplicates, twelve studies that investigated the role of S100b serum concentration at hospital admission were

included. Our search found evidence that patients who developed delirium during hospitalization had, at hospital admission, a mean serum concentration of S100b significantly greater than patients who did not develop delirium during hospitalization. The mean difference in S100b serum concentration was independent of other confounding variables such as the patient's severity of illness. The mean difference in serum concentration of S100b at hospital admission between patients who developed delirium and those who did not was 0.07 ng/ml, $p < 0.00001$ for Chi-square, I2 of 96%, and $p < 0.00001$ for the total overall effect (Figure A). A subgroup analysis that included exclusively post-orthopedic surgical patients showed no heterogeneity between the papers and a mean difference in serum concentration of S100b at hospital admission between patients who developed delirium and those who did not was 0.04 ng/ml, $p = 0.76$ for Chi-square, I2 of 0%, and $p < 0.00001$ for the total overall effect (Figure B).

Conclusions. Our findings indicate that a greater serum concentration of S100b at hospital admission is associated with an increased risk of developing delirium during hospitalization.

Family burden after critical illness: lets not forget the caregivers!

J. Tejero Aranguren[1], M. E. Poyatos Aguilera[2], M. T. Cruces Moreno[2], M. Colmenero Ruíz[2]
[1]Intensive Care Unit, Faculty of Medicine-University of Granada, Granada, Spain; [2]Intensive Care Unit, Hospital Universitario San Cecilio, Granada, Spain

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000297

Introduction. It is increasingly recognized that the consequences of critical illness also place considerable strain on the families of ICU survivors, who often bear the burden of high levels of informal care. The term Post-Critical Care Family Syndrome (PICS-F) is considered to be the family member's response to the stress caused by the ICU admission of a loved one. Between 1 in 4 and 1 in 2 patients who survive ICU admission will need family support for care.

Objectives. To identify patient and caregiver risk factors for caregiver burden in the setting of critical care.

Methods. Prospective observational cohort study, from 2019 to 2021.

Setting: ICU of a university hospital with 20 beds and an average of 1200 admissions per year.

Sample: Primary caregiver of patients with risk factors for development of PICS, i.e. admission > one week and also at least one of the following: 3 > days of mechanical ventilation, delirium or shock during admission. Follow-up protocol: Assessment 3 months after discharge from the ICU in consultation. The scales used in the patients were Barthel, SF-12, HADS, IES-6 and in the relatives Apgar and Zarit. The questionnaires were administered by two of the investigators, each of whom had demonstrated competence in the completion of the questionnaires after a mock interview with the principal investigator.

PICS-F was considered to be the presence of caregiver overload with a Zarit test score > 46.PICS definition: PICS was considered to be the appearance of alterations in any of the three spheres. Impairment in physical sphere was defined as deterioration in one category on the Barthel dependency scale with respect to admission to the ICU; impairment in cognitive sphere a score of more than 3 points on the Pteiffer test; and impairment in mental health sphere a score of more than 11 on the HADS test and/or 1.75 on the IES-6 score for post-traumatic stress.

Statistical analysis: As this was a descriptive study and with the aim of generating working hypotheses, the sample size is that of the number of patients included. Univariate analysis was performed using binary logistic regression and odds ratio (OR) estimation. Differences with a $p < 0.05$ were considered statistically significant. Data were anonymised for analysis. R software version 4.0.3 (R Foundation for Statistical Computing Platform, Vienna, Austria) r-commander 2.6–2 package was used. Ethical considerations: The project was approved by the centre's Research Ethics Committee and consent to participate was requested from patients and relatives.

Results. A total of 93 patients were included in the follow up. 15 relatives did not complete the follow-up questionnaires and have been excluded from the study. The incidence of SPCI-F defined by the presence of primary caregiver overload in our cohort of patients is 34.6% (n = 27), with a 95% CI of 25–45.7.

The incidence of PICS-F as defined by the presence of primary caregiver overload in our cohort of patients is 32.9%. Patient risk factors during ICU admission associated with the presence of PICS-F are days of mechanical ventilation (IC 1.01–1.06, $p < 0.008$), sedation (IC 0,99–1,10, $p < 0.06$), ICU admission (IC 1.01–1.05, $p < 0.01$) and hospital stay (IC 1.01–1.03, $p < 0.03$); in the follow-up consultation the risk factor is the presence of PICS-F in the patient in any of the 3 spheres. We did not identify in our sample family member risk factors for the development of PICS-F.

Conclusions. One in 3 family members of patients with risk factors for the development of PICS have caregiver overload at 3 months. The presence of physical deterioration, anxiety or post-traumatic stress in the patient is related to primary caregiver overload. The identification of patients with risk factors for the development of PICS during their stay in the ICU as well as the presence of PICS in the follow-up consultation should raise the alarm that the family member should also be assessed and provided with the corresponding therapeutic assistance.

Introduction. Critical care survivors experience multiple care transitions (1, 2). Internationally, there is limited specialised Intensive Care Unit (ICU) follow-up service data for these patients (3). Given the relative ubiquitous nature of primary care, general practitioners (GPs) are ideally positioned to provide support post-hospital, however are rarely included in post-ICU care research (3).
Objectives. To identify unmet care needs and solutions to improve the coordination and integration of care following an ICU admission—from the perspective of patients, their caregivers, intensivists, and GPs.
Methods. Qualitative study using the Framework Analysis Method, reported using the COREQ (4) checklist. Participants were ICU patients, their caregivers and intensivists, recruited from three academic hospitals; and GPs, recruited from a state-wide, academic-affiliated network. Purposive sampling was used to achieve socio-economic diversity (using the Australian Bureau of Statistics Index for Relative Socioeconomic Advantage and Disadvantage), and differing survivorship experiences. Individual semi-structured interviews were completed, and patient demographic information was collected from medical records. Qualitative data were audio-recorded, transcribed, and coded independently by two experienced researchers to synthesise and generate themes.
Results. Forty-six interviews (15 patients, 8 caregivers, 15 intensivists, and 8 GPs) were conducted between 6 and 12 months post ICU discharge. The majority of patients were originally admitted to ICU for cardiac or respiratory failure, or COVID-19 diagnoses, and received mechanical ventilation.
Within these feedback loops, eight major themes were identified and categorised. *Feedback loop 1:* Increased linkages and collaboration between ICU and GP, ICU and GP clinician education on screening for post ICU issues and the role of ICU respectively. *Feedback loop 2:* Improved survivorship focussed communication from ICU to GP utilising digital health, Role of allied health to support across the recovery care arc, Patient information portal; and *Feedback loop 3:* Comprehensive post-ICU care pathway model akin to existing cancer pathways, Improved awareness and accessibility to community support including virtual rehabilitation, and the Role of ICU follow-up for clinician morale and contribution to ICU care through awareness of critical care outcomes.
A conceptual model (Fig. 1) was identified as foci for research and service improvement initiatives: Feedback loop 1: Between GP and ICU; Feedback loop 2: ICU to GP; and Feedback loop 3: ICU follow-up programs back to the ICU.
Conclusions. Eight major themes to improve enhanced recovery support for critical care survivors within existing healthcare system structures by leveraging existing resources and expertise were identified. Our data highlights the importance of comprehensive communication, active relationships between primary and intensive care clinicians, and the value of allied health in managing this cohort. These themes are mapped to a novel conceptual model that includes key feedback loops for health system improvements and foci for future interventional trials to improve ICU survivorship outcomes.

Trends of neuro-intensive care unit admission in South Korea: a nationwide population-based cohort study

S. Kim[1], T. K. Oh[2], S. In-Ae[2], Y. T. Jeon[2]
[1]Critical Care Medicine, Seoul National University Bundang Hospital, Seongnam-si, Republic of Korea; [2]Department of Anesthesiology and Pain Medicine, Seoul National University Bundang Hospital, 성남시, Republic of Korea

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000299

Introduction. Clinical outcomes of critically ill neuroscience patients are better when treated in the neurointensive care unit (NCU). To plan how to allocate the limited resources and specialty-trained workforce of the NCU, it is important to explore the recent trends of NCU admissions and prioritize the patients in the most need.
Objectives. To study nationwide trends in NCU admissions and identify risk factors for in-hospital mortality in NCU patients.
Methods. This nationwide population-based retrospective cohort study enrolled adult patients admitted to the NCU from 2010 to 2019 extracted from The National Health Insurance Service. The primary outcome was the trends of NCU admissions, mean age, and the mean total medical expense per patient. Multivariable logistic regression models were used to identify risk factors related to in-hospital mortality among NCU patients.
Results. A total of 845,474 admissions of 679,376 patients were identified. During the 10-year period, the mean age and total cost of hospitalization per patient admitted to the NCU gradually increased. The most common diagnosis in the NCU was cerebrovascular disease (55.7%), followed by intracranial injury (16.5%), benign

neuroendocrine tumor (3.6%), and epilepsy or seizure (3.1%). Risk factors strongly associated with in-hospital mortality were the usage of mechanical ventilator (adjusted odds ratio [aOR]:19.83, 95% confidence interval [CI]: 19.42–20.26; $P < 0.001$), extracorporeal membrane oxygenation (aOR: 3.49, 95% CI: 2.42–5.02; $P < 0.001$), and continuous renal replacement therapy (aOR: 6.47, 95% CI: 6.02–6.96; $P < 0.001$).
Conclusions. Patients admitted to the ER, registered in the neurosurgery department, in need of aiding equipment, and diagnosed with malignancy are potential risk factors for in-hospital mortality. Patients with supporting equipment and cancer diagnosis require greater attention among NCU patients.

Topic: Neurointensive care.

Megadose intravenous sodium ascorbate has widespread benefit in experimental and human septic shock

C. N. May[1], R. Bellomo[2], F. Yanase[2], Y. Lankadeva[1]
[1]Preclinical Critical Care Unit, The Florey Institute of Neuroscience and Mental Health, Parkville, Australia; [2]Intensive Care, Austin Hospital, Heidelberg, Australia

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000302

Introduction. High doses of intravenous vitamin C (ascorbic acid) have mild variable effects in experimental and human sepsis. Megadoses of intravenous vitamin C (110 g+) have been given to cancer patients without side-effects but have not been used in critically ill patients. We have shown in an ovine model of septic shock, with a similar phenotype to human sepsis, that intravenous megadose sodium ascorbate (a pH balanced formulation of the sodium salt of vitamin C) reversed sepsis-induced vasoplegia, improved vital organ function and restored a normal clinical state (1).
Objectives. (1) To determine the effect of intravenous sodium ascorbate (3.75 g/kg) on brain tissue perfusion, oxygenation and temperature, and plasma levels of inflammatory biomarkers and ascorbate in ovine septic shock. (2) To assess the safety and physiological responses to intravenous sodium ascorbate (60 g/day) in patients with septic shock in a Phase 1a randomised controlled trial [ACTRN12620000651987p].
Methods. (1) Sepsis was induced in non-anesthetised adult Merino ewes (n = 8) by intravenous infusion of live *Escherichia coli* obtained from a septic patient. After 23-h, fluid resuscitation was started (30 mL/kg), followed by intravenous megadose sodium ascorbate (0.5 g/kg over 30-min + 0.5 g/kg/h for 6.5-h) or fluid-matched placebo (n = 6/group). Noradrenaline was titrated to restore mean arterial pressure to 70–80 mmHg. (2) Patients with septic shock were randomised to receive either intravenous sodium ascorbate (30 g over 1-h, n = 15) followed by 30 g over 5-h, or fluid-matched placebo (n = 15).
Results. (1) At 23-h of ovine septic shock, mean arterial pressure (MAP; 85 ± 2 to 64 ± 2 mmHg; mean ± SE), plasma ascorbate (27 ± 2 to 15 ± 1 µmol/L) and urine flow decreased (1.2 ± 0.4 to 0.3 ± 0.1 mL/kg/h) (all $P < 0.01$). Cerebral tissue ischemia (901 ± 58 to 396 ± 40 units), hypoxia (34 ± 1 to 19 ± 3 mmHg) and hyperthermia (39.5 ± 0.1 to 40.8 ± 0.1 ºC (all $P < 0.001$) developed, accompanied by malaise, lethargy, and somnolence. Sodium ascorbate rapidly restored MAP while noradrenaline was withdrawn, and urine flow increased (11.4 ± 2.6 mL/kg/h). Cerebral tissue perfusion (703 ± 121 units), and oxygenation (30 ± 2 mmHg) improved and temperature decreased (39.2 ± 0.1 °C) (all PTreatment < 0.05), which was associated with restoration to a normal healthy behavioural state. Sodium ascorbate reduced the sepsis-induced increase in plasma interleukin-6 (PGroupxTime = 0.003) and increased the plasma level of ascorbate (to 20,000 ± 300 µmol/L; PGroup < 0.001). (2) In patients with septic shock treated with sodium ascorbate, plasma ascorbate levels increased from 28.7 ± 2.6 to 5652 ± 450.9 µmol/L ($P < 0.0001$) and urine output, the primary outcome for the trial, increased to 2948 (2181–3715; Mean [95% CI]) mL compared with placebo at 2056 (1520–2593) mL, an 892 mL difference (95% CI: − 2.1 to 1785.2 mL, p = 0.051) (PGroup < 0.001), requirement for noradrenaline decreased (PGroup < 0.001) and the Sequential Organ Failure Assessment (SOFA) score improved (PGroup < 0.042). The arterial blood sodium level, however, was higher with sodium ascorbate therapy ($P < 0.001$). There was no statistical difference in alive and vasopressor free hours, alive and ICU-free days, and alive and ventilator-free days.
Conclusions. In experimental sepsis megadose intravenous sodium ascorbate was safe and had potent effects to reverse vasoplegia, increase urine flow, restore brain microcirculatory function and tissue oxygenation, and improve the clinical state. In septic patients a lower dose of sodium ascorbate had qualitatively similar but reduced effects with increases in urine flow, decreased vasopressor requirement and improved SOFA score.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000304

Introduction. Sepsis is a dysregulated immune response to infection that affects principally the lungs and causes, in many cases, an acute respiratory distress syndrome (ARDS) (1). ARDS is associated with a mortality rate of 40% (2) and its biological heterogeneity is one of the main reasons why there is still a lack of a definitive treatment (3). Our group has very recently demonstrated that intratracheal instillation of Mesenchymal Stem Cells (MSCs) diminishes inflammation andimproves lung damage in acute lung injury (ALI) model (4). Interestingly, there is evidence that MSCs' effect occur without significant cell engraftment to the tissuesuggesting that MSCs action is mainly due to a paracrine mechanism which is mediated, in part, by extracellular vesicles (EVs) (5). EVs bring along promises fortailoring sepsis treatment, since they possess several potential advantages that could adress the inherent risks associated with live-cell transplants (6).
Objectives. The main objective of this study is to determine the effect of the MSCs-derived EVs on immune response in an ALI pre-clinical model, and to study how priming MSCs with lipopolysaccharide (LPS) can affect their therapeutic potential.
Methods. The ALI model was induced in male rats by the intratracheal administration of HCl (0.1 M) and 2 h (h) later LPS (30 µg/g body weight). Nine h after the injury, animals were administered

with Control or LPS EVs, isolated from MSCs supernatant (normal and primed conditions). Animals were scarified after 72 h. Proinflammatory and chemoattractant mediators were evaluated in lung tissue and blonchoalveolar lavage's (BAL) macrophages at mRNA levels. Flow cytometry was used to perform differential and total cell count on BAL.
Results. Regarding the inflammation in lung tissue, we observed that both control and LPS EVs reduced the expression of inflammatory cytokines (IL-1β and IL-6) and chemoattractant mediators (CCL2 and CXCL-1) (Fig. 1 A and B), as well as, in the macrophages from BAL, which in addition, showed an increased expression of M2 phenotype markers, such as MR and Arg-1 compared to non-treated animals (Fig. 1 B). However, only rats that were treated with LPS EVs exhibited a significant reduction of the percentage of infiltrated neutrophils in the intraalveolar space (Fig. 1 C).
Conclusions. EVs secreted by MSCs reduce lung inflammation in a pre-clinical model of ALI.
- Priming MSCs with LPS enhances the immunomodulatory effect of their secreted EVs by decreasing intraalveolar neutrophil infiltration.

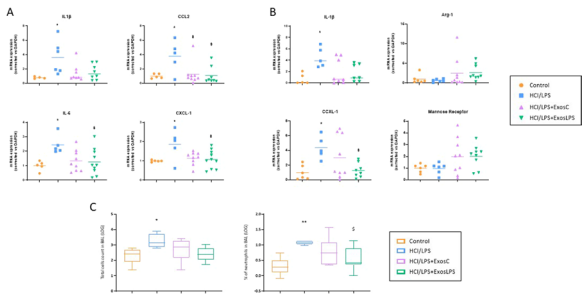

Figure 1 (abstract 000304) Results of administration of EVs from non-activated MSCs with LPS (control and LPS EVs). Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000305

Introduction. Diaphragm dysfunction frequently develops in ICU patients and is associated with difficult weaning and mortality (1–3). Using muscle biopsies, we recently reported that fibrosis in the diaphragm could be one of the pathophysiological pathways contributing to diaphragm dysfunction (4, 5). As biopsies are invasive and difficult to obtain, we aimed to quantify fibrosis with imaging, specifically using density and thickness measurements on CT. If CT could serve as surrogate measure for diaphragm fibrosis this would have great impact on future research and possibly treatment strategies.
Objectives. We hypothesized that diaphragm density on CT, potentially combined with diaphragm thickness, correlates with severity of fibrosis on histological analysis of diaphragm biopsies.
Methods. Fibrosis was quantified using biopsies from the left midcostal diaphragm in diseased ICU patients and non-ICU patients using a picrosirius red staining, as described in (4). We measured diaphragm density on unenhanced thorax CT or contrast enhanced thorax CT acquired during the arterial phase in a web based DICOM-viewer. Three regions of interest were manually drawn in the same axial slice and mean Hounsfield Unit (HU) and standard deviation (std) (see Fig. 1) were computed. The regions were selected within left and right posterior diaphragm crura and the left anterior part of the diaphragm. We additionally measured diaphragm thickness in the posterior crus at the anterior border of the vertebra. The slice was selected at T12 level based on presence of the aforementioned regions in the slice. Data was acquired in the axial slice because this provided good visibility of the diaphragm in all subjects.
Results. 11 COVID-19 ICU patients, 6 non-COVID-19 ICU patients and 3 non-ICU patients were included in this study (mean ± std age 64.5 ± 10.2 years, 5 women). There was no significant correlation between diaphragm density and fibrosis fraction (Fig. 2A), but mean diaphragm thickness showed a negative and weak correlation with fibrosis fraction (Fig. 2B, P = 0.005, adjusted R2 = 0.36). Mean ± std diaphragm density was 38.2 ± 13.6, 28.3 ± 9.4 and 26.1 ± 14.1 HU for right and left posterior crus and left anterior region respectively, with a significant difference between the right posterior crus and left anterior region (p = 0.011, post-hoc ANOVA analysis with Tukey correction). Mean ± std diaphragm thickness was 5.4 ± 1.2 and 4.4 ± 1.0 mm for left and right posterior crus respectively. Diaphragm density was comparable with results from previous work (6), but thickness was higher than previously reported (7).
Conclusions. Diaphragm density on CT cannot be used to estimate diaphragm fibrosis. Diaphragm thickness was weakly negatively correlated with diaphragm fibrosis, indicating that atrophy of the diaphragm might be accompanied with an increase of fibrosis. This finding supports the proposition that an increase in extracellular matrix contributes to development of diaphragm dysfunction. Lastly, diaphragm density was spatially different between anterior and posterior parts of the muscle.

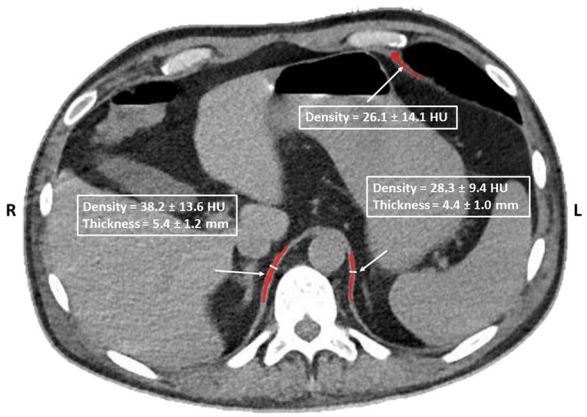

Figure 1 (abstract 000305) Example of CT slice with three regions of interest in red and two thickness measurements in the posterior part of the diaphragm. Values inside white boxes are mean values ± standard deviation for the complete population. HU = Hounsfield Unit, Std = Standard deviation

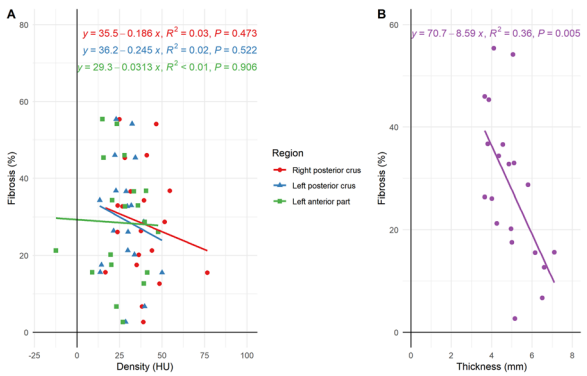

Figure 2 (abstract 000305) Association between fibrosis and diaphragm density (A) and thickness (B). Fibrosis is presented as a percentage of total field of view of the biopsy. Figure A is subdivided in the three regions that were selected. It can be appreciated that density does not significantly correlate with fibrosis, while mean thickness is negatively correlated with fibrosis

Rapamycin reduces hypothalamic damage in rats with Exertional heatstroke via the mTOR signaling pathway

Y. X. Zhang[1], L. Xuan[1]
[1]Critical Care Medicine, The Eighth Medical Center of Chinese PLA General Hospital, Beijing, China

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000306

Introduction. Heatstroke is a life-threatening illness typically associated with an uncontrolled rise in core body temperature above 40 °C and central nervous system (CNS) dysfunction, such as delirium, convulsions, or coma. The Paraventricular nucleus (PVN) is the important vulnerable part of the central nervous system. Small cell neurons in the PVN region are damaged after heat stress, resulting in decreased thermal tolerance and impaired thermoregulation function, which seriously affects the prognosis. Studies have shown that heat stress causes neuronal cell necrosis in the hypothalamus similar to hypoxic ischemic encephalopathy. Enhancement of autophagy can improve the survival rate of neurons in hypoxic ischemic areas. Rapamycin (Rapa) can reduce neuronal damage by regulating mTOR pathway and enhancing autophagy, which plays a role in hypoxic ischemic encephalopathy. However, its effect on hypothalamic neuron injury caused by EHS is relatively unexplored. Therefore, it is very important to study the role of Rapa in EHS and hypothalamic autophagy. This will contribute to a better understanding of the mechanism of EHS central nervous system injury and provide new ideas for the prevention and treatment of EHS.
Objectives. To investigate the protective mechanism of rapamycin on the hypothalamus of rats with exertional heat stroke by inhibiting the mammalian target of rapamycin (mTOR) signaling pathway.
Methods. Eighty male wistar rats were randomly divided into four groups: control group (CON group), control + rapamycin group (CON + Rapa group), exertional heat stroke group (EHS group) and exertional heat stroke + rapamycin group (EHS + Rapa group), with 20 rats in each group. The rats in the CON + Rapa and EHS + Rapa groups were intraperitoneally injected with Rapa (1 mg/kg, once daily for four consecutive days).before modeling, the rats in the CON and EHS groups were given the same dose of 0.9% normal saline. The general state, core temperature and the survival rate of the rats were observed. The levels of neuron-specific enolase (NSE), brain active peptide 100β protein (S100β), interleukin-6 (IL-6) and tumor necrosis factor-α (TNF-α) in arterial serum were detected by ELISA. The morphological changes of hypothalamus were observed by naked eye, HE and Nissl staining. Western blot was used to detect the expression of mammalian target of rapamycin (mTOR) and (pmTOR), autophagy effector protein (Beclin-1), ubiquitin-binding protein (p62) and autophagy marker microtubule-associated protein 1 light chain 3(LC3) in the hypothalamus of rats. The ratios of pmTOR/mTOR and LC3-II/LC3-I were calculated. Immunofluorescence was used to observe the apoptosis of hypothalamus.
Results. Compared with CON group, the core temperature of EHS group and EHS + Rapa group was significantly increased ($P < 0.05$). Compared with the EHS group, the 5-h survival rate of the EHS + Rapa group was increased ($P < 0.05$). HE and Nissl staining showed that the pathological damage of hypothalamic nerve cells in the EHS group was more serious, while in the EHS + Rapa group was significantly less than that in the EHS group ($P < 0.05$).Western blot results showed

that compared with the CON group, the ratio of pmTOR/mTOR, Beclin-1 expression, LC3-II/LC3-I ratio in the hypothalamus tissue of the EHS group were increased ($P<0.05$) and 62 expression was decreased ($P<0.05$); Compared with the EHS group, the ratio of pmTOR/mTOR and p62 expression in the hypothalamus of the EHS + Rapa group were decreased ($P<0.05$), Beclin-1 expression and LC3-II/LC3-I ratio were increased ($P<0.05$). The expression levels of NSE, S100β protein and TNF-α in serum of EHS group were significantly increased ($P<0.05$). Compared with the EHS group, the expression levels of NSE, S100β protein, IL-6 and TNF-α in the serum of the EHS + Rapa group were significantly decreased($P<0.05$). The results of immunefluorescence showed that the cell apoptosis in the hypothalamus of EHS rats was significantly increased d($P<0.05$). Compared with the EHS group, the EHS + Rapa group had significantly reduced apoptosis in the hypothalamus ($P<0.05$).

Conclusions. Rapamycin can alleviate the hypothalamus tissue damage caused by exertional heat stroke, improve the function of brain cells, reduce the levels of inflammatory factors and the apoptosis of tissue cells, which is related to the inhibition of mTOR signaling pathway and the enhancement of hypothalamus autophagy level.

The choice of creep and maintenance fluids affects mean daily sodium intake in critically ill patients—systematic review and meta-analysis

J. Waskowski[1], S. M. Salvato[1], M. Müller[2], D. Hofer[1], N. Van Regenmortel[3], C. A. Pfortmueller[1]
[1]Department of Intensive Care Medicine, Inselspital, Bern University Hospital, University of Bern, Bern, Switzerland; [2]Emergency department, Inselspital, Bern University Hospital, University of Bern, Bern, Switzerland; [3]Department of Intensive Care Medicine, Het Ziekenhuisnetwerk Antwerpen Vzw, Antwerpen, Belgium
Correspondence: J. Waskowski
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000308

Introduction. "Non-resuscitation fluids" namely maintenance fluids and creep fluids are a major source of fluid, sodium and chloride intake in critical illness [1]. Currently, it is unclear whether low sodium content solutions e.g. glucose 5% might decrease the daily sodium load and improve patient outcome compared to standard high sodium content solutions, e.g. normal saline. While some research suggested an increased risk of hyponatremia and delirium with the use of low sodium versus high sodium content solutions [2, 3], others indicate a decrease in daily fluid load and hypernatremia [4, 5]. Therefore, we conducted a systematic review (SR) and meta-analysis to evaluate the impact of maintenance and creep fluids on daily sodium intake in an adult general ICU population.
Objectives. The primary objective was to assess if the choice of sodium concentration (high vs low) in maintenance and creep fluids might reduce daily ICU sodium intake. Secondary objectives were the rate of hypo-/hypernatremia and hyper-/hypochloremia and fluid balance.
Methods. Systematic literature review and meta-analysis registered on PROSPERO (CRD42022300577) including randomized controlled trials (RCTs) and observational studies investigating the influence of maintenance or creep fluid choice on sodium intake in ICU patients. We excluded studies not written in English, without control patients, evaluating resuscitation fluids only, and investigation in selected patient populations (children, patients with neurologic disease, burn

patients). The conduct of this SR was based on the Cochrane Collaboration Guidelines. We performed a systematic search on PubMed, EmBase, and the Cochrane Library databases and in references of all eligible publications published until 31th December 2022. We systematically assessed the risk of bias.
For the outcomes, pooled unstandardized mean difference or odds ratios (OR) with 95% confidence intervals (CI) were obtained.
Results. We identified 21 out of 7,370 articles eligible for full-text analysis. Four studies, thereof one RCT [5] and three observational studies [3, 4, 6] (951patients) were eligible for meta-analysis. Risk of bias was moderate across studies. Our meta-analysis showed a mean difference in daily sodium intake of − 117 mmol/d (95%CI − 174; − 59; $p < 0.001$) with the use of low sodium versus high sodium content solutions. This corresponds to a mean reduction in sodium intake of 2.7 g on average. We observed considerable heterogeneity ($I2 = 95\%$) but no evidence of small-study effects ($p = 0.34$). We noted no differences in the incidences of hypernatremia (OR 0.85; 95% CI 0.51; 1.41) nor hyponatremia (OR 2.21; 95% CI 0.77; 6.33). Risk of hyperchloremia was lower (OR 0.26; 95%CI 0.1; 0.64) in the low sodium group. Observational data hints towards a higher fluid balance in the high sodium group.
Conclusions. The use of low sodium content maintenance and creep fluids reduces sodium burden by a relevant amount compared to the use of standard high sodium content fluids.

Does increased staffing lead to increased patient mortality? An analysis

A. Walker[1]
[1]Critical Care Medicine, Surrey and Sussex Healthcare NHS Trust, Redhill, United Kingdom
Correspondence: A. Walker
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000311

Introduction. Intensive Care Units normally have improved doctor to patient ratios compared to general hospital wards, however even ICUs have variation in staffing levels depending on the time of day. Typically, the levels are better during the daytime, whereas evening and overnight shifts rely on fewer clinicians. This analysis aimed to evaluate the impact of this discrepancy on patient mortality.
Objectives. To determine if there was a significant difference in mortality between ICU patients admitted during the fully staffed daytime period and the on-call staffed evening and overnight periods.
Methods. ICU admissions in a single district general hospital ICU were analysed, using WardWatcher software.
Inclusion criteria were all unplanned adult ICU admissions during a 16 year period (2006 to 2022). Exclusion criteria were patients < 18 years old; planned admissions and transfers from other hospitals.
The data was divided into 2 time periods based on when the patient was admitted to ICU:
In hours (08:00 to 17:30)—the period when the ICU was fully staffed.
Out of hours (17:31 to 07:59)—the period of on-call ICU staffing.
Primary outcomes were patient deaths during ICU stay and patient deaths during entire hospital stay.
One tailed Chi squared test was used for all statistical analyses with a significance level of $p < 0.05$. Microsoft Excel was used for the calculations.
Results. A total of 10,946 admissions were analysed. 3907 were in hours, 7039 were out of hours.
There were 879 ICU deaths for the in hours group (mortality 22.5%) and 1251 ICU deaths for the out of hours group (mortality 17.8%). The overall in ICU mortality of 19.5% was comparable to the national level of 18.1% (1).

Table 1 (abstract 000311) ICU mortality for in hours admissions vs out of hours admissions

	Admissions	ICU deaths	ICU Mortality (%)
In hours	3907	879	22.5
Out of hours	7039	1251	17.8
			P < 0.0001

There were 1150 total hospital stay deaths for the in hours group (mortality 29.4%) and 1762 total hospital stay deaths for the out of hours group (mortality 25.0%).

Table 2 (abstract 000311) Total hospital stay mortality for in hours admissions vs out of hours admissions

	Admissions	Hospital stay deaths	Hospital stay mortality (%)
In hours	3907	1150	29.4
Out of hours	7039	1762	25.0
			P = 0.0002

Conclusions. Both ICU and total hospital stay mortality were significantly higher for patients admitted during the fully staffed daytime period compared to the on-call staffed evening and overnight period. This is in keeping with the higher mean APACHE II score (2) for in hours ICU admissions (16.3) compared to out of hours admissions (15.3) demonstrating that these patients were more severely unwell at time of admission.
One possible explanation for this difference is that unwell patients on the hospital wards are not monitored as closely out of hours hence may not be identified and escalated during this period of reduced staffing. These patients will then only be identified and referred to ICU during the daytime and admitted once they have become more unwell.

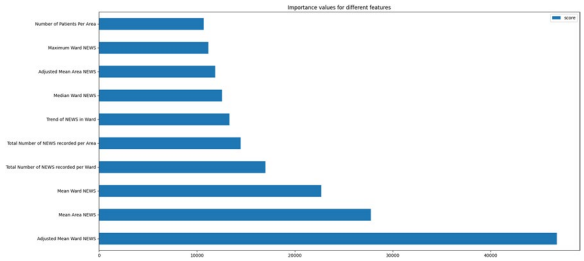
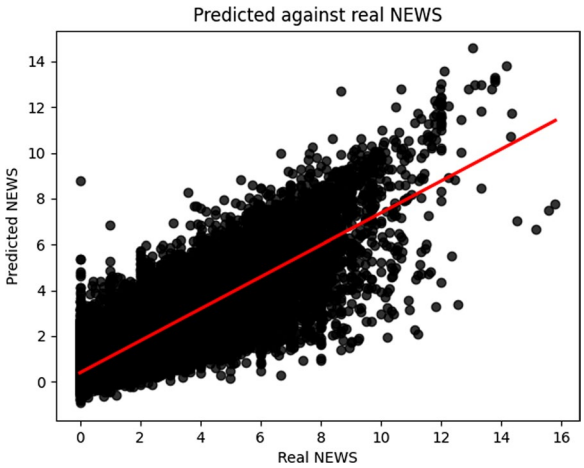
Health system (inpatient ward) strain and acute physiological deterioration: a retrospective observational study

K. Kohler[1], D. Stein[1], V. Sarah[1], D. Hanlon[1], T. T. W. Hla[1], S. Harris[1]
[1]Institute of Health Informatics, University College London, London, United Kingdom
Correspondence: K. Kohler
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000312

Introduction. The role of the ward environment rarely features in patient-level early warning systems, despite the evidence linking ward strain to compromised patient care and outcomes. In the emergency department, patient capacity strains were associated with longer length of stay (Chiu et al., 2018), increased risk of preventable medical errors (Epstein et al., 2011) and increased in-patient mortality (Sun et al., 2013).
Patients with low acuity but high dependency may still absorb nursing time that would otherwise be spent on care processes such as vitals monitoring, medication administration, patient repositioning. Delays in such care processes put other patients on the ward at an increased risk of deterioration (Ball et al., 2014). The NEWS score defines the future risk of the individual (index) patient. Aggregating NEWS scores for the non-index patients within a ward may provide a useful metric of health system strain that affects the outcome of the index patient.
Patient deterioration on wards is both a care quality and patient safety challenge.
Objectives. To measure the association between the overall burden of physiological risk (derived from NEWS/NEWS2) from the community of patients on a ward and the index patient's risk of referral to a rapid response (outreach) team (RRT).
Methods. The study was approved by NHS REC 21/LO/0437—as part of larger piece of work on managing bed demand. We used a 90-day convenience sample (August–November 2022) of all inpatients at an urban teaching hospital in the UK. We abstracted demographics (age, gender), ward location and specialty group (e.g. surgery, medicine, etc.), and all NEWS measurements during the inpatient episode.
We created a 12-h lookback table for the ward and group, and a 3-h lookback for measuring patient deterioration. We calculated ward-based aggregates (mean, maximum and median ward NEWS for each patient-hour) in addition to aggregates for physician specialty group (referred to as 'area' below). These were normalised to account for the usual level of acuity in each location. The aggregates were re-calculated to exclude the index patient. We defined future deterioration as an increase in NEWS for the index patient, or a referral to the RRT. We used Python v3.9.5 and Scikit-learn v1.0 for data preparation and analysis, and built an ensemble decision tree using XGBoost. Code is available upon request.
Results. Our model (with hyperparameter tuning via a search grid) showed a good predictive power with R2 = 0.757 using a random 70/30 test-train split and a fivefold cross-validation. The most important features were the normalised ward mean NEWS in the preceding 12 h, the uncorrected area and ward mean NEWS and the number of NEWS observations recorded in the ward (perhaps a proxy for strain/busy-ness) [Fig. 1].
In Fig. 2, we should the actual and the predicted NEWS for this model with a fit line. While the model fit shows clear correlation, significant variation remains from unmodelled patient and system level effects. Health system factors at both the ward and area (specialty) levels are strongly associated with future deterioration.
Conclusions. This is the first report demonstrating that aggregate physiological risk derived from the community of patients within a ward, or managed by a specialty is associated with individual patient deterioration. The aggregate risk is derived from routinely measured data (NEWS score) and therefore readily generalizable. Future work will compare the relative contribution of individual physiological risk in the index patient to the aggregate physiological risk from the community, and expand the range of inputs to define ward strain.



Plot of feature importance—the highest importance features implicate normaised mean NEWS in the ward and physician on-call cover areas and the the number of NEWS observations taken.



Actual patient NEWS versus predicted NEWS using the XGBoost model with only ward and area-based factors.

Patient and staff experience of a dedicated Thirst Bundle; can patient thirst be effectively managed in critical care?

J. Clark[1], P. Mccready,[2], S. Archer[3]

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000313

Introduction. Patients report thirst as one of the most distressing symptoms of critical illness (1). A dedicated thirst intervention based on the Puntillo thirst bundle (3) has been successfully piloted at our Trust (2).
Objectives. To describe the launch of a Thirst Bundle as part of routine care in critical care and examine patient outcomes and staff confidence.
Methods. The Thirst Bundle was launched in 4 mixed cohort ICU units (54 beds) through a Plan Do Study Act (PDSA) approach. Thirst Bundle contents was reviewed by an cross-specialty steering group and former patient advisors. Staff training was provided during the launch period. A reporting system was established in the electronic notes to capture outcomes. Equipment including access to ice was set up for each unit. Each unit was reviewed for one month resulting in data collection of between 100–120 applications of the Bundle. Thirst was assessed before and after application of the bundle using patient or clinician report of thirst severity via anchor word rating (none, mild, moderate, severe). The intervention included iced swabs, ice cold sprays and a menthol balm. Staff feedback was gained via anonymous questionnaires distributed across the units to explore awareness of the Thirst Bundle, perceptions of its effectiveness and confidence in its use.
Results. Data were collected from 106 patients who received 441 applications of the Thirst Bundle in the study period. Median length of stay was 12 days. 56% (n = 245) of interventions were provided to nil by mouth patients and 52% (n = 228) had their own airway, the remainder having tracheostomy (40%, n = 179) or endotracheal (8%, n = 34) tubes in-situ. Thirst was reported in 67% (n = 295) of thirst assessments. Incomplete reporting led to data loss in 15% (n = 67). 75% (n = 171) of applications resulted in reduction in thirst following application of the bundle. Twenty-three staff feedback forms were collected during the study period and 78% (n = 18) of responders had used the Thirst Bundle with patients. Of staff who had used the bundle, effectiveness and confidence were both reported as a median of 8.5/10. Results were deemed as favourable to staff and patient experience and a Thirst Bundle procedure with video guide was subsequently created and approved for local publication via local governance processes.
Conclusions. We have used existing evidence (3) to adapt a Thirst Bundle for clinical application in large critical care provision. Data examining reduction of thirst symptom burden showed effectiveness in 75% of applications. Staff feedback suggested good awareness of the bundle and high levels of perceived efficacy and confidence in usage. Production of a clinical procedure guide inclusive of a video now aims to support ongoing usage. Further work will now seek to maintain the Thirst Bundle as part of routine critical care symptom management.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000315

Introduction. Covid-19 is a global pandemic that does not affect respiratory system alone. Severe covid-19 cases involve multiple organs, exhibit high morbidity and mortality and are often admitted to ICU. Various cardiovascular complications have been described. Arrhythmias are found in 7% of patients and 44.4% in the ICU (1). Atrial fibrillation (AF) is the most common. Preexisting and new-onset AF is related to mortality. CHA2DS2-VASc score was designed to evaluate thromboembolic risk in AF but now is related to mortality in different pathologies, new AF episodes and AF recurrence (2).
Objectives. To investigate the association of CHA2DS2-VASc with new-onset AF, mortality and ICU stay in covid-19 patients admitted to a medical ICU.
Methods. This study is an retrospective, observational, single-center, case series study. It was conducted in a medical ICU of a tertiary hospital in northern Greece. Sample of the study included 163 patients that were admitted to the ICU between March 2020 and April 2022 with the diagnosis of covid-19 infection verified by PCR testing. In order to study new-onset AF, 12 patients with history of AF were excluded. We gathered information about demographics, medical history, clinical and laboratory presentation and outcome.
Results. Mean age of patients was 64 (IQR 56.5–71) years and the majority of them (67.5%) were males. About half of them were hypertensive (52.15%) and obese (51.53%). Median value of APACHE II score was 15 (IQR 13–18) indicating a relatively low 15% mortality. Median value of SOFA score was 6 (IQR 4–8) that corresponds to 10% mortality. CHA2DS2-VASc score exhibited a median value of 2 (IQR 1–3). Advanced age was significantly related to new-onset AF ($p < 0.001$, 95% CI − 11, − 4). Increased CHA2DS2-VASc was significantly associated with new-onset AF ($p = 0.003$, $p < 0.05$, 95%CI − 2, − 2.46e−05). Other factors that predicted new-onset AF were arterial hypertension ($p = 0.042$, $p < 0.05$, OR = 2.29, 95%CI 1.02,5.15) and stroke ($p = 0.047$, $p < 0.05$) that are components of CHA2DS2-VASc score. CHA2DS2-VASc was also strongly related to ICU mortality ($p = 0.029$, 95%CI − 1, 8.6e−5). Mortality was associated with new-onset AF ($p < 0.001$, OR 5.87, 95% CI 2.43,14.17), ICU stay ($p = 0.016$, $p < 0.05$, 95%CI − 7, − 1), advanced age ($p = 0.001$, $p < 0.05$, 95%CI − 9, − 2), APACHE II ($p = 0.04$, $p < 0.05$, 95%CI − 3, − 7.67e−5) and SOFA score ($p = 0.033$, $p < 0.05$, 95%CI − 1, − 2.61e−5). CHA2DS2-VASc was not associated with ICU stay ($p = 0.842$, 95%CI − 1.21,1.48).
Conclusions. In our sample of ICU covid-19 patients CHA2DS2-VASc score was significantly associated with new-onset AF and ICU mortality, but not with ICU stay.

Introduction. Hyper- and hypo-inflammatory subphenotypes have been described in patients with acute respiratory distress syndrome (ARDS) [1]. However, whether these subphenotypes precede the development of ARDS is unclear. We hypothesized that inflammatory subphenotypes can be identified in patients at risk of ARDS presenting to the emergency department.
Methods. LIPS-A, a double-blind, randomized, placebo-controlled trial evaluating the efficacy of aspirin in preventing ARDS, was conducted at 16 US hospitals between 2012 and 2014 [2]. Patients at risk of ARDS (Lung Injury Prediction Score [LIPS] $\geq$ 4) who presented to the emergency department were included. Development of ARDS by day 7 was the primary outcome. In this secondary analysis, we applied latent class analysis (LCA) to data collected in the emergency department (day 0, before treatment initiation) to test for the presence of inflammatory subphenotypes before the onset of ARDS. To assess stability of identified subphenotypes over time, we repeated LCA on day 1 and 4, respectively. Class-defining variables were selected based on published literature and availability in LIPS-A, including patient demographics, vital signs, and inflammatory biomarkers. We further explored whether outcomes and treatment effects of aspirin varied across subphenotypes.
Results. 376 (96%, 189 received aspirin) of 390 patients in the LIPS-A trial were included in this analysis after excluding patients with missing data for inflammatory biomarkers on day 0. LCA upon admission to the emergency department suggested strong evidence for the presence of two latent classes at baseline: 72 (19%) patients demonstrated characteristics of a hyper-inflammatory subphenotype and 304 (81%) had a hypo-inflammatory subphenotype (Fig. 1). The two-class model performed better than the single-class model, while additional classes did not improve model fit. Presence of the subphenotypes identified at baseline was confirmed on day 1 and 4 in a subgroup with available data (n = 244, Fig. 2A). Class assignment of patients at day 0 remained mostly stable throughout day 1 (93%). 44 (18%) patients switched class from day 1 to 4. Of these, 42 (95%) improved from the hyper-inflammatory to hypo-inflammatory class (Fig. 2B). Incidence of ARDS did not differ significantly between subphenotypes identified at baseline (Table 1). However, patients consistently assigned to the hyper-inflammatory class throughout the study period were at increased risk of ARDS compared to the rest of the cohort (32% versus 10%, p = 0.010). Patients presenting hyper-inflammatory characteristics at baseline had higher 1-year mortality, fewer ventilator-free days, and longer ICU and hospital length of stay. Baseline subphenotypes did not modify the treatment effect of aspirin (Table 1).

Table 1 (abstract 000316) Outcomes by subphenotype at baseline

Outcome	Hypo-inflammatory	Hyper-inflammatory	p-value	p-for-aspirin-interaction
ARDS	25 (8.2%)	10 (13.8%)	0.14	0.36
28-day mortality	25 (8.2%)	9 (12.5%)	0.26	0.68
1-year mortality	61 (20.0%)	25 (34.7%)	0.008	0.54
VFD (days)	28 (27 to 28)	28 (23 to 28)	0.010	0.88
ICU LOS (days)	0 (0 to 3)	3 (2 to 6)	< 0.001	0.16
H LOS (days)	5 (3 to 9)	9 (6 to 18)	< 0.001	0.46

Medians (IQR) or frequencies (%) with p-values for between-group comparison and p-for-interaction of baseline subphenotype with aspirin treatment regimen from logistic or negative binomial regression. Abbreviations: VFD, Ventilator-free days; LOS, Length of stay; H, Hospital.
Conclusions. Previously described hyper- and hypo-inflammatory subphenotypes precede the development of ARDS, remain stable over time, and can be identified in patients at risk of ARDS presenting to the emergency department. Patients consistently demonstrating hyper-inflammatory characteristics are at increased risk of ARDS. Early identification of inflammatory subphenotypes could be considered as potential target and predictive enrichment strategy in future trials on the prevention of ARDS.

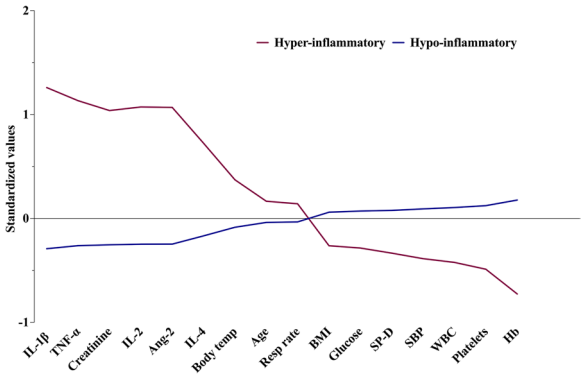

Figure 1 (abstract 000316) Subphenotypes identified in patients at risk of ARDS presenting to the emergency department
Standardized values of continuous class-defining variables upon presentation to the emergency department (day 0, before treatment initiation). Variables are ordered by degree of separation between the identified classes, with those that were highest in the hyper-inflammatory subphenotype on the left. The y-axis represents standardized variable values with a mean of 0 and a standard deviation of 1. To visualize class profiles, values of individual variables are connected by lines.
Abbreviations: IL, Interleukin; TNF, Tumor necrosis factor; Ang, Angiopoietin; Temp, Temperature; Resp, Respiratory; BMI, Body mass index; SP-D, Surfactant protein D; SBP, Systolic blood pressure; WBC, White blood cells; Hb, Hemoglobin.

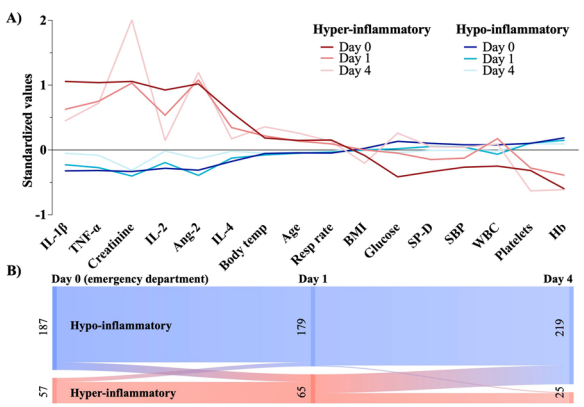

Figure 2 (abstract 000316) Stability of subphenotypes over time. Panel A shows standardized values of class-defining variables by

subphenotypes identified on day 0, 1, and 4. Latent class analysis was performed in a subgroup of patients with available data for inflammatory serum biomarkers on all reassessments (n = 244). For better comparison, variables are ordered based on their degree of class separation in the full cohort on day 0 (as shown in Fig. 1). Panel B shows the number of patients assigned to the hyper- and hypo-inflammatory subphenotype for each respective time point. Connecting lines represent switching of classes. 228 (93%) patients remained in their assigned class from day 0 to day 1. 44 (18%) patients switched class from day 1 to 4. 42 (95%) of class switches during this period were improvements of patients from the hyper-inflammatory to hypo-inflammatory subphenotype. Among those consistently assigned to the hyper-inflammatory subphenotype throughout the study period, 32% developed ARDS, significantly more than in the rest of the cohort (10%, p = 0.010)

Abbreviations: IL, Interleukin; TNF, Tumor necrosis factor; Ang, Angiopoietin; Temp, Temperature; Resp, Respiratory; BMI, Body mass index; SP-D, Surfactant protein D; SBP, Systolic blood pressure; WBC, White blood cells; Hb, Hemoglobin.

Impaired metabolic pathways in experimental sepsis-induced myocardial dysfunction: impacts of mitotropes Apelin-13 and Elabela

O. Lesur[1], K. Rego[1], F. Chagnon[1], D. P. Blondin[2], P. Sarret,[3], M. Auger-Messier[4]
[1]Icu, CRCHUS, Sherbrooke, Canada; [2]Medicine, CRCHUS, Sherbrooke, Canada; [3]Pharmacology, ips, CRCHUS, Sherbrooke, Canada; [4]Cardiology, CRCHUS, Sherbrooke, Canada

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000318

Introduction. Metabolic disturbances induced by sepsis include hyperlactatemia with enhanced glycolysis and impaired glucose homeostasis, protein hyper-catabolism, and altered fatty acid (FA) metabolism. Prevalently dysfunctional hearts during the acute phase of septic shock, with unclear preferences for energetic fuels, are usually supported by catecholamine infusions. Amongst alternative candidates to catecholamines, apelinergics apelin-13 (APL-13) and Elabela (ELA) efficiently support myocardial contractile impairment in experimental sepsis and purport to be mitotropes and energy protectors.

Objectives. To establish the impact of apelinergics on cardiac tissue & cardiomyocyte`s glucose and fatty acid metabolism and associated key-limiting enzymes in an experimental model of septic shock in rats.

Methods. Sepsis-induced Myocardial dysfunction is induced by Cecal Ligation and Puncture (CLP) -vs sham- in male adult rats chronically i–v infused with saline; APL-13 (15 µg/kg/hr); or ELA (39 µg/kg/hr, respectively) for 18 h. Heart tissues are used to measure major glucose and fatty acid transporters GLUT4 and CD36 expressions by WB, as well as pyruvate dehydrogenase (PDH), carnitine palmitoyl transferase 1 (CPT1) and citrate synthase (CS) enzymatic activities. In addition, adult cardiomyocytes (acm) are isolated from CLP (vs. sham) rats and exposed to APL-13; ELA (1-3 mg/mL, 30 min^{-1} h) for main transporters GLUT4 and CD36 expressions and associated glucose (2-NBDG) and FA (Bodipy-C16) real-time uptake assays. Oroboros respirometry is additionally studied on fresh heart fibers.

Results. Although apelin receptor (APJ) overall expression is decreased in CLP hearts, the infusion of apelinergics enhances APJ sarcolemmal-to-endosomal distribution in acm (see jpg picture), with potentially increased receptivity. Apelinergics tend to favour (increase) glucose use in normal hearts (i.e., enhanced GLUT4 expression and 2-NBDG uptake). On the opposite, APL-13 -not ELA- rather rises CD36 expression in CLP hearts (+43[27–88] %, p = 0.004 vs. sham), and both apelinergics further increase amounts of FA taken up by acm isolated from CLP hearts (APL-13: + 30 ± 6%; ELA: + 19 ± 9%, p < 0.0001 and = 0.004 vs. control, respectively). In parallel, CPT1 (FA pathway rate-limiting enzyme) but not PDH (glucose pathway rate-limiting enzyme) activity is further increased by apelinergics (APL-13 p = 0.002, ELA, p = 0.03 vs. CLP-saline) in CLP hearts, and ELA more specifically reduces the effectiveness of malonyl CoA to inhibit CPT-1 in CLP heart fibers (p = 0.05). CLP-induced reduction of CS activity (mitochondrial function) is restored by APL-13 (p = 0.002 vs. CLP-saline).

Conclusions. Experimental sepsis shifts the apelinergic-driven dominant metabolic pathway from glucose to FA oxidation in the heart and restores mitochondrial function. Already established improvers of heart function and outcome in experimental sepsis, apelinergics confirm their status of mitotropes.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000320

Introduction. The number of patients with solid cancer admitted to the ICU is growing, reaching 15% of ICU admissions in some series. Respiratory failure due to infections, lung toxicity and cancer progression is one of the leading causes of critical illness in this population.

Objectives. To describe the cohort of patients with cancer admitted to the ICU due to respiratory failure and to analyse risk factors associated with mortality.
Methods. Ten-year (2010–2019) retrospective study, including consecutive adult patients with solid cancer admitted to the ICU due to respiratory failure. Respiratory failure was defined as PaO2 < 60 mmHg or SpO2 < 90%, tachypnea > 30 bpm, or respiratory distress at rest. Chi-Square, Fisher´s test, T test, U Mann–Whitney and logistic regression (including all variables with p < 0.1 in the univariate analysis) were employed as appropriate. Quantitative variables are reported as median (IQR) and categorical as frequency (%).
Results. One hundred and ninety-five patients were admitted for respiratory failure during the study period, 122 (62.6%) men, with a mean age of 65 (55–71) years. ECOG 0–1 was present in 137 (70.1%) of the patients. Lung 67 (34.4%), gastrointestinal 50 (25.6%), head and neck 16 (8.2%) and urologic 16 (8.2%) were the most frequently involved cancers. Metastatic disease affected to 109 (55.9%) and neutropenia was present in 13 (7%) patients. The leading cause of respiratory failure was pneumonia 94 (48%). SOFA score was 7 (3–10). On admission, 57 (29%) patients required invasive mechanical ventilation (IMV) and 138 (81%) non invasive respiratory support (low flow oxygen (LFO) 16 (82%), high flow oxygen (HFO) 116 (59.5%) and non-invasive mechanical ventilation (NIMV) 6 (3.1%). One (0.5%) patient treated with LFO and 2 (1%) treated with NIMV required HFO, so 119 (61%) were treated with HFO. Sixty-two (52% of those treated with HFO) were affected by HFO failure (14 patients were not intubated due to a do not intubate order). During de ICU course 109 (55.9%) patients required IMV. One hundred and twenty-nine (66.2%) were treated with vasoactive drugs and 26 (13.3%) required renal replacement therapy (RRT). In-ICU, in-hospital and one year mortality affected to 78 (40%), 102 (52.3%) and 151 (78.7%), respectively. Differences between in hospital survivors and non- survivors are summarized in table 1. Patients whose performance status was ECOG 0 or 1 had a lower risk for in-hospital mortality (OR: 0.37; CI 95%: 0.18–0.76; p = 0.007) while HFO failure (OR: 6.2; 95% CI: 2.8–13.3; p < 0.001) and mechanical ventilation (OR: 6.2; 95% CI: 2.8–13.3; p < 0.001) were associated with a higher in-hospital mortality.

Table 1 (abstract 000320) Differences between in-hospital survivors and non-survivors

Variables	Survivors (n = 93)	Non-survivors (n = 102)	p-value
Age (years)	66 (55–72)	65 (56–71)	0.385
Lung cancer	27 (29)	40 (39.2)	0.225
Metastatic disease	51 (54.8)	42 (45.2)	0.776
ECOG 0–1	73 (79.4)	64 (62.8)	0.011
SOFA (day 1)	6 (3–9)	7 (3–11)	0.101
Neutropenia	7 (7.6)	6 (6.4)	0.743
Pneumonia	39 (41.9)	55 (53.9)	0.115
VAD	56 (60.2)	73 (71.6)	0.094
RRT	12 (12.9)	14 (13.7)	0.866
IMV	39 (41.9)	72 (70.6)	< 0.001
HFO	57 (56.8)	62 (60.8)	0.942
HFO failure	11 (11.8)	54 (52.9)	< 0.001
Time to IMV (HFO failure)	1 (0–3)	1 (0–5)	0.878

Conclusions. Respiratory failure is still associated with a significant in-hospital mortality, which is not associated with baseline disease, even in metastatic cancer, but with organ failure. Patients requiring invasive respiratory support and those failing on HFO had a higher mortality, so better strategies for optimizing and selecting patients under non-invasive support are needed. A good performance status (ECOG 0–1) had a protective effect.

Topic: Haematologic-oncologic issues in the ICU.

Introduction. Extracorporeal albumin dialysis (ECAD) might be indicated for acute-on-chronic liver failure (ACLF). ADVOS is an advanced ECAD system intended for multiple organ support. The EMOS-Registry (DRKS00017068) collected real world data in patients treated with ADVOS.
Objectives. This analysis of the EMOS-Registry compares the effects of ADVOS in patients with ACLF.
Methods. In this fourth analysis [1], all patients enrolled until close-out were assessed for eligibility. Patients with documented pre-existing liver disease and a complete dataset allowing the calculation of CLIF-C ACLF score were included. Demographic characteristics and surrogate markers before the 1st ADVOS treatment and after the 1st and last ADVOS sessions were analyzed for patients with ACLF 1, 2 and 3. CLIF-C ACLF Score was used to calculate the 1-month standardized mortality ratio (SMR) based on [2] and [3].
Results. 87 patients with documented ACLF before the first ADVOS treatment were included (8 with ACLF 1, 26 with ACLF 2 and 53 with ACLF 3). Significant differences were observed in vasopressor use, hepatic encephalopathy grade and presence of acidosis according to the ACLF grade. 29, 97 and 233 ADVOS sessions were documented, respectively. Median low blood (120–150 ml/min) and concentrates flows (160 ml/min) were set for treatments with a median duration of 16 h. As shown in Table 1, patients with ACLF 3 showed significantly improved values of creatinine, BUN, pH and base excess. The analysis of the CLIF-C ACLF score-standardized mortality rate (SMR) showed a trend towards improved survival in patients with ACLF 3, especially when CLIF-C ACLF score was ≥ 55. In this group a 31% survival rate was observed, while only 9% was expected [3]. This SMR of 0.76 (0.52–1.00) can be translated into a 22% absolute risk reduction and a number needed to treat (NNT) of 4.6 (Fig. 1). In all patients, few clotting events and 1 bleeding episode were associated with the intervention.

Table 1 (abstract 000321) **C**ourse of treatment performance parameters. Median (IQR). *p < 0.05. ** p < 0.01 vs. before 1st ADVOS

Parameter	Before 1st ADVOS	After 1st ADVOS	After last ADVOS
Bilirubin total [mg/dl]			
ACLF 1	2.7 (1.6, 7.2)	3.3 (0.8, 8.5)	5.7 (1.25, 15.8)
ACLF 2	5.6 (2.8, 13.1)	6.1 (3.5, 14.5)	7.8 (3.6, 15.5)
ACLF 3	14.9 (4.8, 25.6)	12.6 (5.1, 22.2)	11.8 (6.1, 18.9)
Creatinine [mg/dl]			
ACLF 1	1.45 (0.77, 1.69)	1.35 (0.5, 2.4)	1.69 (1.69, 0.88)

Parameter	Before 1st ADVOS	After 1st ADVOS	After last ADVOS
ACLF 2	1.85 (0.71, 3.10)	0.92 (0.58, 1.61)*	0.83 (0.68, 1.60)
ACLF 3	1.93 (1.25, 3.92)	1.57 (0.86, 2.60)	1.34 (0.96, 1.80)*
BUN [mg/dl]			
ACLF 1	14 (8, 38)	9 (5, 20)	13 (5, 13)
ACLF 2	32 (18, 52)	17 (12, 28)*	24 (14, 30)
ACLF 3	36 (19, 78)	30 (15, 45)*	25 (14, 36)*
pH			
ACLF 1	7.35 (7.28,7.45)	7.40 (7.30, 7.47)	7.44 (7.42, 7.49)
ACLF 2	7.37 (7.29, 7.44)	7.45 (7.40, 7.49)*	7.42 (7.38, 7.44)
ACLF 3	7.33 (7.25, 7.41)	7.41 (7.38, 7.46)**	7.40 (7.27, 7.44)
Base Excess [mmol/l]			
ACLF 1	− 3.1 (− 8.6, 3.3)	0.2 (− 0.3, 2.7)	3.6 (1.2, 5.5)
ACLF 2	− 2.0 (− 7.5, 1.5)	2.1 (0.5, 4.5)*	1.6 (− 2.7, 6.1)
ACLF 3	− 7,6 (− 11.2, 1.4)	0.5 (− 4.4, 3.3)**	− 1.2 (− 8.4, 3.2)*

Conclusions. Results of this subgroup analysis of the EMOS registry are in line with a recent expert consensus reporting that ECAD may improve short-term survival, its efficacy appearing to be correlated with patient selection and intensity of treatment [4]. Patients with ACLF 3 seem to benefit most from the ADVOS therapy. Registry data must be carefully analyzed and should be validated in randomized controlled trials.

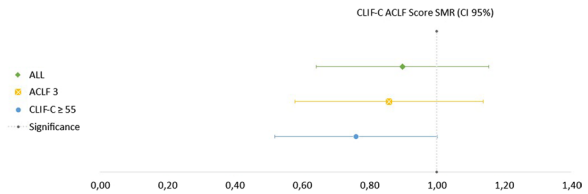

Figure 1 (abstract 000321) CLIF-C Score-standardized 28-day mortality rates. Data for ALL and ACLF 3 are based on expected mortality based on [2]. Data for CLIF-C ≥ 55 are based on [3]

Preoperative renal resistive index is associated with persistent renal dysfunction and major adverse kidney- and cardiovascular events up to 5 years after cardiac surgery

M. Renberg[1], U. Sartipy[2], M. Bell[1], D. Hertzberg[1]
[1]Department of Perioperative Medicine and Intensive Care, Karolinska University Hospital, Stockholm, Sweden; [2]Department of Cardiothoracic Surgery, Karolinska University Hospital, Stockholm, Sweden
Correspondence: M. Renberg

Introduction. Renal resistive index (RRI) is a bedside ultrasonographic quantification of renal perfusion obtained by using pulse waved Doppler (*Fig. 1*). Elevated RRI has shown promise in early prediction of acute kidney injury in critically ill patients and after major surgery, but its role for risk assessment of long-term outcomes in these settings is not known.
Objectives. To investigate the association of preoperative RRI elevation and persistent renal dysfunction, major adverse kidney events (MAKE) and major adverse cardiovascular events (MACE) after cardiac surgery.
Methods. In this observational cohort study, RRI was measured in patients the day before undergoing on-pump cardiac surgery at a Swedish University Hospital. RRI ≥ 0.70 was defined as elevated. Persistent renal dysfunction was defined as a decline in estimated glomerular filtration rate ≥ 25% compared to the preoperative value that sustained for more than three months. MAKE was a composite of persistent renal dysfunction, renal replacement therapy, or death. MACE was a composite of myocardial infarction, unstable angina, decompensated heart failure, stroke, or cardiovascular death. The Kaplan–Meier method and Cox proportional hazard regression was used to investigate the association between elevated RRI and the outcomes up to five years after surgery.
Results. The study included 96 patients, of which 58 (60%) had elevated preoperative RRI. Five years after surgery persistent renal dysfunction had occurred in 25 patients (26%), MAKE in 34 patients (35%), and MACE in 28 patients (29%). RRI was higher in patients developing persistent renal dysfunction (median RRI 0.78 (interquartile range (IQR) 0.74–0.82) vs 0.70 (IQR 0.66–0.77), p = 0.001), MAKE (median RRI 0.77 (IQR 0.72–0.81) vs 0.68 (0.65–0.76), p = 0.002), and MACE (median RRI 0.77 (IQR 0.72–0.81) vs 0.70 (IQR 0.66–0.77), p = 0.006) compared to those not developing the outcomes. Patients with elevated RRI had higher cumulative incidences of persistent renal dysfunction (log-rank p < 0.001), MAKE (log-rank p < 0.001) and MACE (log-rank p = 0.007) (Fig. 2). After adjusting for multiple preoperative risk factors, elevated RRI was associated with persistent renal dysfunction (adjusted hazard ratio (aHR) 4.73 (95% confidence interval (CI) 1.37–16.2)) and MAKE (aHR 2.83 (95% CI 1.03–7.73)), but not with MACE (aHR 2.37 (95% CI (0.80–7.03)).
Conclusions. Elevated preoperative RRI is associated with persistent renal dysfunction and MAKE after cardiac surgery, with a strong tendency for an association also with MACE. RRI may be used to tailor long-term follow-up of renal- and cardiovascular function in cardiac surgery patients.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000328

Introduction. Rapid response systems have been implemented with the aim of preventing patient deterioration, in-hospital cardiac arrest (CA) and related deaths. In our hospital, rapid response team (RRT) was introduced in 2012. In early April 2020, COVID-19 outbreak compelled rapid response team to pause due to insufficient staff.
Objectives. To investigate changes in unexpected CA with comparison between RRT-working period and the hiatus period.
Methods. A single center, cohort study of all unexpected CA in two periods. One is one-year period from April 2019 to March 2020 for which RRT was in operation before COVID-19 outbreak. The other is one-year period from May 2020 to April 2021 for which RRT was on hiatus after COVID-19 outbreak. Unexpected CA were identified from the rapid response systems database and patients' case histories were reviewed from their medical records.
Results. The incidence of unexpected CA increased from 24 (0.78/1000 admissions) in RRT-in-operation period to 35 (1.58/1000 admissions) in RRT-on-hiatus period. The median age was 72 (IQR45-79) with 45.8% male in RRT-in-operation period and 75 (IQR68-80.5) with 77.1% male in RRT-on-hiatus period. There were no COVID-19-related CA. The rate of death in unexpected CA was 71% (17/24) in RRT-in-operation period and 80% (28/35) in RRT-on-hiatus period. Any warning signs preceding cardiac arrest were identified in 83% (20/24) in RRT-in-operation period and 71% (25/35) in RRT-on-hiatus period. We investigated which checkpoints for preventing CA were passed from identifying warning signs to appropriate intervention. As shown in the Table, appropriate monitoring, timely recognition of warning signs, timely communication with physicians and appropriate intervention were seen in 71%, 42%, 50% and 38%, respectively in RRT-in-operation period. On the other hand, each checkpoint pass rates decreased to 57%, 31%, 26% and 11% in RRT-on-hiatus period, respectively.
Conclusions. Unexpected CA increased on the hiatus of RRT. Several checkpoints involved with afferent component including monitoring, recognition of warning signs and communication with physicians were not passed in many cases in RRT-on-hiatus period, indicating that vigorous education about afferent component for general ward staffs was necessary. Furthermore, it was suggested that RRT activity itself was critical for appropriate intervention for preventing CA.

Table (abstract 000328) Comparison of unexpected cardiac arrest between RRT-in-operation period and RRT-on-hiatus period. CA: cardiac arrest

RRT activity	in operation	on hiatus
unexpected CA	24	35
death	17 (71%)	28 (80%)
presence of warning signs preceding CA	20 (83%)	25 (71%)
appropriate monitoring	17 (71%)	20 (57%)
timely recognition of warning signs	10 (42%)	11 (31%)
timely communication with physicians	12 (50%)	9 (26%)
appropriate intervention preceding CA	9 (38%)	4 (11%)

Topic: Cardiac arrest.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000329

Introduction. Sepsis-associated acute kidney injury (SA-AKI) severity and trajectory correlated with mortality. Early recognition of different subphenotypes of SA-AKI could help to customize their management during the first stage of care. In this line, Acute Dialysis Quality Initiative (ADQI) expert panel suggest that combine kidney stress/damage biomarkers with kidney function parameters, could help to better-characterize AKI and help physician to early individualize particular phenotypes of patients in view to customize their management during the first stage of care.
Methods. In this post hoc analysis of prospective multicenter study. We combined kidney function parameters: prior serum creatinine (SCr) and eGFR, SCr at inclusion (0 h) and 24 h, blood urea nitrogen at 0 h, weight-corrected urine output (UO) at 0 h, 6 h,12 h and 24 h with serial measures of urine [TIMP-2]*[IGFBP7] at 0 h, 6 h, 12 h and 24 h; using an unsupervised hierarchical clustering of principal components approach; to identify different phenotypes of SA-AKI. We compared start of RRT and seven-day survival rates in the different subphenotypes.
Results. One hundred and eighty-four patients presenting SA-AKI within the first six hours of septic shock diagnosis were included. Three distinct subphenotypes were identified: subphenotype A (99 patients) characterized by conserved UO, low SCr and low [TIMP-2]*[IGFBP7] level, subphenotype B (74 patients) characterized by prior chronic kidney dysfunction, higher SCr, low UO, intermediate [TIMP-2]*[IGFBP7] level and subphenotype C characterized by very low UO and very high [TIMP-2]*[IGFBP7] level. Renal replacement therapy was initiated within the first seven days in four (4%), 27 (36%) and three (27%) patients of sub-phenotype A, B and C, respectively ($p < 0.001$). After adjustment for confounding factor, seven-day survival rate [95% CI] was respectively of 88% [80–96], 80% [72–88] and 75% [56–94] in the subphenotype A, B and C. With subphenotype A as reference, the adjusted hazard-ratio [95%CI] for seven-day mortality was 1.53 [0.76–3.08]; $p = 0.24$ in the subphenotype B and 5.90 [2.04–17.07]; $p = 0.001$ in the subphenotype C.
Conclusions. Combining classical kidney function indicators to a cell-cycle arrest urine biomarker, we identified three distinct subphenotypes of SA-AKI, with different short-term trajectory and survival rate. This could be useful to better stratify patients at the early phase of septic shock, but need to be confirm in an independent and larger cohort.

Respiratory muscle hibernation in mechanically ventilated ICU patients: Super-relaxed myosins contribute to contractile weakness of the diaphragm and novel slow and fast skeletal muscle troponin activators restore contractility

M. van den Berg[1], Z. Shi[2], W. Claassen[1], A. Girbes[2], S. Stapel[2], A. Beishuizen[3], J. Ochala[4], L. Heunks[5], C. Ottenheijm[1]

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000330

Introduction. Intensive care unit (ICU) patients frequently develop contractile weakness of the diaphragm, the main muscle of inspiration. ICU patients with diaphragm weakness are at much higher risk for difficult weaning from the mechanical ventilator, which contributes to mortality and poses a high economic burden (1). Due to a lack of knowledge regarding the molecular changes in the diaphragm, no pharmacological treatment is available to improve diaphragm contractility.
Methods. We compared diaphragm biopsies from ventilated ICU patients ($N = 54$) to those of non-ICU patients ($N = 27$) and integrated ultrastructural, biophysical, biochemical and clinical data. Furthermore, we studied quadriceps muscle biopsies of mechanically ventilated patients and the diaphragm in mechanically ventilated rats to elucidate the role of unloading due to mechanical ventilation opposed to critical illness.
Results. In diaphragm myofibers of ventilated ICU patients, the key contractile protein myosin is trapped in the energy-sparing, super-relaxed state. This state impairs the binding of myosin to actin during diaphragm contraction. Proteomics studies indicate that super-relaxed myosins in the diaphragm are evoked by dephosphorylation of myosin regulatory light chains, and studies in ventilated rats identified contractile inactivity of the diaphragm as a cause of myosin light chain dephosphorylation. Increased super-relaxed myosins were not found in myofibers of leg muscles of ICU patients. We re-activated the contractile proteins in diaphragm myofibers from ventilated ICU patients with novel small molecule compounds targeting another contractile protein, troponin, and this restored the contractile force to normal levels.
Conclusions. In conclusion, our results reveal a new pathomechanism underlying diaphragm contractile weakness in ventilated ICU patients, i.e., an increased population of SRX myosins due to hypophosphorylation of RLCs. We also show that novel small molecule compounds restore physiological force levels.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000331

Introduction. The association between CT hypotension complex findings reflected in initial contrast-enhanced CT and early mortality or prediction of massive transfusion is not well known.
Objectives. To evaluate the usefulness of initial contrast-enhanced CT findings for predicting early mortality and/or massive transfusion in patients with traumatic injury.

Methods. We retrospectively reviewed patients with traumatic injury who visited a single tertiary trauma center between January 2020 and December 2021. Patients with injury severity score under 9, patients who expired 7 days after arriving at the emergency department, or patients who did not undergo initial contrast-enhanced CT were excluded. The subjective CT hypotension complex findings values of abdominal solid organs including liver, spleen, pancreas, kidneys, adrenal glands, thickened bowel loops finding and the diameters of the abdominal aorta and inferior vena cava were used to evaluate the association with mortality.

Results. Of 432 patients with traumatic injury 250 patients were included. Twenty-one patients died within 7 days of admission and 229 patients survived until 30 days of admission. When analyzed the 8 variables by multiple regression analysis adjusting by stepwise regression, hypo-enhancement of spleen (OR 17.09, 95% CI; [4.89–62.13] $p < 0.001$) and IVC diameter (OR 0.85, 95% CI; [0.73–0.98] $p = 0.034$) were related to 7 days mortality. Of the 8 variables collected on initial contrast-enhanced CT scan, thickened bowel loops (OR 6.26, 95% CI; [1.52–26.12] $p = 0.01$), and IVC AP diameter (OR 0.85, 95% CI; [0.75–0.97] $p = 0.017$), showed the correlation with prediction of massive transfusion.

Conclusions. In patients with traumatic injury, the contrast-enhanced CT hypotension complex can help predict the patient`s prognosis by reflecting the hypovolemic state as well as evaluating the extent of trauma. Among these complexes, hypo-enhancement of spleen and IVC diameter findings can predict the early mortality of trauma patients, and thickened bowel loops and IVC AP diameter can be feasible for predicting massive transfusion.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000332

Introduction. Recently, it has been suggested that patients with high respiratory effort during mechanical ventilation (MV) may induce lung injury. Therefore, proper control of respiratory effort in patients on MV is considered important for the prevention of lung injury. In addition, as a general clinical indicator, patients with high respiratory effort are often considered to be associated with dyspnea. However, the relationship between dyspnea and respiratory effort has not been clarified yet.
Objectives. The primary objective of this study was to examine the relationship between three dyspnea rating scales and respiratory effort in patients undergoing MV.
Methods. We performed a prospective observational study of patients admitted to intensive care unit (ICU) of the University Hospital in Japan between February 2020 and March 2022. Patients who were at least 20 years old and expected to require MV for more than 24 h were included in this study. Dyspnea was measured using Respiratory Distress Observation Scale (RDOS), Intensive Care Respiratory Distress Observation Scale (IC-RDOS), and Mechanical Ventilation Respiratory Observation Scale (MV-RDOS). Respiratory effort was measured using airway occlusion pressure: the negative pressure at the start of spontaneous inspiration (the first 0.1 s) (P 0.1). Measurements were performed at a maximum of 2 points between the ICU admission day and day 4. Measurements were performed independently by two investigators, who were blinded to each other's data. Pearson's correlation coefficients (r) were used to examine relationships between variables.
Results. A total of 253 patients were eligible, 122 were excluded, and finally 131 were included in the study. Of the included patients, 69 patients on MV were able to measure P 0.1 and were included in the statistical analysis. Data including total 105 observation points from the 69 patients were collected. Low negative correlation were confirmed between RDOS, IC-RDOS, MV-RDOS, and P 0.1 ($r = -0.293$, $p = 0.003$; $r = -0.240$, $p = 0.014$; $r = -0.260$, $p = 0.008$, respectively) (Fig. 1). Stratified analysis by baseline disease, severity, and depth of sedation showed that RDOS, IC-RDOS, MV-RDOS, and P 0.1 had a low negative correlation only in the deep sedation group ($r = -0.347$, $p = 0.020$; $r = -0.325$, $p = 0.029$; $r = -0.352$, $p = 0.018$, respectively) (Fig. 2). This correlation tended to be stronger compared to all patients. On the other hand, no significant correlations were demonstrated in the other stratified analyses.
Conclusions. Dyspnea and respiratory effort showed a low negative correlation in patients using MV. This correlation was stronger in the analysis of the deep sedation group only. It was suggested that depth of sedation may have affected the correlation between dyspnea and respiratory effort.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000333

Introduction. Selective digestive decontamination (SDD) has been associated with a reducution in mortality and ICU-acquired infection (NI) rates However, the effect SDD in areas where multidrug-resistant Gram-negative bacteria (MRGNB) are endemic is of great interest.
Objectives. To analyze the impact on MRGNB NI, antibiotic comsumption and colistin and trobramycin colonization in patients with NI in an ICU after 11 years of SDD.
Methods. This study was conducted in a 30-bed-medical-surgical ICU. All consecutive patients admitted to the ICU between October 1, 2011 and September 30, 2022 who were expected to require tracheal intubation > 48 h were administered SDD (SDD study group) with a 4-day course of intravenous cefotaxime plus enteral colistin, tobramycin, nystatin in an oropharyngeal paste and digestive solution. Oropharyngeal and rectal swabs were obtained on admission and once a week. We used ENVIN NI criteria. All patients admitted to ICU with NI in ICU between October 1, 2010 and September 30, 2011 (non-SDD group) were compared with the SDD study group. A univariate and a multivariate logistic regression analysis were performed. For each of the NIs, incidences per 1000 days of exposure in each cohort and the corresponding relative risks were obtained using Poisson regression. Statistical significance was $p \leq 0.05$. Colistin- and tobramycin-resistant colonization and antibiotic consumption as defined daily doses of antibiotics (DDD) were also analyzed.
Results. The results are shown in Tables 1, 2 and 3.A total of 12,016 were admitted to ICU, 990 patients developed NI and 780 of them who received SDD. There were no statistically significant differences between the two groups in terms of admission type or demographics. SDD patients had significantly fewer Extended Spectrum Betalactamase (ESBL) infections $p = 0.015$, Gram Negative Multidrug Resistant Bacteria (GNB-MR) $p = 0.002$ and *Acinetobacter spp*. infections $p < 0.001$. There was also a significant reduction in the rates of ventilator-associated pneumonia (VAP), urinary tract infections, other secondary bacteremia and multidrug-resistant bacteria infections (MR-GNB) in the SDD group versus the non-SDD group. There was no *Clostridium difficile* infection. Colistin-resistant colonization was 18.9% and tobramycin-resistant colonization was 27.8% of samples. There was a decrease in DDD/100 ICU stays after SDD.
Conclusions. After eleven years of SDD implementation, a significant reduction in ESBL, GNB-MR and *Acinetobacter* infections was persistently observed. A significant decrease in the rates of VAP, secondary bacteremia, urinary tract infections and MRNI was also observed. A reduction in antibiotic consumption was observed after SDD. Low rates of colonization by colistin- and tobramycin-resistant bacteria were also observed throughout these years.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000334

Introduction. Hemodynamic monitoring is of utmost importance when treating critically ill patients, but the currently used techniques are invasive and related with catheter-related complications. Over the last two decades, carotid artery ultrasound (US) was investigated as a non-invasive alternative for hemodynamic monitoring, including cardiac output estimation. Both vessel diameter and blood velocity are needed to compute blood flow in a vessel. Traditionally, carotid flow measurements are performed with the US probe oriented in the long-axis (LA) view [1]. Assuming a circular cross-section of the vessel and a parabolic flow profile, the probe should be properly positioned along the mid-axis to obtain an accurate blood flow estimation. However, obtaining and maintaining this mid-axis parallel view is difficult and literature describes that operator experience may impact the reliability of carotid flow measurements [2]. While the short-axis (SA) view allows for measurement of the true diameter, it does not allow for velocity estimation as the Doppler frequency shift approaches 0 degrees. Another way of assessing the cross-section of the carotid artery is by rotating and tilting (RT) the probe, a view that is easier to visualize and assess for sonographers. Regarding velocity measurements, preliminary research showed that the RT view was more robust to motion and less operator-dependent than the LA view [3]. To our knowledge, there is no literature regarding clinical diameter estimates with the RT view.
Objectives. To evaluate the use of the RT view in a clinical setting, and to compare it with the LA and SA views using systolic diameter and spread of systolic diameter estimates per acquisition. The spread of systolic diameter values serves as a measure of robustness.
Methods. We performed 30 s US acquisitions of the carotid artery in adult cardiac surgery patients, with a LA, SA, and RT probe orientation. The 30 s US recordings were analyzed to derive a diameter waveform. From this, we computed the systolic diameter values and a measurement of spread (calculated as the IQR of the systolic diameter estimates per acquisition) and investigated for potentially significant differences between views.
Results. US acquisitions were performed in 29 patients. The median systolic diameter (IQR) per 30 s acquisition was 7.08 (1.59) mm, 7.22 (1.20) mm, and 6.95 (1.77) mm for the LA, SA, and RT views, respectively (Fig. 1). The median spread (IQR) per 30 s acquisition was 0.12 (0.13) mm, 0.10 (0.10) mm, and 0.09 (0.10) mm for the LA, SA, and RT views, respectively. Normality was checked using the Shapiro–Wilk test and Friedman tests showed no statistically significant difference between the views for either the median ($p = 0.142$) or spread ($p = 0.786$) of systolic diameter per 30 s acquisition.
Conclusions. It was feasible to acquire data and derive diameter estimates using the three probe orientations. The median and spread in systolic diameter values per 30 s acquisition were comparable for the LA, SA, and RT views, suggesting that the different views result in evenly robust measurements and can be used interchangeably to obtain diameter estimates. This study opens the path for further investigation of the newly introduced RT view for new applications and possibilities, such as hands-free measurements.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000335

Introduction. Recognition of risk factors for mortality and early intervention with appropriate administration of broad-spectrum antimicrobials in patients with nosocomial infection (NI) can significantly improve outcomes. Selective digestive decontamination (SDD) has been associated with reduced ICU mortality and acquired infection rates.
Objectives. To analyze the risk factors for mortality in patients with NI in an ICU after 11 years of SDD.
Methods. Patients with NI from October 1, 2010, to September 30, 2022, in a 30-bed polyvalent ICU were prospectively included. The SDD was applied for 11 years, from October 1, 2011 to September 30, 2022. Patients who required mechanical ventilation for more than 48 h were given an enteral solution and a paste containing colistin, tobramycin and nystatin every 8 h until discharge. Intravenous cefotaxime was also administered during the first 4 days. Rectal and pharyngeal exudates were collected on admission and weekly. ENVIN NI criteria were used. Categorical variables were summarized as frequencies and percentages and numerical variables as means and standard deviations or medians and interquartile ranges. Percentages were compared with the X2 test or Fisher's exact test, means with the t-test and medians with the Wilcoxon test for independent data. A multidimensional logistic analysis was performed. It was considered significant if $p \leq 0.05$.
Results. Of the 12,016 patients admitted, 313 (35.16%) of the 890 patients with NI died. In a univariate analysis, no statistically significant differences in ICU stay were found. Multidrug-resistant (MR) *Pseudomonas* and MR Gram-negative bacteria (GNB) were significantly higher in patients who died (Table 1). Independent mortality risk factors were: renal replacement therapy Odds Ratio (OR): 4.662 (3.373; 6.444), neoplasm OR: 2.567 (1.532; 4.304), ventilator-associated pneumonia (VAP):OR: 1.980 (1.407; 2. 787), parenteral nutrition OR: 1.927 (1.322; 2.809), chronic obstructive pulmonary disease (COPD) OR:1. 852 (1.223; 2.805), septic shock OR: 1.817 (1.307; 2.527) and APACHE II OR:1.054 (1.031; 1.077). (Table 2).
Conclusions. In an ICU with SDD, the factors that were independently associated with mortality were: renal replacement therapy, neoplasia, VAP, parenteral nutrition, COPD, septic shock and APACHE II. *Pseudomonas* MRs and GNB MRs also had significantly higher mortality.

Introduction. Despite the wide diffusion of oral anticoagulation in patients at risk for thromboembolism and cardioembolic stroke, major and clinically relevant bleedings remain the dominant adverse events of such therapy(1). Thromboelastography (TEG) is a point-of-care viscoelastic test that assesses coagulation throughout all phases of clot formation, allowing one to detect alterations of the coagulation cascade(2). Although its use in the emergency and critical care setting is increasing, TEG characteristics in anticoagulated patients with significant bleeding undergoing reversal therapy need to be explored.
Methods. In this preliminary evaluation of our ongoing observational prospective monocentric study, consecutive adult patients taking anticoagulants admitted to the ED for either *major* (fatal and/or symptomatic bleeding in a critical organ with acute decrease in hemoglobin concentration $\geq$ 2 g/dL or transfusion of $\geq$ 2units of red blood cells) or *clinically relevant* (bleeding that requires medical intervention to control) bleeding and for whom reversal therapy with prothrombin concentrated complex was required were enrolled. Demographic, clinical and blood tests data were collected at ED admission (T0) and a TEG analysis through 4 reagents (kaolin, kaolin + heparinase, tissue factor, platelet inhibitor GPIIb/IIIa) was performed. At 48 h (T1) possible failure of reversal therapy (namely recurrent bleeding despite any associated therapy with hemostatic intent or death) was assessed.
Results. Between November 2022 and March 2023, 35 patients were enrolled, of 71% which were male. The median age of the population was 83[75–90] years and the BMI was 26[24–28]. 69% of patients came from home and the 94% was hospitalized. The most represented anticoagulant was Apixaban (31%), followed by Rivaroxaban (23%). The most common type of bleeding was muscle/soft tissue arterial hematoma (51%) followed by gastrointestinal bleeding (26%). 34% of patients underwent angioembolization and 20% endoscopic intervention. Red blood cells transfusion was performed in 51% (2 [1–3] units), fresh frozen plasma was administered in 60% (400 [400–600] mL). Table 1 summarizes vital signs, laboratory tests and TEG parameters. Three patients failed the reversal therapy: one had an increased intracranial bleeding at the control CT scan, one needed a new embolization attempt and another patient died for hemorrhagic shock.

Table 1 (abstract 000336) .

Kaolin TEG	
Reaction time, min	6.9 [5.4–9.8]
K, min	1.25 [0.9–5.15]
α-angle	73.55 [38.65–77.2]
Maximum amplitude, mm	64.55 [60.7–67.1]
LY30, %	0 [0–0.3]
Kaolin TEG with heparinase	
Reaction time, min	6 [5.5–8.2]
K, min	1.1 [0.9–1.3]
α-angle	75.55 [72.5–77.5]
Maximum amplitude, mm	67.25 [64.2–68.9]
Rapid TEG (with tissue factor)	
Reaction time, min	0.4 [0.3–1.1]
K, min	1.1 [0.8–2.2]
α-angle	76.8 [63.6–78.5]
Maximum amplitude, mm	66.7 [61.6–68.9]
LY30, %	0 [0–0.1]
Functional fibrinogen (with platelet inhibitor GPIIb/IIIa)	
Maximum amplitude, mm	29.05 [23.1–35.05]

Conclusions. The preliminary data of our ongoing study describe the main TEG characterstics of bleeding patients, in which the failure of reversal therapy appeared to be low. By increasing patient enrollment we aim at identifying those parameters that may predict such adverse outcome.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000338

Introduction. During hemodynamic monitoring, a blind spot appears when a fall in left ventricular (LV) function precedes the fall in either cardiac output or blood pressure. Yet, LV dysfunction is common and detrimental (1). Thus, to continuously monitor LV systolic function and thereby uncover this blind spot, we have developed a method that automatically obtains mitral annular plane systolic excursion (MAPSE) using artificial intelligence and hands-free transesophageal echocardiography (autoMAPSE, Fig. 1) (2).

Objectives. Our objectives were 1) to assess the feasibility of continuous autoMAPSE using hands-free transesophageal echocardiography and 2) to compare autoMAPSE with manual measurements.

Methods. We monitored 50 intensive care patients for two hours immediately after cardiac surgery. We recorded a set of hands-free images every five minutes. Each set comprised 10 heartbeats of midesophageal two-chamber (2C) and four-chamber (4C) views. Next, we used autoMAPSE to obtain MAPSE of four walls and of every heartbeat. Thus, when we finally report MAPSE, we report the average of every heartbeat from a specific wall in a specific set of images. We categorized *monitoring feasibility* as 'excellent' if the same wall for the same patient could be monitored $\geq$ 90% of the time. Likewise, we categorized monitoring feasibility as 'good' and 'poor' when the same wall could be monitored 50–90% and $\leq$ 50% of the time, respectively.

During hemodynamic stability, we recorded three sets of 2C and 4C images in rapid succession; only in these images did we also measure MAPSE manually. As our measurements were not independent, we used a linear mixed model to assess bias and agreement (3). From the same model, we used the residual standard deviations of each measurement method to estimate the precision of that particular method. We report bias and agreement as a modified Bland–Altman analysis with limits of agreement and report precision as the least significant change.

Results. AutoMAPSE had excellent monitoring feasibility in almost all patients (88%), good in three patients (6%) and poor in three patients (6%). Of note, we did not exclude any images due to poor quality.

Compared with manual measurements, autoMAPSE had no significant bias (− 0.2 mm, p = 0.1) and had good agreement (limits of agreement − 3.4 to 2.9 mm, Fig. 2). Even when manually measuring and averaging the MAPSE of 10 heartbeats, manual measurements could not detect smaller changes than autoMAPSE (p = 0.24, Fig. 3). On the other hand, by averaging more measurements, autoMAPSE can easily detect even smaller changes in MAPSE (Fig. 3).

Conclusions. Continuous monitoring of LV function in intensive care had excellent feasibility. When we compared autoMAPSE with manual measurements, autoMAPSE was more precise, had no bias and had good agreement.

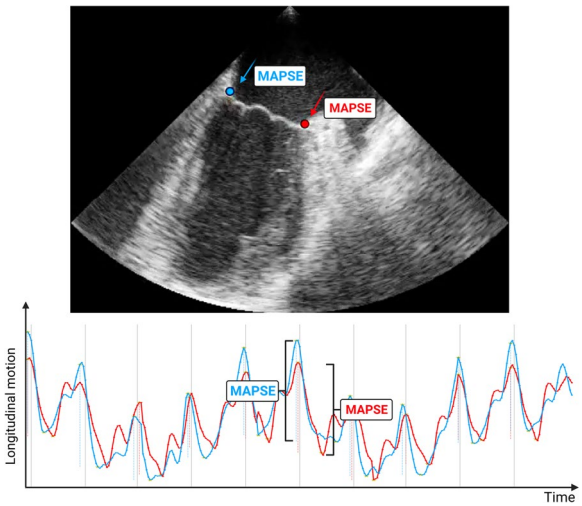

Figure 1 (abstract 000338) Automatic measurement of mitral annular plane systolic excursion (autoMAPSE) on a hands-free image. Top panel: The mitral annulus is detected automatically using artificial intelligence (red and blue dots). Bottom panel: The longitudinal motion of the mitral annulus for 10 heartbeats. For each heartbeat (vertical lines), MAPSE is the distance between the highest and the lowest point. Brackets, demonstrating the MAPSE of one particular heartbeat; MAPSE, mitral annular plane systolic excursion

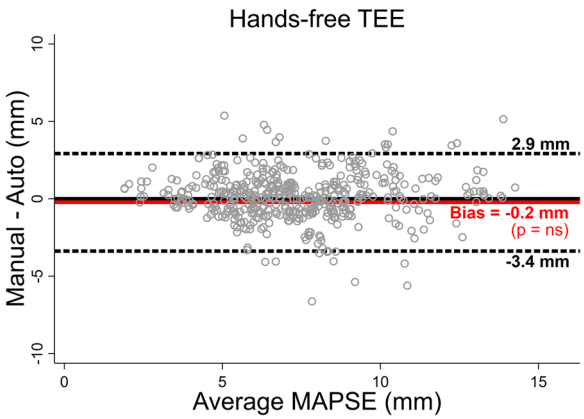

Figure 2 (abstract 000338) Bland–Altman plot of automatic vs. manual measurements on hands-free images. Red line, bias; dashed lines, limits of agreement; MAPSE, mitral annular plane systolic excursion; ns, non-significant; TEE, transesophageal echocardiography

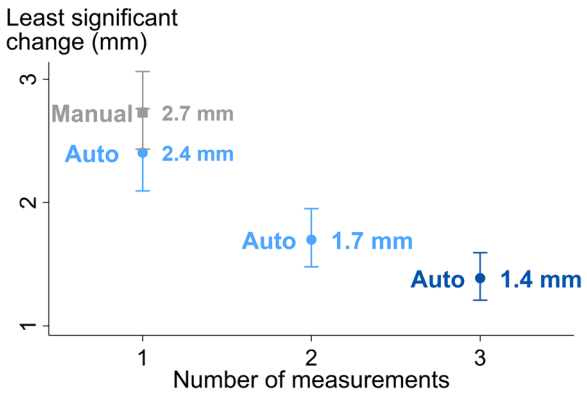

Figure 3 (abstract 000338) Least significant change of automatic vs. manual measurement. Lower least significant change equals better precision. Each measurement is the average mitral annular plane systolic excursion of a recording that consisted of 10 heartbeats

Introduction. Spontaneous breathing in patients with ARDS may have both protective and negative effects, that have been attributed according to the severity of lung injury [1–3].
Objectives. This study aimed at describing the effects of different levels of pressure support on V/Q matching in patients recovering from ARDS, using electrical impedance tomography (EIT).
Methods. We performed a single-centre prospective observational cohort study (EC Palermo I 14/09/22), including adult mechanically ventilated patients admitted to the ICU with a diagnosis of ARDS and reaching clinical stability and pressure support ventilation. Patients with contraindications to the use of EIT, other causes of acute respiratory failure, neuro-muscular disease, or limitation of care were excluded. Patients were evaluated in two different conditions sequentially, using Pulmovista 500 Draeger. The first observation condition was identified within the first 24 h of PSV ventilation, at a clinically selected level of pressure support under stable clinical conditions. This condition was labeled according to P0.1: pressure support level determining a P0.1 < 2, was considered "High", and the one determining a P0.1 > 2 was considered "Low". After data collection at a clinically selected level of pressure support, the pressure support level was transiently increased or decreased (i.e. from "high" to "low"/ from "low" to "high") to the lowest/highest clinically tolerated level, aiming at the predefined P0.1 thresholds, and then kept for 20 min at stable clinical conditions. Data collection was repeated and then the clinically selected level of pressure support was restored. Data collection consisted of 180 s of EIT recording, and the performance of a 3 s inspiratory hold pause during which a 10 ml of 5% hypertonic saline bolus was administered to evaluate lung perfusion [4,5]. Offline analyses on ventilation and perfusion distribution were conducted using Pulmovista 500 Draeger dedicated software. Data on arterial blood gas analysis and ventilatory parameters were also recorded. No changes in analgo-sedation were performed during the observations. The primary outcome was V/Q matching at the two different conditions. Statistical analysis was conducted using descriptive statistics, Wilcoxon signed-rank test, and Pearson correlation. Data are presented as median [IQR] or percentages. Clinicaltrial.gov:NCT05781802.
Results. We present preliminary data on 5 patients, undergoing PSV ventilation after a median of 48 h of protective controlled ventilation. The median age was 70 y.o and P/F at ICU admission was 151 [151;155] mmHg. The first PSV observation was conducted at a clinical pressure support, which was "low" in 2 patients and "high" in 3 patients, and then in the other condition. The high ΔPsupport was 15 [12;17] cmH2O, and the low was 5 [5;10] cmH2O. The respiratory rate (14 [10;14] bpm at high support; 14 [14;17] bpm at low support) and pCO2 (40 [37;50] mmHg at high support; 43 [42;49] mmHg at low support) remained stable at the two conditions. Vt/IBW decreased from high to low support (10.3 [9.3;13.7] ml/kg high; 8.4 [7;10.2] ml/kg low). V/Q matching improved from high-pressure support to low-pressure support (50.5% [47.1; 68.8] high; 71.4% [68.6; 72.1] low; Fig. 1), despite not significantly (P = 0.188). Interestingly, the difference in V/Q matching showed a trend of correlation with the difference in pressure support level (ρ = 0.866; P = 0.058; Fig. 2).

	High PSV	Low PSV	P value
P/F, mmHg	220 [220;260]	224 [214;258]	0.881
ΔPsupport, cmH2O	15 [12;17]	5 [5;10]	0.003
PEEP, cmH2O	12 [10;12]	12 [10;12]	-
Respiratory rate, bpm	14 [10;14]	14 [14;17]	0.111
Pdriving, cmH2O	13 [10;14]	11.5 [9;16]	0.904
Vt/IBW, ml/kg	10.3 [9.3;13.7]	8.4 [7;10.2]	0.006
P0.1, mbar	1.5 [1.1;1.6]	3.1 [2.7;3.1]	< 0.001
PMI, cmH2O	-2 [-6;-2]	6 [4;6]	0.004
ΔPocc, cmH2O	-8 [-9.8;-6]	-15.8 [-16;-13]	0.004
V/Q Matching, %	50.5 [47.1; 68.8]	71.4 [68.6; 72.1]	0.149

Conclusions. Preliminary data show a trend towards improved V/Q matching using low pressure support. Data from a larger cohort of patients are needed to adequately test this hypothesis.

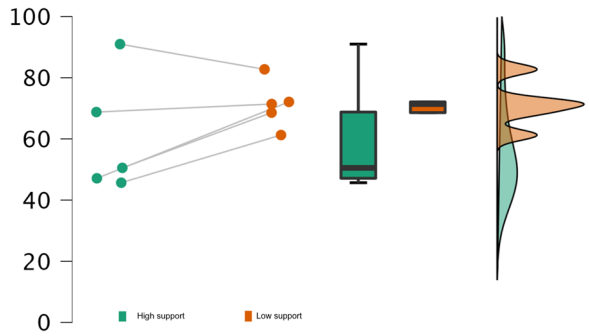

Figure 1 (abstract 000339) Raincloud plot showing V/Q matching at the two observation conditions

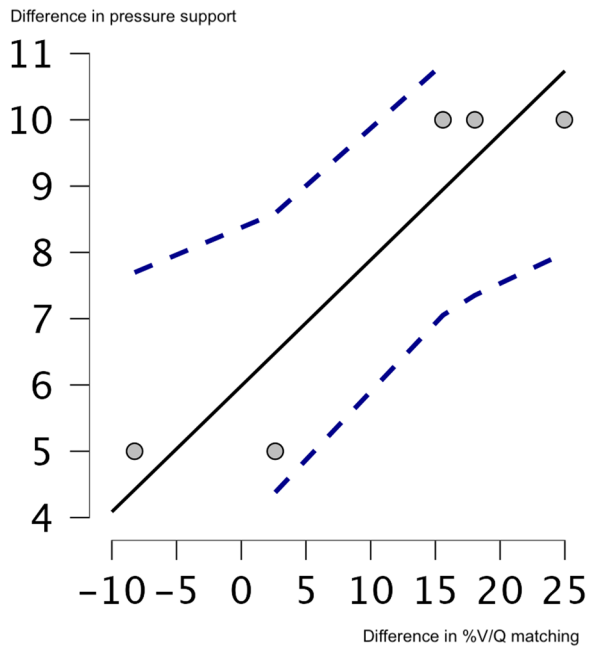

Figure 2 (abstract 000339) Correlation plot between difference in V/Q matching and difference in pressure support at the two observation conditions

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000341

Introduction. Chest trauma is a significant cause of morbidity and mortality, especially among the young. A significant proportion of patients with severe chest trauma require mechanical ventilation (MV). Early prediction of the duration of MV may influence clinical decisions and interventions.
Objectives. We aimed to determine early risk factors for prolonged MV among adults suffering from severe blunt thoracic trauma.
Methods. This was a retrospective, single-center, cohort study of all patients admitted between January 2014 and December 2020 due to severe blunt chest trauma, which was defined as a chest abbreviated injury score ≥ 3. The primary outcome was prolonged MV defined as invasive MV lasting more than 14 days. Multivariable logistic regression was performed to determine independent risk factors for prolonged respiratory support.
Results. The final analysis included 378 patients (Fig. 1). The median duration of MV was 9.7 (IQR 3.0–18.0) days. 221 (58.5%) patients required MV for more than seven days and 143 (37.8%) for more than 14 days. In the entire cohort, male gender (aOR 2.55, 95% CI 1.41–4.58, $p=0.02$), age (aOR 1.43, 95% CI 1.24–1.66, $p<0.001$), and the presence of severe head trauma (aOR 3.37 95% CI 2.03–5.58, $p<0.001$) were independently associated with prolonged MV. The number of fractured ribs and the extent of lung contusion were associated with MV lasting for seven, but not 14 days. The probability of prolonged MV (> 14 days) by age and presence of concomitant severe head injury, is presented in Fig. 2. In the subgroup of 134 patients without concomitant head trauma, age (aOR 2.08, 95% CI 1.50–2.89, $p<0.001$), presence of abdominal trauma (aOR 3.33, 95% CI 1.22–9.12, $p=0.02$), and a spinal injury (aOR 3.83, 95% CI 1.17–12.50, $p=0.03$) were independently associated with MV for more than 14 days. The probability of prolonged MV by age and the presence of concomitant injuries is presented in Fig. 3.
Conclusions. Among patients with severe blunt thoracic injury, older age, male gender, and concomitant severe neurotrauma are independently associated with prolonged MV. Among patients without concomitant head injury, age and abdominal-pelvic and spinal injuries were associated with prolonged MV. Patients fulfilling these criteria are at high for prolonged MV and should be considered for interventions potentially shortening MV duration and its complications. Young patients suffering from isolated severe thoracic trauma, including those with extensive lung contusions and ribs fractures, have a benign course and a low risk of prolonged MV.

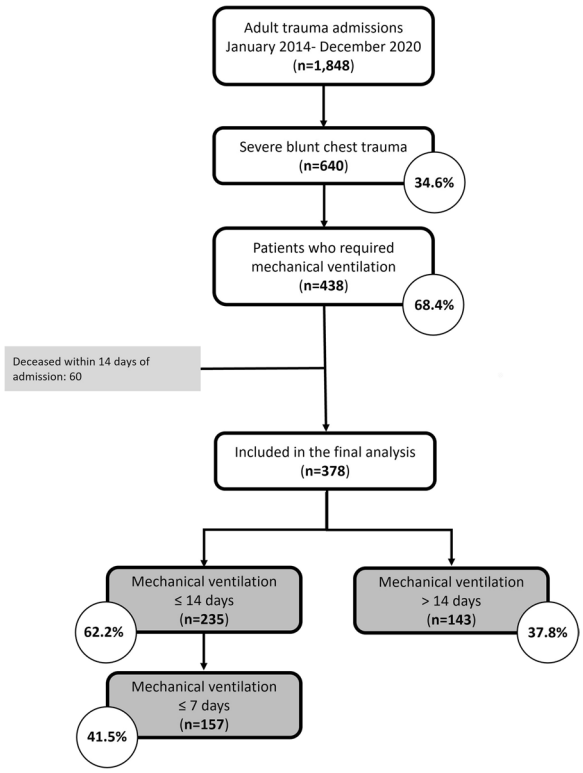

Figure 1 (abstract 000341) Study flow chart

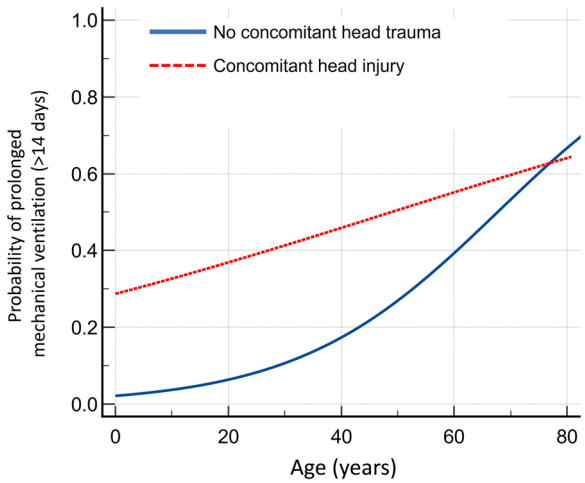

Figure 2 (abstract 000341) Probability of prolonged mechanical ventilation by age and presence of concomitant severe head injury

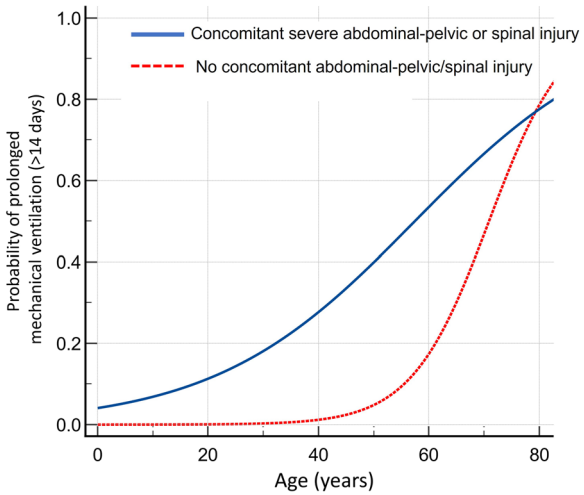

Figure 3 (abstract 000341) Probability of prolonged mechanical ventilation by age and presence of concomitant severe abdominal-pelvic or spinal injury among 134 patients without head injury

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000342

Introduction. Acute respiratory distress syndrome (ARDS) is a common cause of acute hypoxemic respiratory failure that is difficult to recognize. The clinical diagnosis for ARDS may be improved by means of objective biological markers. Exhaled breath contains volatile metabolites that can reflect pulmonary pathophysiological process. Changes of the composition of exhaled metabolic biomarkers have been associated with the diagnosis of different respiratory diseases. Gas chromatography-mass spectrometry (GC–MS) is regarded as a gold standard for volatile organic compounds (VOCs) identification.
Objectives. We aim to develop and validate a diagnostic model for ARDS patients based on exhaled VOCs.
Methods. In this prospective two-center observational study in unselected critically ill patients receiving invasive ventilation, breath metabolites were captured on sorbent material and quantified using GC–MS [Hagens, ATM 2021]. ARDS was diagnosed by three experts using the Berlin definition. All patients were labeled as "certain ARDS", "certain no ARDS" and "uncertain ARDS" ("likely ARDS" or "likely no ARDS") based on the experts' assessment. The patients with "certain" labels from one hospital (Amsterdam UMC, AMC) were used as derivation cohort to train a classifier, the "VOC-ARDS score", which is built based on the five most significant breath metabolites selected by a random forest model. The diagnostic accuracy of the VOC-ARDS score was assessed in all patients in the second hospital (Maastricht University Medical Center, MUMC), and combined with the lung injury prediction score (LIPS).
Results. In total, 499 patients were included in the study. 357 patients were included in the AMC cohort (60 with certain ARDS (*i.e.* derivation cohort); 17%), and 142 patients in the MUMC cohort (47 with certain ARDS (*i.e.* validation cohort); 33%). The metabolites 1-methylpyrrole (Mey), 1,3,5-trifluorobenzene (Tri), methoxyacetic acid (Mea), 2-methylfuran (Fur) and 2-methyl-1-propanol (Mep) were included in the classifier. The VOC-ARDS score had an area under the receiver operating characteristics curve (AUROCC) of 0.71 (CI: 0.63–0.78) in the derivation cohort and 0.63 (CI: 0.52–0.74) in the validation cohort. Combining the breath test with the LIPS increased the AUROCC to 0.75 (CI: 0.68–0.82) and 0.64 (CI: 0.53–0.75) respectively (Fig. 1). When patients who had uncertain labels were also considered, the diagnostic accuracy of VOC-ARDS score decreased, both in AMC (AUROCC of 0.67, CI 0.61–0.73) and MUMC (AUROCC of 0.58, CI 0.48–0.67) cohort.
Conclusions. An exhaled breath metabolomics-based classifier has moderate diagnostic accuracy for ARDS, but is not sufficiently accurate for clinical use, even after combination with LIPS.

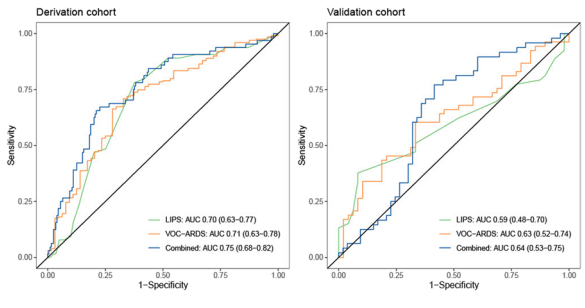

Figure 1 (abstract 000342) Receiver operating characteristics (ROC) curve of the classifier (VOC-ARDS score) and combined the classifier with the lung injury prediction score (LIPS) in the different cohorts. AUC = Area Under Curve

Usefulness of the Cell Index in the diagnosis and therapeutic management of infections related to external ventricular drainage

Introduction. Critically ill patients are characterized by a baseline situation of extreme severity and by the high number of device implantations. That carries risks and complications where infectious complications are those that produce the most serious adverse effects and the highest rates of morbidity and mortality.
Ventriculitis associated with external ventricular drainage (EVD) is a serious complication related to the use of these devices. The importance lies in its difficult diagnosis, interfered on many occasions by the pathology itself that motivated the placement of the EVD.
Some studies propose the calculation of the "Cell Index" (CI), based on the relationship between leukocytes and erythrocytes in CSF and peripheral blood as a diagnosis of ventriculitis.
It is based on the fact that neurocritical patients with intraventricular hemorrhage, since the CSF is contaminated with blood, it is assumed that erythrocytes and leukocytes will be present in the CSF in a proportion similar to that of peripheral blood. Any change in the CSF leukocyte count can be detected by altering this ratio and may be an earlier tool than the usual confirmatory method (microbiological culture).
Studies have shown good results with the increase in CI and the incidence of ventriculitis but it has not been possible to specify an absolute value.
Objectives. To study and compare the Cell Index value between different groups on the day ventriculitis is suspected in neurocritical patients with EVD.
Methods. Retrospective study of a polyvalent ICU where 208 patients were analyzed and, 191 neurocritical patients admitted to the ICU were included between January 2007 and December 2018 with the need for EVD and CSF and blood samples were obtained. Patients < 18 years of age, with active central nervous system (CNS) neoplasia, previous ventriculoperitoneal drainage, CNS infection at the time of EVD placement, without intraventricular hemorrhage or who did not obtain a CSF/blood sample were excluded. They were classified into 2 groups according to whether they presented CDC/NHSN criteria for ventriculitis: ventriculitis group and control group. Different variables are analyzed, such as epidemiological data, evolution variables during the ICU stay and analysis of biological sample variables such as CSF and blood. From the CSF and blood samples extracted for clinical purposes, the CI and glucose ratio CSF/PB (peripheral blood) is calculated in the ventriculitis group the day when ventriculitis clinically manifests, and the result is compared with the control group, in this case the CSF sample analyzed is the closest to the EVD placement.
Results. Of the 198 patients included in the study, 29 (15.2%) evolved to ventriculitis and 162 (84.8%) patients had no suspicion of ventriculitis (control group). Of the patients who developed ventriculitis, 17 (58.6%) were female, with a mean age of 53 years. The reason for admission that predominated in all groups was subarachnoid hemorrhage, with 112 patients in the control group (69.1%) and 24 (82.8%) in the ventriculitis group.
Subjects with ventriculitis had a significantly higher CI value of 5.1 [3–9.5] compared to the control group 0.2 [0–0.8] $p < 0.01$. They also had more proteins in CSF (median ventriculitis group 59,4 [35,1–185,4]

vs 50,3 [23,2–86,9] $p < 0.03$) and low glucose ratio CSF/PB levels (median ventriculitis group 0.2 [0.1–0.4] vs 0.6 [0.5–0.7] group control, $p < 0.01$). The greater number of days of EVD ($p < 0.01$) and the greater number of exchanges ($p < 0.02$) have also been found as risk factors for developing ventriculitis. Other variables such as the lactate value have not obtained statistically significant results. Neither were acute phase reagents found in peripheral blood, such as C-reactive protein (CRP) or leukocytosis. Patients with ventriculitis have higher readmission rates and prolonged hospital stay.

Conclusions. The value of the CI and glucose ratio CSF/PB could be useful for the diagnosis of ventriculitis. The greater number of days of EVD and the greater number of replacements of the same are associated as risk factors for the development of ventriculitis. Further studies are needed to further establish the role of CI for diagnostic and prognostic value.

Pilot study to evaluate the role of molecular markers to predict organ failure in patients with sepsis using "gene set" approach

L. P. Emerson[1]
[1]Department of Critical care, Christian Medical College, Vellore, India
Correspondence: L. P. Emerson
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000344

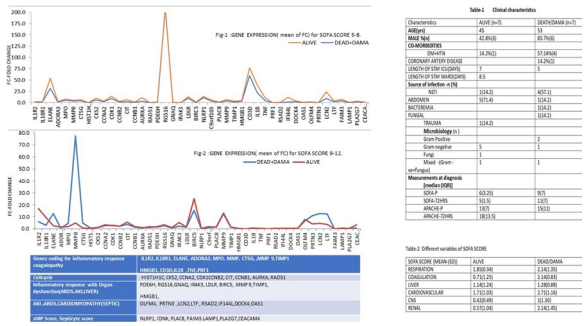
Introduction. Transcriptomic profile of septic patients who progress to organ failure.

Objectives. The aim of this study is to generate predictive models of organ failure from the transcriptomic profile of patients with sepsis at presentation.

Methods. In this study, critically ill patients who met consensus criteria for sepsis were included. we choose 21 patients with proven sepsis and one volunteer with no known comorbidities to provide control values for mRNA expression. Blood samples were collected within 6 h and 72 h and genomic response was evaluated using microarrays. Whole blood samples approximately 10 ml was collected and RNA was extracted from the whole blood using QiAmp blood mini kit (Qiagen). A quantitative PCR for a panel of number 44 genes already implicated in sepsis was performed using a custom R2 PCR array (Qiagen) in our institute using ABI quant gene instrument. The "Gene set" was selected from literature based on the cannonical pathways for predicting organ dysfunction in patients with proven sepsis.The Acute Physiology and Chronic Health Evaluation II (APACHE II) scores on admission and the Sequential Organ Failure Assessment (SOFA) scores on days 1, 3, were calculated. Gene expression profiles of sepsis patients across the two time points, grouped by septic status with a 1.5 to twofold expression of genes with respect to normal was considered as significant.We categorised patients depending on the SOFA score into < 4, 5–8, 9–12, > 13. One patient had SOFA score of 2(survivor), and 2 patients had SOFA score of > 13(non-survivors). Mean of Fold change of the genes were compared between survivors and non survivors in SOFA score of 5–8 and 9–12.

Results. 15 patients were selected, complete data was available for 14 patients. Principal sources of infection were the abdomen (42.85%) and NSTI (35.71%). Trauma, fungal sinusitis and blood infections constituted the rest (7.41% each). Of the septic patients, 78.5% had a confirmed microbial diagnosis. In 14.2% of the cases, the infection was caused by Gram-positive bacteria and 42.8% of the cases were caused by Gram-negative bacteria. Fungal infection was seen in one patient. 14.28% of the patients had a polymicrobial infection. (Table-1) The analysis of individual components of SOFA score revealed that mortality was associated with organ dysfunction in lungs, cardiovascular, renal and coagulation profile (Table-2). Transcriptomic analysis showed significant fold change in sepsis patient compared with the control. This increased expression was noted in Genes encoding for neutrophil-mediated response and innate pro-inflammatory response (ELANE, ADORA3, MPO, MMP8, CTSG and IL-1 and IL- 18) Genes participating in cell cycle viz, HIST1H1C, CKS2, CCNA2, CDK1, CCNB2, CIT, CCNB1, AURKA, RAD51 showed significant increase in fold change which indicates response to severity of sepsis in increasing the cells involved in innate immunity. Mean expression of GENES showed significant fold change between survivors and non-survivors which increased as SOFA score increased. (Fig. 1,2). For diagnosing Abdominal sepsis, a sepsis NLRP1, IDNK, and PLAC8 gene expression score [sNIP score, equation: (NLRP1-IDNK)/PLAC8) was defined with a threshold at -0.12. Abdominal sepsis(perforation) showed a (median = 0.02; IQR = − 0.63) score with other infections (median = 0.41; IQR = 2.19), demonstrating the utility of the score in diagnosing patients. 'SeptiScore' using a 4-gene signature (Septicyte™ LAB) was validated in both survivors and non survivors with an average score of 5 and above.

Conclusions. In this Pilot study "Gene set approach" was used to assess the severity of sepsis and predict the progression of organ dysfunction and improvement.The transcriptomic response of genes encoding for neutrophil-mediated response and innate pro-inflammatory response along with "GENE SET'S" encoding for ARDS and AKI,showed ability to predict organ dysfunction in Lung, Kidney, cardiomyopathy and coagulopathy.Further study is ongoing in standardising the expression of Genes/"SET'S" i.e. the threshold (cut off value) at which organ failure can be predicted and to include this approach along with other biomarkers in routine evaluation of patients Sepsis.



Clinical charecteristics and Transcriptomic profile.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000345

Introduction. In the last 15 years, monitoring of peripheral tissue oxygenation by near-infrared spectroscopy (NIRS) systems has demonstrated prognostic value in different critical pathology scenarios. In addition to the baseline tissue oxygen saturation (StO2) value, informative parameters of the individual's metabolic state and microvascular reactivity (endothelial function) can be obtained from a transient vascular occlusion (TOV) test. However, commercial NIRS systems use continuous wave (CW)-NIRS technology, associated to much variability and unreliability in obtaining actual oxy- and deoxy-hemoglobin values. The VASCOVID project is a European framework project, financed by Horizon2020 funds from the European Commission, and born from the association of different academic, research, clinical and industry actors, to develop a new, more robust and reliable NIRS system for application in the critical care setting. The VASCOVID project is based on time resolved (TR)-NIRS technology, with improved performance in the quantification of hemoglobin oxygenation, and incorporates Diffuse Correlation Spectroscopy (DCS), which allows to obtain values of hemoglobin movement in the tissue, deriving microvascular flow [1].
The first clinical work of VASCOVID has been aimed at characterizing the microcirculatory state with the new technology in healthy population and patients admitted to the ICU.
Methods. Prospective observational study in a 30-bed general ICU. The microcirculatory status was analyzed using the VASCOVID system, placed on the brachioradialis muscle, in healthy population and in critical, septic and non-septic patients, during the first days of admission. A baseline measurement of StO2 and blood flow index (BFi) was performed, followed by TOV, from which local metabolism (nirVO2), reoxygenation rate (ReO2), and hyperemia in oxygenation (AUCH) and flow (AUCBFi) in response to ischemia were derived. A comparative analysis was performed with t-Student test for independent samples of the populations studied.
Results. A total of 20 healthy individuals and 60 critically ill patients, 13 septic and 47 non-septic, were included. The critical patient population presented significant alterations with respect to the healthy population in all microcirculatory parameters with the exception of microvascular flow (Fig. 1). When the septic population and the non-septic critically ill patient population were compared, significant differences were found in basal microvascular flow (septic BFi 0.32 ± 0.18 cm^2/sec vs non-septic 0.46 ± 0.37 cm^2/sec) and metabolic rate (septic nirVO2 -12.2 ± 10.7 U vs non-septic -19.1 ± 11.3 U).
Conclusions. The VASCOVID project aims to validate TR-NIRS/DCS technology as an evolution of traditional CW-NIRS systems, incorporating the possibility of quantifying microcirculatory flow at the bedside. Preliminary results of the project show that the system can detect differences between healthy and impaired microcirculation, as well as detect alterations specific to septic patients. This new technology may be a useful tool for the assessment of the microcirculatory status of the critically ill patient.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000346

Introduction. There have been many studies evaluating different strategies for ventilator-associated pneumonia (VAP) prevention, including single interventions and devices, bundles and protocols. However, other institutional risk factors that could be associated with the risk of VAP have not been deeply explored, especially in low and middle-income countries.
Objectives. To evaluate institutional risk factors (from the perspective of ICU staffing and protocols and infection control services) for ventilator-associated pneumonia (VAP) in a middle-income country.
Methods. This observational prospective cohort study was nested on the IMPACTO-MR platform, which comprised 51 centers in Brazil, from September 2019 to December 2021. Individual patients' data was prospectively collected and institutional data was collected with surveys. VAP diagnosis was prospectively reported by each center. We fit Cox models with institutional risk factors modelled as fixed effects accounting for patients' confounding variables at baseline. We explored two sets of institutional risk factors: ICU staffing patterns and protocols and infection control services protocols. For ICU staffing, we included an interaction term to allow for their possible dependencies. Results are presented as hazard ratios (HR) with respective 95% confidence intervals (95%CI).
Results. Of 17,027 patients at risk, 1958 patients (with 198,980 patient-days) were diagnosed with VAP. 43 (84.3%) hospitals had a VAP prevention protocol and 27 (52.9%) had a mechanical ventilator weaning protocol. Staff and infection control services factors associated with a lower risk of VAP were respiratory therapists empowerment to wean invasive mechanical ventilation (HR 0.43, 95%CI 0.37–0.50, $p < 0.001$), annual or semiannual hand hygiene training (both $p < 0.001$ compared to never training), single use protective gowns (HR 0.78, 95%CI 0.69–0.87, $p < 0.001$), personal protective equipment use training (HR 0.68, 95%CI 0.59–0.78, $p < 0.001$) and a VAP prevention protocol (HR 0.21, 95%CI 0.16–0.28, $p < 0.001$). Risk factors for VAP were a higher number of patients per physician (HR 1.20, 95%CI 1.11–1.30, $p < 0.001$), a higher number of patients per bedside-health professional team (nurses and respiratory therapists) member (HR 6.91, 95% 3.85–12.40, $p < 0.001$), which negatively interacted (HR 0.76, 95%CI 0.70–0.83, $p < 0.001$), and a higher proportion of single-bed rooms in ICU (HR 1.50, 95%CI 1.26–1.77, $p < 0.001$). Family visitation duration (hours) was not associated with higher risk of VAP.
Conclusions. VAP prevention may be better accomplished if institutional processes and structure are considered. Avoiding a high number of patients per physician and bedside-health professionals, along with empowering the team towards faster weaning may reduce the risk of VAP. Infection control services could further reduce the risk of VAP by routine institutional training.

Comparing lung mechanics of patients with COVID related respiratory distress syndrome versus non-COVID acute respiratory distress syndrome: a retrospective observational study

F. Chacón Lozsán[1], P. Tamasi[1]
[1]Anesthesia and Intensive Care Unit., Péeterfy Sándor Hospital, Budapest, Hungary
Correspondence: F. Chacón Lozsán
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000347

Introduction. Most patients admitted to the intensive care unit with coronavirus disease (COVID-19) develop severe respiratory failure. Understanding lung mechanics helps to guide protective mechanical ventilation, improve oxygenation, and reduce the ventilator induce lung injury.
Objectives. This study aims to describe lung mechanics characteristics of patients with COVID -19 related acute respiratory distress syndrome (CARDS) and to compare them with non-COVID-19 associated ARDS.
Methods. We performed a retrospective observational study of lung mechanics: plateau pressure (Pplat), Driving pressure (DP), Mechanical power (MPw), Elastic (dynamic) power (EdPw), Total ventilatory power (TPw), and oxygenation parameters (ratio of arterial oxygen partial pressure to fractional inspired oxygen (PaO2/FiO2), the ratio of arterial oxygen partial pressure to fractional inspired oxygen multiplied by PEEP [PaO2/(FiO2 x PEEP)], arterial and venous carbon dioxide partial pressure (PaCO2, PvCO2), and Ventilation dead space (VD) were measured and compared between the two groups after initiation of mechanical ventilation.
Results. 30 CARDS and 10 ARDS patients fulfilled the study requirements. We observed a significant higher MPw in the CARDS group (29.17 ± 8.29 J/min vs 15.78 ± 4.45 J/min, P 0.007), similarly observed with EdPw (256.7 ± 84.06 mJ/min vs 138.1 ± 39.15 mJ/min, P 0.01) and TPw (289.1 ± 84.51 mJ/min vs 161.5 ± 45.51, P 0.007). Inside the CARDS group, we found 2 subgroups, a low shunt subgroup and a higher shunt (Qs/Qt (%): 6.61 ± 2.46 for vs 40.3 ± 20.6, P 0.0009), however,

between these two subgroups we didn't find statistical differences on lung mechanic parameters but only in oxygenation parameters (PaO2/FiO2 and PaO2/FiO2*PEEP). When comparing these two subgroups with ARDS patients, we found more similarity between the low shunt CARDS and the ARDS patients on MP (R2 0.99, P 0.001), EdPw (R2 0.89, P 0.05) and TPw (R2 0.99, P 0.0009).

Conclusions. Our study suggests important differences between CARDS and ARDS regarding mechanical parameters that could lead to more complicated management of CARDS patients and a higher prevalence of VILI. However due to the study limitations, a bigger study is necessary to corroborate our findings.

Topic: Acute respiratory failure and mechanical ventilation.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000348

Introduction. Second-level therapeutic actions to control intracranial hypertension (ICH) proposed by the European Brain Trauma Foundation include barbiturates, moderate hypothermia, and decompressive craniectomy (DC), but the results are controversial. Our aim was to evaluate factors associated with disability and mortality after ICU discharge in patients undergoing DC.

Objectives. To evaluate factors associated with disability and mortality, after ICU discharge, in patients with DC after 9 years.

Methods. Prospective study of patients admitted between January 1, 2013 and December 1, 2022 who required DC. The DC was performed for ICH refractory to medical treatment.The following were analyzed: main admission diagnosis; demographic data;neurological data (clinical examination and Glasgow Coma Score: GCS); hypotension;type of craniectomy and DC complications; Rankin scale and Glasgow Outcome Scale (GOS) at 30 and 60 days after ICU admission, at ICU discharge and 6 months after ICU discharge; preoperative serum lactate levels; hypo- and hyperglycemia;application of mannitol or hypertonic saline before and after DC; leukocytes andplatelets before and after DC and other factors related to prognosis. Univariate analysis was performed for disability (Rankin ≥ 3) and ICU mortality, 60 days after ICU admission and 6 months after ICU discharge. Statistical significance was set at $p \leq 0.05$. Data were analyzed using the R package version 4.2.1 (R Development Core Team, 2022).

Results. Fifty-five patients with DC were collected. Demographic data and types of admission are shown in Table 1. The majority of the DC were subarachnoid hemorrhage (SAH) 26 (47.3%), and traumatic brain injury (TBI) 20 (37.0%). The most frequent complications were hydrocephalus 22 (40.7%) and reoperation for complications 18 (34.6% % of them). Ten patients died at ICU discharge (18.5%), 7 (41.2%) of them due to SAH. Of the 20 (37.0%) patients with TBI 6 (35.3%) patients with DC died, 3 of them at ICU discharge. Rankin score at ICU discharge was 5 and GOS was 3. Rankin score 6 months after ICU discharge was 4 and GOS was 3.No significant risk factors associated with disability after ICU discharge were found. Mortality at 6 months after discharge was significantly associated with bilateral pupillary reactivity prior to DC (Table 2).

Conclusions. DC patients had a low mortality rate in the ICU (18.5%). The DC patients with TBI also had a low mortality rate of 15% at ICU discharge. Rankin and GOS reflected moderate/severe disability in these patients, in the ICU and 6 months after ICU discharge. Mortality, 6 months after discharge, was significantly associated with bilateral pupillary reactivity before DC.

Table 1 (abstract 000348) Univariate analysis of DC disability at ICU dischage 9 years

	Rankin at ICU discharge		
	< 3 N = 10	≥ 3 N = 45

Introduction. Unplanned return to the intensive care units (ICUs) is an important quality indicator for the care continuum across critical care and general care settings. Detection and timely management of physiologic deterioration in patients transferred to the general wards from the ICUs might be of prognostic importance.
Objectives. To investigate whether the detection and alerts of vital signs deterioration and the notifications to the rapid response system (RRS) of physiologic abnormalities are of prognostic importance in patients who returned to the ICUs.
Methods. We retrospectively analyzed the demographic and clinical data of the patients who returned to the ICUs within 7 days of stay of their transfer to the general wards in 2019–2021. The hospital established a healthcare information system (HIS)-based automated alert system for vital sign abnormalities by immediate screening after the nurses' entry of vital sign data. The nurses were provided with decision support pop-ups to notify the rapid response system of the hospital for timely patient management. Relevant information regarding the occurrence of vital sign alerts automatically generated by the hospital's healthcare information system and the notifications to the hospital's rapid response system were retrieved and analyzed for association with the outcomes of those patients in the hospital. The restrictive cubic spline method was applied to assess the probability of the non-linear relationship between the variables and the in-hospital mortality rate.
Results. During the study period, 474 patients returned to the ICU within 7 days at wards, of whom 59.7% were male, 53.6% were from medical ICUs, and 27.4% and 25.5% had the main diagnosis of cardiovascular diseases and malignancies, respectively. Their medium stay at the general ward was 3.1 [Interquartile, 1.3–4.9] days, and their medium hospital stay after the returned ICU was 25.2 [11.6–48.6] days. Male (13.8% vs. 7.3%, $p = 0.029$) and medical patients ($p < 0.001$) had poorer in-hospital outcomes (in-hospital mortality). Patients with early (< 72 h) returns ($p = 0.014$) and early occurrence of vital sign alerts ($p = 0.011$) had higher mortality rates. Restrictive cubic spline analyses for a non-linear relationship showed that the in-hospital mortality rate was the lowest for those patients with the interval between transfer to the general ward and first vital sign alert. An interval shorter than 48 or longer than 72 h indicated a trend of increased risk of in-hospital mortality, with a U-shaped relationship (Fig. 1). In contrast, the relationship between general ward stay time, and mortality remained more linear, with a gradually reduced mortality rate when the ward stays time was longer (Fig. 2).
Conclusions. The detection and alerts of vital sign abnormalities after the transfer to the generl wards of ICU patients are associated with in-hospital morality by a non-linear relationship.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000350

Introduction. Positive fluid balance is correlated with worse outcomes in pediatric acute respiratory distress syndrome (PARDS). However, there are scarce data on particularly 'when' in the illness time-course significantly affects prognosis. We aimed to determine the trend of daily and cumulative fluid management practices and the relationship between the timing of fluid overload and clinical outcomes in PARDS.
Methods. The study included 320 children who required invasive mechanical ventilation and were diagnosed with PARDS according to the oxygenation index of Pediatric Acute Lung Injury Consensus

Conference definition from June 2009 to March 2021. Daily and cumulative total intake, output, and balance data were retrospectively collected from days 1 to 7 after PARDS onset. Association between fluid metrics and clinical outcomes of PARDS were tested.
Results. Daily and cumulative total intake show a decrease over time during the study period. In multivariable analysis, fluid intake on day 6 and 7 was significantly associated with increased mortality (OR [95% CI]; 1.019 [1.006–1.031]. P = 0.003, and 1.022 [1.009–1.035], P = 0.001, respectively). The fluid intake on day 1 was significantly associated with decreased ventilator-free days (VFDs) (β = − 0.030, P = 0.002). Cumulative fluid balance in the early period (through day 4 and day 3, respectively) was significantly associated with risk of increased mortality (OR [95% CI]; 1.007 [1.002–1.012], P = 0.005) and decreased VFDs (β = − 0.026, P = 0.002).
Conclusions. Positive fluid balance in the acute phase is associated with risk of increased mortality and decreased VFDs in PARDS. Moreover, increased fluid intake itself is significantly associated with adverse outcomes in PARDS.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000352

Introduction. The gray-white matter ratio (GWR) obtained from brain CT scans is a crucial factor in the early prediction of cardiac arrest patient outcomes. However, manual annotation by physicians is impractical in emergency and critical care situations.
Objectives. To devolop an automatic method which can rapidly compute the GWR and predict outcomes, aiding physicians in decision making.
Methods. A retrospective study of 684 patients who underwent brain CT imaging within 12 h after return of spontaneous circulation (ROSC) was conducted. The primary outcomes were favorable neurological outcome and survival to hospital discharge. Physicians manually annotated 16 regions of interest (ROIs) on each CT image. In addition, an automatic method derived the ROIs by registering the brain CT image to the Eve template. The performance of the automatic method was compared with that of manual annotation to evaluate its accuracy.
Results. After removing outliers, we examined the data from 525 CT scans of the brain as shown in Fig. 1. The proposed method for calculating the GWR yielded better results for patients with the favorable neurological outcome (1.140 [SD 0.046] vs. 1.100 [0.054], $p < 0.0001$), and Fig. 2 showed a strong correlation with manual calculation (0.872 [95% CI 0.849 to 0.891], $p < 0.0001$). Additionally, compared with the manual method (0.679), the proposed method gave a higher AUROC (0.729) for outcome prediction as shown in Fig. 3(A). The automatic method was a significant indepent predictor for favorable neurological outcome in multiple logistic regression analysis ($P < 0.001$) with a high AUROC (0.841) for the modle (Fig. 3B).
Conclusions. The study revealed that the incorporation of the automatically computed GWR led to a significant enhancement in the prediction of favorable neurological outcomes. These findings suggest that the proposed method could efficiently and accurately determine the GWR, providing valuable information for predicting patient outcomes.

The relationship between level of Piezo2 in BALF and prognosis of ARDS patients

H. Xiong[1], G. Jun[1], X. Yu[2], H. Xiangjun[1], P. Feng[1], W. Bo[1]
[1]intensive care unit, West China Hospital, Sichuan University, Cheng Du Shi, China; [2]School of nursing, Qingdao University Medical College, Qing Dao Shi, China

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000353

Introduction. Mechanosensing and mechanotransduction are important processes that regulate pulmonary motility. Piezo2, as a mechanosensitive ion channel, was reported to be involved in the regulation of respiratory function in mice. However, it is unclear whether Piezo2 expression plays a role in disease progression in pulmonary dysfunction patients (such as ARDS patients).
Objectives. The aim of this study was to compare the expression of Piezo2 in the bronchoalveolar lavage fluid (BALF) of ARDS patients and the association between Piezo2 and the prognosis of ARDS patients.
Methods. This study was approved by the Biomedical Ethics Review Committee of West China Hospital of Sichuan University. Patients diagnosed with ARDS from May 2022 to December 2022 in the Department of Critical Care Medicine, West China Hospital, Sichuan University were prospectively included. Then BALF was collected from every patient. The BALF was centrifuged and the supernatant was taken for ELISA analysis. Basic information of the patients was recorded through the electronic medical record information system.
Results. We finally included 80 patients in this study. Compared with mild ARDS group, the level of piezo2 in BALF was significantly higher in moderate ARDS group (54.11 ± 8.113, 95%CI 37.75–70.48, $P < 0.0001$) and severe ARDS group (84.10 ± 15.44, 95%CI 53–115.2, $P < 0.0001$). To assess the Piezo2 value in predicting the development of ARDS patients, we graphed the ROC curve. It is revealed that Piezo2 in BALF could distinguish ARDS patients of different severity with areas under the curve (AUC) 0.9358 (95%CI 0.8667–1.00, $P < 0.0001$). Patients with higher level of Piezo2 had higher APACHE II score (16 ± 6.517 vs 24.4 ± 6.845, 95%CI 4.983–11.81, $P < 0.0001$), longer length of ICU stays

(16.71 ± 9.717 vs 28.21 ± 13.78, 95%CI 4.84–18.15, $P = 0.001$). There was no significant difference in mortality with two groups (OR 1.42, 95%CI 0.43–4.66, $P = 0.57$).

Conclusions. Higher level of Piezo2 was correlated to worse progression of ARDS patients.

Delirium and Subsyndromal delirium in the step-down unit in Japan; Incidence, risk factors and outcomes

T. Kamo[1]
[1]Critical Care Medicine, Tokyo Metropolitan Bokutoh Hospital, Sumida City, Japan
Correspondence: T. Kamo
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000354

Introduction. ICU acquired delirium is a spectrum of illnesses associated with prolonged ventilator use and increased mortality. Subsyndromal delirium (SSD) is considered a pre-delirium state and has received recent attention in terms of early prevention. There have been many studies of delirium in ICUs and SSD, but few studies in step down unit (SDU) and none in Asian populations.

Objectives. To investigate the incidence of delirium, SSD or both in the SDU, as well as their respective risk factors and clinical outcomes.

Methods. Medical records of patients admitted to an SDU in a tertiary care facility between April 1, 2021 and March 31, 2022, and whose length of stay was at least 4 days, were retrospectively reviewed from an electronic database. The Intensive Care Delirium Screening Checklist (ICDSC) was used for the diagnosis of delirium and SSD. The following data were recorded: patient characteristics, severity score (SOFA), reason for admission, duration of admission, time to discharge, Barthel index at discharge, and antipsychotic medications used.

Results. A total of 470 patients were screened and 326 were finally analyzed. Of these, 73 and 86 had SSD and delirium, respectively, and 65 had both. Age 70 or older and a SOFA score of at least 2 points were independent risk factors for each (SSD; Age > 70 OR 2.97, 95%CI:1.49–5.91, SOFA > 2 OR 2.54, 95% CI:1.27–5.60: Delirium; Age > 70 2.84, 95% CI 1.35–6.0, SOFA > 2 OR 2.39 95%CI 1.12–5.10).

As for in-hospital deaths, there was only one death in the SSD group (1.3%), whereas there were seven deaths in the delirium group (8.1%), a significant difference.

The length of hospital stay was longer for each group compared with patients who did not develop psychiatric symptoms, but only in the delirium group. With regard to the duration of SDU admission, the SSD and Ddelirium groups were significantly longer than the group that did not develop psychiatric symptoms.

Conclusions. Elderly individual and higher SOFA score were independent risk factors to develop SSD and delirium, with longer days to discharge and higher mortality in the delirium group. SSD has a lower mortality rate, but may result in longer hospital stays and requires early and appropriate action.

Topic: Sedation, analgesia and delirium.

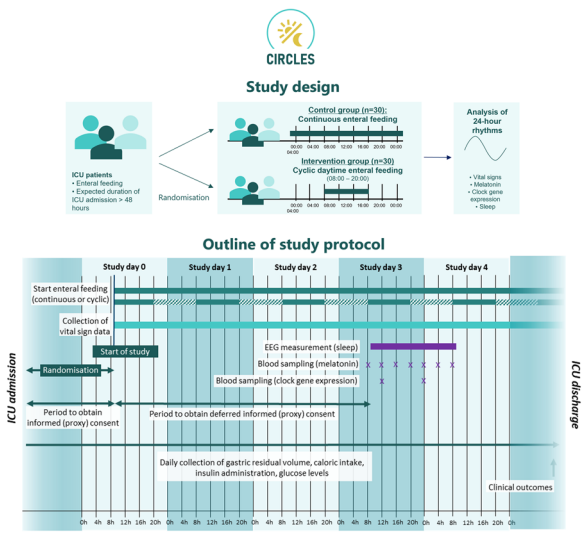
Circadian rhythms in critically ill patients during continuous versus daytime enteral nutrition: protocol for a randomized controlled trial

F. W. Hiemstra[1], E. de Jonge[2], J. Meijer[3], D. J. Van Westerloo[2], L. Kervezee[3]
[1]Department of Intensive Care & Department of Neurophysiology, Leiden University Medical Center, Leiden, Netherlands; [2]Department of Intensive Care, Leiden University Medical Center, Leiden, Netherlands; [3]Department of Neurophysiology, Leiden University Medical Center, Leiden, Netherlands
Correspondence: F.W. Hiemstra
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000358

Introduction. Critically ill patients in the intensive care unit (ICU) commonly experience severe disruptions in their circadian rhythms, which have been associated with unfavorable clinical outcomes [Knauert et al. (2023), Felten et al. (2023)]. The administration of enteral nutrition, typically provided around the clock, may be a contributing factor to this disruption. Evidence suggests that rhythmic feeding-fasting cycles may provide a powerful synchronizing cue for the circadian

clock, indicating that optimizing feeding-fasting cycles in the ICU could potentially enhance circadian rhythms.
Objectives. The aim of the CIRCLES study is to investigate the effect of cyclic daytime enteral nutrition compared to continuous enteral nutrition on circadian rhythms in critical illness.
Methods. The CIRCLES study is an investigator-initiated randomized controlled trial and is conducted in a tertiary care ICU in the Netherlands. Critically ill patients aged 18 years or older with an expected ICU stay ≥ 48 h who are receiving or intended to receive enteral nutrition are eligible for inclusion. A total of 60 patients will be included in the study and randomized to either the *continuous enteral nutrition* (control) group or the *cyclic daytime enteral nutrition* (intervention). In the *continuous enteral nutrition* group, nutrition will be administered 24 h a day, according to the local standard of care protocol. In the *cyclic daytime enteral nutrition* group, administration of nutrition will be restricted to a 12-h period during daytime hours (between 8 AM and 8 PM). In both groups, similar daily nutrition goals are pursued. The study intervention will be followed until the enteral nutrition is stopped or discharge from the ICU. On the third day after the initiation of enteral nutrition, seven 4-hourly blood samples will be collected. These samples will be used to determine the plasma melatonin levels and expression levels of peripheral clock genes (blood monocytes. Additionally, a 24-h electroencephalography recording will be conducted on the same day, using a headband sleep wearable (ZMax Lite, Hypnodyne Corp., Sofia, Bulgaria), from which depth of sleep will be assessed using spectral analysis. High-resolution waveform and numerical data are captured from the patient monitor (Philips IntelliVue, Philips, Eindhoven, The Netherlands) throughout the whole study period to obtain vital sign time series (core body temperature, heart rate variability, heart rate, blood pressure). 24-h rhythms in vital signs are assessed using cosinor analysis. Additional data will be collected from the electronic patient record. Primary outcomes are amplitude of 24-h rhythms in melatonin and vital signs. Secondary outcomes include peripheral clock gene expression, sleep quality, glucose regulation, insulin administration, caloric intake, feeding intolerance and clinically relevant outcome measures.
Results. The study was approved by the Dutch national ethical review board in December 2022 and is registered at ClinicalTrials.gov in April 2023 (identifier NCT05795881). Inclusion of patients is planned to start in May 2023.
Conclusions. Increasing evidence shows that misalignment of circadian rhythms in ICU patients are linked to poor clinical outcomes. Next, it is well-known that the timing of nutrition is a crucial circadian timing cue, suggesting that cyclic daytime feeding may be more optimal than a continuous feeding schedule. However, to date, to what extent the timing of enteral nutrition influences circadian rhythms in critically ill patients is unknown. The current study aims to shed light on strategies for enhancing circadian rhythms in the ICU setting.



Study design and outline of study protocol of CIRCLES trial. ICU = intensive care unit, EEG = electro-encephalography.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000360

Introduction. At a given lung strain, a proportion of static greater than dynamic components demonstrated its potential benefit in terms of protective effect on lung edema in healthy animal research (1). However, this hypothesis has not been tested in humans, especially ARDS. Therefore, from a different point of view, we hypothesized that excessive static components might be harmful. In addition, a suitable proportion of dynamic and static components of lung strain could be obtained in terms of lung protective ventilation.
Objectives. Our study aimed to identify the relationship between the proportion of dynamic and static component of lung strain with lung stress and percentage of overdistension area, and the suitable proportion to protect the ARDS lungs.
Methods. We conducted this study in adult ARDS patients. Those patients received mechanical ventilation and recruitment maneuver followed by decremental PEEP titration. The esophageal balloon catheter was inserted to calculate elastance-derived lung stress (DPtp_ed). The dynamic and static components of lung strain, including overdistension (%OD) and collapse (%Col), were assessed by electrical impedance tomography (EIT). All data were recorded during each PEEP step.
Results. Data from 105 events were analyzed. The most common cause of ARDS in our study was pneumonia. The mean PaO2/FiO2 was 103.6 ± 32.01 mm Hg. The increased proportion of static components was significantly associated with that of DPtp_ed ($P < 0.001$) and %OD ($P < 0.001$). The higher proportion of the static component was significantly related to the decrease in %Col ($P < 0.001$). We divided all events into eight groups regarding a similar value of DPtp_ed. The ratio of dynamic to static lung strain showed a significant inverse correlation to the %OD in 5 of 8 groups with Spearman's rho of − 0.896 ($P = 0.003$), − 0.929 ($P = 0.003$), − 0.807 ($P = 0.015$), − 0.944 ($P < 0.001$), and − 0.833 ($P = 0.005$). The overall relationship (8 groups) also showed a significant correlation (Spearman's rho of -0.852, $P < 0.001$). The suitable dynamic to static lung strain ratio regarding DPtp_ed, %OD, and %Col was 1.007, 0.861, and 0.908, respectively.
Conclusions. The proportion of static greater than the dynamic component of lung strain was not associated with lung protection in ARDS. The excessive contribution of static components was related to the risk

of overdistension, including in groups with lung stress equivalence. Regarding lung protection, the static component should approximate the dynamic component.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000361

Introduction. Despite advances in the diagnosis and treatment of severe infectious processes, the morbidity and mortality of severe community-acquired pneumonia remains high. In the United States, an estimated 500,000 adults are admitted each year for community-acquired pneumonia (CAP), 10–20% of whom will require admission to an Intensive Care Unit. 1–2.

Despite the existence of many tools to predict which patients would benefit from early admission to the ICU3-4, it has been shown that there is still a delay in the admission of these patients to the ICU and consequently higher mortality. 5–8.

Direct admission of these patients to the ICU is conditioned by the need for vasoactive support when admitted for septic shock and those patients requiring orotracheal intubation (OTI) and connection to non-invasive and invasive mechanical ventilation (NIV and IMV), but there is a group of patients who are not admitted directly to the ICU, who are initially admitted to hospital wards or receive more prolonged management in the ED and whose delayed admission to the ICU entails a higher rate of complications and mortality. 6,8,9

Objectives. The primary objective of the study was to determine whether delayed admission to the ICU of patients suffering from severe community-acquired pneumonia leads to higher 30-day mortality compared to patients admitted directly to the ICU.

Secondary objectives included determining whether there is a higher rate of associated complications during admission (need for RRT, mechanical ventilation, tracheostomy, use of vasopressors, infectious complications) in patients with delayed ICU admission.

Methods. Retrospective cohort study of patients admitted to the ICU of a third level reference hospital with a diagnosis of severe community-acquired pneumonia.

Patients admitted between January 2018 and December 2021 with a diagnosis of severe community-acquired pneumonia (CAP) were included. Patients admitted with a non-intubation order and with a diagnosis of SARS-CoV-2 Pneumonia were excluded.

Data were obtained on demographic variables (age, sex), history of illness prior to admission, date and time of admission to ICU and hospital, place of origin (emergency department or ward), laboratory and microbiology data, as well as the use of antibiotics and the time of initiation of their administration. For data analysis, patients were assigned to two groups, differentiating two admission times (< 6 h and < 24 h after arrival in the ED). The rate of complications during admission was also analyzed in both groups.

Statistical analysis was performed with Stata for Mac, version 14.2. Continuous variables with normal distribution were expressed as mean ± standard deviation, or median with interquartile range (IQR) when the distribution was not normal; and qualitative variables were expressed as numbers and percentages. Qualitative variables were analyzed using the Chi2 test (or Fisher's exact test depending on the number of cases). Quantitative variables were evaluated using the t test (or a nonparametric test according to the normality of the distribution).

Results. A total of 45 patients with diagnosis of CAP were included in the study period. 77.8% of the patients were admitted within the first 24 h after contact with the Hospital and within this group, 85.7% were admitted within the first 6 h. In 26.7% of the cases the germ was not identified, the most frequent germ identified was Streptococus pneumoniae (35.6%). The 85.3% of patients received correct empirical antibiotic therapy on admission.

There were no differences in the baseline characteristics of the two groups, except for pO2 and CRP values on admission to the ICU (Table I).

Regarding the primary endpoint of the study, a higher 30-day mortality was observed in the group of patients with delayed admission (OR 5.17 [95% CI 1.004–26.6; p = 0.05). As for the secondary endpoints, there was a greater need for both invasive and noninvasive mechanical ventilation in the group admitted for more than 24 h, as well as a longer stay in the ICU and in hospital, with no significant differences between the two groups.

Conclusions. Delayed ICU admission in patients diagnosed with severe community-acquired pneumonia leads to higher 30-day mortality, as well as a greater need for invasive and noninvasive ventilatory support and longer ICU and hospital stay.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000363

Introduction. The relationship between post-rewarming body temperature after targeted temperature management (TTM) and prognosis remains controversial yet in cardiac arrest patients. We hypothesized that low body temperature after rewarming may be associated with poor prognosis in patients with out-of-hospital cardiac arrest (OHCA) who received TTM.
Objectives. This study aimed to identify the relationship between post-rewarming body temperature and the neurological outcome and mortality through multicenter OHCA registry in South Korea.
Methods. We retrospectively reviewed the 3SNU-PCAS registry which prospectively obtained from 3 urban hospital EDs from December 2013 to May 2021. Patients with sustained ROSC after out-of-hospital cardiac arrest were enrolled. Patients who recieved TTM were included. Primary outcome was relationship between body temperature at 72 h after TTM initiation and clinical outcomes including 1-year favorable neurological outcome (Cerebral Performance Categories Scale, CPC 1–2) and 1-year mortality.
Results. Among 1599 patients enrolled in the registry, 596 met inclusion criteria and 311 were excluded, 285 were analyzed. Of 285, 74 had favorable 1-year neurological outcome while 211 were not. Favorable 1-year neurological outcome group was younger (52.0 vs 62.0, P = 0.001), more witnessed (85.1% vs 65.4%, P = 0.002), more bystander cardiopulmonary resuscitation provided (68.9% vs 50.2%, P = 0.004), showed more initial shockable rhythm (87.1% vs 25.1%, P < 0.001), and was more presumed as cardiac etiology (89.2% vs 28.9) whereas no difference between two groups were presented about TTM information including time interval from collapse to TTM, targeted temperature, duration of induction and maintainence phase, and use and location of feedback device. Favorable 1-year neurological outcome group showed higher body temperature than unfavorable neurological outcome group at emergency department and after initiation of TTM until 4 h, and there was no difference between the two groups from 8 to 44 h after TTM, and then again favorable neurological outcome group had significantly higher body temperature from 48 h onwards. Low body temperature at 72 h after TTM was independently associated with 1-year mortality (adjusted OR 0.51, CI 0.37–0.87, P = 0.011) while Body temperature at 72 h was not associated with 1-year favorable neurological outcome (adjusted OR 1.10, CI 0.77–1.56, P = 0.573).
Conclusions. In conclusion, low body temperature after rewarming was independently associated with 1-year mortality. Post-rewarming body temperature tends to be higher in favorable neurological outcome patients although there was no significant association between body temperature after rewarming and neurological outcome.

Introduction: A major change in the airway management practices during the COVID-19 pandemic has been the recommendation for the use of videolaryngoscope (VL) and PPE for protected intubation. Laryngoscopy after donning PPE labelled as "protected intubation" is a major change from the conventional techniques and so various manikin-based studies have been conducted to assess time to intubation, number of laryngoscopy attempts and first-pass success rate.
Objectives: In this retrospective study, we assessed the applicability and efficiency of this new airway management algorithm in untested trauma victims on arrival to hospital requiring immediate airway intervention.
Methods: The present study was conducted from April 2020 to September 2020. All proformas are filled by the anesthesiology residents who are members of the trauma airway management response team (TART). The approach to airway management in COVID times was based on three principles; (1) all TART members to be in PPE; (2) drug assisted intubation; (3) VL to be preferred over DL even for first laryngoscopy attempt. Patients who arrived intubated were excluded. Study end points were the feasibility of use of VL for "protected intubation"

and comparison of the time to intubation, number of laryngoscopy attempts and first-pass success rate with VL and DL in trauma centre in COVID times. It is to be noted that all patients included were untested for severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) at time of airway management in trauma centre and were considered as COVID "suspects."

Results: Data from 296 intubations performed by TART members in level C PPE in different resuscitation areas of trauma centre during different duty hours was compiled.

A GCS score of less than 8 was the reason for intubation in 72% of cases followed by type 1 respiratory distress in the remaining. Majority were males (230) and 84.8% were aged between (18–60 years). Road side accident (n = 243), fall from height (n = 19), assault (n = 13), trauma with thermal burns (n = 10) and others (animal injury, trivial fall, etc. n = 11) were the mechanisms of trauma.

Videolaryngoscope was used in 87.2% of patients (258); direct laryngoscopy (DL) was used in the remaining. Time taken for intubation in first attempt was 28.95 ± 14.51 s in 24 patients with DL and 27.14 ± 14.61 s with 35 randomly chosen intubations in VL group and the difference was statistically non significant (p value = 0.6402; *t*-test). The laryngeal view during airway management with the two devices was compared using Cormack-Lehane (CL) classification. 7 Maximum glottis visualization is in CL grade I and was 57.14% in VL vs 50% in DL; 42.86% patients intubated with VL had CL grade II whereas 50% patients had CL grade 2 in DL group. The difference was nonsignificant with p value of 0.589. The difference in first attempt success rate; 92% in VL and 79% in DL was also not statistically significant.

Conclusions: We conclude that use of VL with PPE by TART members for drug assisted intubations in untested trauma patients in COVID times is feasible and safe as the time taken for intubation is 27.14 ± 14.61 s.

Introduction: Acute respiratory distress syndrome (ARDS) related to COVID-19 is associated with a high mortality rate and prolonged mechanical ventilation duration. We hypothesized that ultra-low tidal volume ventilation (ULTV) without extracorporeal circulation would minimize ventilator-induced lung injury.

Objectives: To determine whether ULTV, compared with protective ventilation, could improve COVID-19 ARDS 90-day all-cause mortality the number of ventilator-free days (VFD).

Methods: The study is a multicenter open-label randomized controlled superiority trial performed in 10 intensive care units. The study was performed in France from April 15th, 2020 to April 13th, 2021, and final follow-up occurred on July 17, 2021. Patients with COVID-19 ARDS and a $PaO_2/FiO_2 \leq 150$ mmHg were included, and randomly assigned to receive ULTV aiming for VT 4 mL kg^{-1} predicted body weight (PBW, n = 106) or protective ventilation (i.e., VT 6 ml kg^{-1} PBW, n = 109).

The primary outcome was a composite score based on 90-day all-cause mortality as prioritized criterion and the number of VFD as a secondary criterion.

Results: Two hundred and fifteen patients were included (median age [interquartile range (IQR)], 68 [60–74]; 58 women [27%]). The primary endpoint was not significantly different between arms (win ratio of the ULTV arm amounting to 0.85 [95% confidence interval (CI95%), 0.60 to 1.19]; p = 0.38). Forty-six patients [43%] in the ULTV arm and 43 [39%] in the protective ventilation arm died by day-90 (absolute risk difference: 4 [CI95%, − 9 to 18] %; p = 0.52). VFD were not significantly different between the ULTV and the protective ventilation arms (median [IQR]: 7 [0–45] vs. 31 [0–48] days; median of the differences between arms, 0 [CI95%, − 2 to 0] days, p = 0.3). The rate of severe respiratory acidosis was significantly higher in the ULTV arm (35 patients [33%] vs. 14 patients [13%], absolute risk difference: 20 [CI95%, 9 to 31%], p < 0.001). Subgroup prespecified exploratory analysis suggested harm of the ULTV strategy in patients with renal SOFA subscore^{3}2.

Conclusions: In patients with moderate-to-severe COVID-19 ARDS, ULTV compared with protective ventilation resulted in no significant difference of a composite score based on 90-day mortality and VFD. These findings do not support the systematic use of ULTV in COVID-19 ARDS.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000367

Introduction: Nasogastric tube malposition, underfeeding, frequent feeding interruption and reflux are frequent complications related to enteral nutrition (1, 2). SmART + robot feeding system (ART MEDICAL, Natania, Israel) is a new platform trying to overcome all these limitations and improve feeding efficacy.
Methods: Mechanically ventilated patients were prospectively randomized to receive enteral nutrition using standard protocol through an usual nasogastric tube vs study group supported by SmART + platform composed of a nasogastric tube with sensors detecting reflux and preventing aspiration through an inflated balloon. Energy administration was based on indirect calorimetry (REE). Primary endpoint was feeding efficacy. Length of ICU stay and Length of ventilation were also analyzed. Parametric independent samples t-test and non-parametric Wilcoxon rank sum test were applied. All tests were two-tailed, with a p-value significance level of < 0.05.
Results: 50 patients in control group and 50 patients in study group were included. There were no differences between groups except height and REE. No side effects were observed. Primary endpoint (feeding efficiency between days 2 to 14 for control and study group was $37.9 \pm 19.9\%$ and $89.9 \pm 12.2\%$, respectively, $p < 0.0001$). Cumulative energy balance was $-8{,}839 \pm 7{,}897$ kcal; range $-1{,}332$–$31{,}849$ kcal in control group and $-6{,}554 \pm 3{,}315$ kcal; range $-2{,}006$–$13{,}642$ kcal in study group ($p < 0.07$). LOS was low significantly lower in the study group (HR 1.53, 95% CI 1.027–2.29, $p < 0.04$) and LOV was near to significant (HR 1.45, 95% CI 0.977–2.164, $p = 0.06$). ICU mortality was similar in both groups.
Conclusions: No adverse events were report during the study. SmART + robot system improved feeding efficiency and reduced LOS of mechanically ventilated patients in general ICU. This new technology may significantly improve the enteral feeding routine in critically ill patients.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000369

Introduction: The partial pressure of arterial carbon dioxide ($PaCO_2$) is a crucial factor in determining cerebral blood flow after brain injury. While deviations in $PaCO_2$ have been linked to worse outcomes in out-of-hospital cardiac arrest (OHCA) patients [1], little is known about the association between $PaCO_2$ and outcomes in patients undergoing extracorporeal membrane oxygenation (ECMO) after OHCA. Therefore, this observational study aimed to investigate the relationship between $PaCO_2$ levels and outcomes in patients on ECMO after OHCA using meticulously classified $PaCO_2$ levels.
Methods: We used a registry database of OHCA cases between 2014 and 2020 in Japan. We included adult, non-traumatic OHCA patients who underwent ECMO before or after the return of spontaneous circulation and whose $PaCO_2$ levels were measured after ECMO initiation. The main exposure was $PaCO_2$ levels, which were divided into eight categories: $PaCO_2 < 30$; $30 - < 35$; $35 - < 40$; $40 - < 45$; $45 - < 50$; $50 - < 55$; $55 - < 60$; ≥ 60 mmHg. The non-linear relationship between $PaCO_2$ levels as a continuous variable and the predicted probability of favorable functional survival was visually described using restricted cubic splines in univariable logistic regression. The primary outcome was favorable functional survival at one month or hospital discharge, whichever came first. Multivariable logistic regression was performed to adjust for clinically relevant variables.
Results: Among 1503 patients who met the eligibility criteria, the proportion of favorable functional survival was highest in the $PaCO_2$ category of $40 - < 45$ mmHg: 12.0% (36/300) in < 30; 13.7% (36/262) in $30 - < 35$; 11.2% (23/205) in $35 - < 40$; 20.4% (38/186) in $40 - < 45$; 18.6% (21/113) in $45 - < 50$; 14.7% (14/95) in $50 - < 55$; 7.3% (6/82) in $55 - < 60$; and 11.9% (31/260) in ≥ 60. When using restricted cubic splines in univariable logistic regression, the relationship between $PaCO_2$ levels and the primary outcome followed an inversed-U-shaped form (Figure). Only the $PaCO_2$ category of $40 - < 45$ mmHg was associated with favorable functional survival, and the adjusted odds ratio was 1.07 (95% CI 1.01–1.14) when compared to the category of < 30 as a reference. For patients whose outcomes at 90 days after resuscitation were available, the association between the category of $40 - < 45$ mmHg and favorable functional survival remained.
Conclusions: This study demonstrated that high normocapnia ($40 - < 45$ mmHg), but not low normocapnia ($35 - < 40$ mmHg), was associated with better functional survival in adult OHCA patients undergoing ECMO. This finding highlights the importance of meticulous $PaCO_2$ level management in the post-cardiac arrest phase.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000370

Introduction: Intensive care unit (ICU) admission of very elderly patients (≥ 90 years) have increased in recent years. To date, it remains unclear if prolonged ICU treatment (≥ 7 days) is justified regarding outcome. Yet, factors associated with prolonged ICU stay remain unknown in the very elderly critically ill population.
Objectives: Identify factors associated with prolonged ICU stay and clinical outcome in very elderly patients.
Methods: Retrospective analysis of all consecutive critically ill patients ≥ 90 years admitted to the Department of Intensive Care Medicine of the Medical University Centre Hamburg-Eppendorf (Hamburg, Germany) during an 11-year period. Clinical and laboratory course were analyzed from all patients. Prolonged ICU therapy was defined as ICU stay ≥ 7 days. Occurrence, clinical characteristics and outcome were assessed and compared between patients with and without prolonged stay.
Results: During the study period 1091 critically ill very elderly patients could be identified. Of those, 10% (n = 110) had a prolonged ICU stay ≥ 7 days. Demographic characteristics including age, gender and BMI were comparable in patients with and without prolonged stay. The median CCI was 1 (0–3) points compared to 1 (1–2) points in patients with and without prolonged ICU stay (p = 0.933). Disease severity represented by SAPS II (47 vs. 35 points, p < 0.001) score on admission was higher in patients with prolonged ICU stay. Invasive mechanical ventilation was required in 78% (n = 86) and 30% (n = 296) (p < 0.001). Renal replacement therapy (RRT) during the ICU stay was applied in 12% (n = 13) and 2% (n = 17) (p < 0.001). Multivariate regression analysis identified mechanical ventilation [OR 3.873, 95% CI (2.026–7.406); p < 0.001], vasopressors during ICU stay [OR 2.921, 95% CI (1.466–5.821); p = 0.002], RRT [OR 4.299, 95% CI (1.513–12.212); p = 0.006] and SAPS II [OR 1.023, 95% CI (1.004–1.043); p = 0.020] as independent factors associated with prolonged ICU stay. In patients with prolonged ICU stay we observed an ICU-mortality of 32% (n = 35) as compared to 17% (n = 164) in patients without prolonged ICU stay (p < 0.001).
Conclusions: About 10% of critically ill ≥ 90-years suffer from a prolonged ICU stay, which was significantly associated with increased mortality. However, ICU therapy in this cohort seems justified.

Introduction: Maintaining adequate perfusion is a pivotal aspect of intraoperative and critical care. Mean arterial blood pressure (MAP) is often used as a surrogate for perfusion pressure [1, 2]. The Hypotension Prediction Index (HPI) is a machine learning-derived algorithm that enables clinicians to initiate hemodynamic interventions prior to the onset of hypotension [3]. The use of HPI in combination with a diagnostic guidance protocol led to a significant reduction in the severity of hypotension in five out of six non-cardiac surgery trials [4–9], but its efficacy during cardiac surgery and intensive care unit (ICU) stay is to be determined.
Objectives: Our primary objective was to test in a randomised trial the efficacy of HPI with a diagnostic guidance protocol on top of standard of care on reducing the severity of hypotension during elective on-pump coronary artery bypass grafting (CABG) procedures and postoperative ICU stay. The secondary objectives were to assess differences in the severity of hypertension and the total dosage of administered fluids and medication.
Methods: Single-centre, single-blinded randomised clinical trial conducted at the Amsterdam University Medical Centres, the Netherlands. Adult patients scheduled for an elective on-pump CABG procedure with or without additional single heart valve surgery were eligible if a MAP of ≥ 65 mmHg was the set target during the off-pump phases of the procedure and the subsequent ICU admission. After providing informed consent, the participants were randomised in a 1:1 allocation ratio to the HPI-guided or standard care arm. An Acumen IQ sensor connected to a HemoSphere monitor was attached to the arterial catheter in all patients (Edwards Lifesciences, Irvine, CA, USA). However, clinicians were only provided with HPI and the additional diagnostic guidance protocol in the HPI-guided arm. In the standard care group, HPI was measured, but the HemoSphere was covered, and alerts were silenced. Once HPI was ≥ 75 for at least one minute, treatment within two minutes was suggested to the clinician (Figure 1). In the operating room, treatment type and dosage were left to the anaesthesiologist's discretion. A nurse-driven hypotension treatment protocol was created for use in the ICU to minimise treatment delay.
Results: Between May 2021 and March 2023, 142 out of 450 eligible patients were enrolled, with 130 included in the final analysis (Figure 2). The patients' baseline characteristics were well-balanced in the two groups. The overall time-weighted average of hypotension was significantly lower in the HPI-guided arm, with a median of differences of 0.40 mmHg (95% CI 0.26–0.65 mmHg; $P \leq 0.0001$) (Figure 3). An overview of the secondary endpoint results is available in Table 1.
Conclusions: The use of HPI in combination with a diagnostic guidance protocol and nurse-driven treatment protocol on top of standard of care significantly decreased the severity of hypotension in elective CABG patients without increasing the severity of hypertension compared to standard care alone.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000372

Introduction: Vilobelimab (Vilo), a first-in-class anti-C5a monoclonal antibody, in a phase 3 adaptively designed multicenter, double-blind, placebo (Plc)-controlled study (N = 369; Vilo n = 177, Plc n = 191) improved survival in invasive mechanically ventilated COVID-19 patients.1 The primary endpoint of 28-day (d) all-cause mortality was not met (HR 0.73; 95% CI 0.50–1.06; P = 0.094) using site stratification within the Cox regression analysis. The prespecified, non-site stratified per protocol analysis, however, showed that Vilo statistically reduced 28-d all-cause mortality compared to Plc (HR 0.67; 95% CI 0.48–0.96; P = 0.027).

Objectives: Additional statistical analysis was performed to confirm the efficacy of vilobelimab in critically ill, COVID-19 patients and to determine if other factors may have contributed to not meeting the primary endpoint.

Methods: Recruitment in each country was analyzed for random effects due to age. Using Cox regression, the primary outcome data for 28-d all-cause mortality was stratified by region, country, pooled sites with 1–3 patients, pooled sites with 1–4 patients and pooled sites with < 10 patients. In addition, a Frailty model was used to evaluate another possibility to adjust for site effects.

Results: Due to missing the primary endpoint using site stratification, a post-hoc analysis was undertaken and found that 61 patients from sites with no death or having enrolled only one patient could not contribute to the Cox regression analysis decreasing the trial's power using site stratification (Fig 1). In addition, the Plc group recruited in Brazil was a median of 9 years younger than the Vilo group and had very low mortality: 25% for 28-d and 32.5% for 60-d mortality. Adjusting the Cox regression for age-groups in Brazil changed the HR from 0.96 (60-d) to 0.77, close to the HR for the entire study, suggesting a similar survival benefit of Vilo in Brazil. Post-hoc analyses of the primary outcome using Cox regression stratified by country (age-adjusted HR 0.61; 95% CI 0.43–0.87; P = 0.0067) and an analysis using a Frailty model (assigning random effects per site; age-adjusted HR 0.65, 0.45–0.93; P = 0.018) both showed that Vilo significantly reduced all-cause mortality at d 28 (Fig 2). Additional post-hoc analysis pooling sites which had 1–3, 1–4 and < 10 patients also demonstrated significantly reduced all-cause mortality at d 28 with HRs of 0.68 (95% CI 0.47–0.98, P = 0.040), 0.68 (95% CI 0.47–0.98, P = 0.041) and 0.65 (95% CI 0.46–0.93, P = 0.019), respectively. Treatment-emergent adverse events (AEs) were well balanced between treatment groups; Vilo 90.9% and Plc 91.0%. Serious AEs occurred in 58.9% of Vilo and 63.5% of Plc patients.

Conclusion: Multiple statistical analyses of PANAMO demonstrate that Vilo significantly reduces 28-d all-cause mortality despite lack of events (deaths) in smaller recruitment sites and age imbalances in one large recruiting country.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000375

Introduction: Central lines are crucial in managing critically ill ICU patients, providing access for monitoring, medications, and nutrition. The use of central lines, however, carries the risk of central line associated bloodstream infections (CLABSIs). CLABSIs are considered the third most common type of healthcare-associated infections (HCAIs) accounting for almost a quarter of all hospital-acquired infections with a mortality rate up to 37%. We sought to determine whether a multifaceted intervention to reduce CLABSIs could be implemented in a low middle income (LMIC) setting in a sustainable manner.

Objectives:

1. To determine whether implementation of a multifaceted intervention would significantly reduce the incidence of central line-associated bloodstream infections
2. To assess the long-term effects of such an intervention and correlate CLABSI rates to the efficacy of the CUSP program intervention.

Methods: The study used a bundled intervention approach to prevent CLABSIs, consisting of the comprehensive unit-based safety program (CUSP) intervention pioneered by the Johns Hopkins University and the Agency for Healthcare Research and Quality (AHRQ). This included clinician education on evidence-based infection prevention, tools for identifying local barriers to implementing these practices, and ideas for ensuring patients received the necessary care. The intervention took place in 3 ICUs which were followed over a period of more than 9 years (May 2009–October 2018). The study had three phases: pre-intervention (6 quarters), intervention (16 quarters), and post-intervention (16 quarters). Each unit was tasked with assembling a multidisciplinary CUSP team to improve safety culture and teamwork. The CUSP team was further divided into 4 sub-groups; the executive group (EG), the physician group (PG), the nursing group (NG), and the CUSP implementation group (CG). Monthly team meetings were held between the CUSP teams where data was shared with the team for further action as needed. Attendance rates during these meetings for each sub-group were recorded. The primary outcome measure to assess the relationship between time since the implementation of the multifaceted program and CLABSI rates was explored by reporting the incidence rate ratios (IRR) using a Poisson regression model. Individual subgroup analysis was conducted to examine the correlation between CUSP meeting attendance percentage and the difference in CLABSI rates pre-intervention and during the intervention phase using the Wilcoxon rank sum test.

Results: The three intervention ICUs combined, where the multifaceted approach using CUSP was implemented achieved an overall 53% reduction (IRR = 0.53, p = 0.001 95% CI 0.36–0.77) in their CLABSI rates. The NICU experienced a decrease of 78% (IRR 0.23, p = 0.0006 95% CI 0.11–0.42) in CLABSI rates during the intervention phase and demonstrated a lasting effect of 1 year (4 quarters) during the post-intervention phase. The attendance rates for the CUSP sub-groups in the NICU were 88% (PG), 100% (NG), 91% (EG), and 97% (CG). The MICU demonstrated a reduction of 28% (IRR 0.72, p = 0.17 95% CI 0.44–1.18) in CLABSI rates during the intervention phase. Attendance in the MICU were 96% (PG), 100% (NG), 43% (EG) and 96% (CG). A 10% reduction in CLABSI rates in the SICU (IRR 0.92, p = 0.71 95% CI 0.56–1.49) was observed during the intervention phase with attendance rates of the subgroups being 71% (PG), 100% (NG), 75% (EG) and 54% (CG). When assessing differences in unit performance to reduce CLABSI rates, an attendance rate above 85% across all sub-groups during the CUSP meetings including senior leadership involvement in each CUSP meeting, correlated with a better infection reduction. This was demonstrated in the NICU with all four CUSP sub groups achieving an attendance rate above 85% ($p < 0.05$). Only 3 sub groups ($p > 0.05$) in the MICU and 2 sub groups ($p > 0.05$) in the SICU had an attendance rate above 85%.

Conclusions: The multi-faceted approach using the CUSP model can reduce the morbidity and mortality associated with CLABSIs in resource limited settings. We noted that in order to achieve sustained effects lasting for at least one-year post-intervention, a minimum attendance rate of 85% from each sub group is imperative.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000377

Introduction: Several authors have been interested in applying Artificial Intelligence (AI) to medicine, using various Machine Learning (ML) techniques: managing septic shock, predicting renal failure… [1, 2] AI has an important place in decision support for clinicians [3].
The weaning period is a really important time in the management of a patient on mechanical ventilation and can take up to half of the time spent in intensive care unit. The first weaning attempt is unsuccessful in 20% of patients However, mortality can be as high as 38% in patients with the most difficult weaning [4]. Only a few studies have looked at the application of machine learning in this area, and only one has looked at the use of biosignals (cardiac rate, ECG, ventilatory parameters…) [5–7]. To improve morbidity, mortality and reduce length of stay, it is essential to predict the success of the spontaneous breathing test and extubation.
Objectives: We propose to develop a predictive algorithm for the success of a ventilatory weaning test based on biosignal records and others features.
Methods: It is a critical care, oligo-centric and retrospective study.
We included biosignal variables extracted from the electronic medical record, such as respiratory (RR, minute volume…), cardiac (systolic pressure, heart rate…), ventilator parameters and other discrete variables (age, comorbidity…). Most biosignal variables are minute-by-minute records. Recording starts 48 h before the test and stops at the start of the weaning test.
We extracted features from these records, combined them with other biomarkers, and applied several machine learning algorithms: Logistic Regression, Random Forest Classifier, Support Vector Classifier (SVC), XGBoost, and Light Gradient Boosting Method (LGBM)… To maximise prediction and minimise the risk of overfitting, we computed different methods: multiple imputation, oversampling and K-fold cross validation. The results are expressed in terms of AUC and AUC precision/recall (a variant of AUC, interpreted in a similar way, that is better suited to imbalanced data sets).
Results: The cohort included 133 patients (85 successful and 48 unsuccessful). The best results were obtained with the SVC algorithm with AUC-PR 0.9379 (AUC: 0.8857, F1 score: 0.8684). The other algorithms are slightly less efficient (Random Forest: 0.9104, Logistic Regression: 0.8765, KNN: 0.8708). The most important features for the prediction were weight gain since the admission, VAP presence, respiratory rate, systolic arterial pressure, PEP value…
Despite the small number of patients, all the techniques used allow good prediction and reproducibility. The main features are consistent with previous findings. In addition, the use of continuous and discrete data is new in this field. The cohort will continue to grow until the congress.
Conclusions: Machine learning applied to ventilator weaning is effective, especially when biosignal is used.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000378

Introduction: Artificial intelligence (AI) has the potential to improve the precision and the effectiveness of the professional medical practice. An AI chatbot named ChatGPT (generative pre-trained transformer) can communicate with people online via text. It is trained by machine learning algorithms using large datasets.
Objectives: In this study, we compare the performance of a ChatGPT API 3.5 Turbo model to a general model, in obtaining accurate, valid, medical information, on critical care topics.
Methods: In this study, we used ChatGPT API 3.5 Turbo, which is a language model developed by OpenAI that can generate natural language text based on prompts provided by the user. The API was accessed through a Python script that was developed specifically for this study. We utilised the ERS/ESICM/ESCMID/ALAT 2023 guidelines [1]. We also used a PDF parsing tool, PyMuPDF [2], which is a collection of enhanced Python bindings for MuPDF to extract data from PDF files. We process embeddings using the OpenAI tokenizer tiktoken, as demonstrated by OpenAI [3]. As the pdf document used in our study contains 25,557 tokens and 98,663 characters, which cannot be handled all at once by OpenAI's GPT3.5-turbo, we segmented the source document into multiple sentences, of at most 300 tokens each.
Results: The ChatGPT models were handed with the same specific questions regarding the management of severe community-acquired pneumonia (sCAP). However, the custom model was trained with more specialized content on the given subject (the pdf file of ERS/ESICM/ESCMID/ALAT 2023 guidelines), while the general ChatGPT model replied to our questions, based on public datasets it was already trained on. For example, some of the answers we received were: Question 1: "When using initial empirical therapy for sCAP, should a macrolide or fluoroquinolone be used as part of combination therapy, to reduce mortality and adverse clinical outcomes?"
Answer to Question 1 of Chat GPT: "For the initial empirical therapy of community-acquired pneumonia (CAP) in adults, the choice of antibiotics depends on various factors. The choice between a macrolide and a fluoroquinolone as part of combination therapy for CAP should be made based on local antibiotic resistance patterns, patient-specific factors such as allergies, potential drug interactions, and the severity of the infection. The decision should be made in consultation with a qualified healthcare professional who can consider the individual patient's condition and provide personalized medical advice".
Answer to Question 1 by using Chat GPT API 3.5 Turbo: "We suggest the addition of macrolides, not fluoroquinolones, to beta-lactams as empirical antibiotic therapy in hospitalised patients with sCAP. Conditional recommendation, very low quality of evidence".
Question 2: "When is the use of PCT recommended in patients with sCAP?"
Answer to Question 2 of Chat GPT: "…It's important to note that the use of PCT should be considered as part of a comprehensive clinical assessment, and should not replace clinical judgment. PCT levels should be interpreted in the context of the individual patient's clinical presentation, other laboratory results, and local antibiotic stewardship guidelines. "
Answer to Question 2 by using Chat GPT API 3.5 Turbo: "The use of PCT is recommended to reduce the duration of antibiotic treatment in patients with sCAP, according to a conditional recommendation with low quality evidence. However, PCT levels may not be useful when clinical stability is achieved and the duration of antibiotic therapy is between 5 and 7 days, and must be considered together with clinical assessment".
The organization of these responses makes it abundantly clear that the trained model provides more accurate, and updated recommendations, on the topic. Further training of the model on specific anonymized patient information derived from the electronic health record, may provide more personalized medical advice.
Conclusions: By giving doctors more succinct, prompt responses about particular critical care topics, this specially trained model enables them to provide better patient care, making specific medical recommendations based on the latest clinical guidelines.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000381

Introduction: Acute onset supraventricular arrhythmias contribute to haemodynamic compromise in septic shock. Both amiodarone and propafenone are drugs of choice but their clinical effects have not been directly compared yet.
Objectives: To test the hypothesis that propafenone is superior to amiodarone in restoring and sustaining sinus rhythm (SR) in patients in septic shock complicated by acute onset supraventricular arrhythmias.
Methods: Randomized prospective controlled parallel group double blind trial (1), ClinicalTrials.gov NCT03029169, was performed in ICUs of two university hospitals.
209 septic shock patients fulfilling the JAMA 2016 criteria with new-onset arrhythmia and left ventricular ejection fraction above 35% were enrolled between October 2018 and July 2022. The patients were randomly assigned in 1:1 ratio to receive intravenous propafenone (70 mg bolus followed by 400–840 mg/24 h) or amiodarone (300 mg bolus followed by a maintenance dose of 600–1800 mg/24 h).
The primary outcomes were the proportion of patients who were in SR at 24 h after the start of the infusion, time to restoration of the first SR and proportion of patients with arrhythmia recurrence that occurred until hospital discharge or death.
The secondary outcomes were rates of electric cardioversions, need for unblinding, cross over, courses of vasopressors and patient outcomes.
Results: Out of 209 randomized patients (105 propafenone and 104 amiodarone), 200 (96%) received the study drug. After 24 h, 77 (72.8%) and 71 (67.3%) were in SR ($p = 0.40$), restored after a median of 4.3 h (95% CI 2.8; 7.3) and 7.8 h (95% CI 5.9; 11), $p = 0.03$, with propafenone and amiodarone, respectively. The arrhythmia recurred at least once in 54 (52%) patients treated with propafenone and in 80 (76%) with amiodarone, $p < 0.001$. Patients with dilated left atrium had better rhythm control in amiodarone (6.4 h (95% CI 3.5; 14.1) until cardioversion vs 14.1 h (95% CI 2.8; 24.7) in propafenone, $p = 0.05$).
40.4% in propafenone vs 32.4% ($p = 0.2$) in amiodarone required electric cardioversion, courses of vasopressors did not differ. 15 (7.2%) patients had to be unblinded. The ICU mortality was not significantly lower in the propafenone group (38% vs 43% in amiodarone, $p = 0.06$) as well as the long-term outcomes.
Conclusions: The administration of propafenone in septic shock does not provide a better rhythm control at 24 h yet offers faster cardioversion with less arrhythmia recurrences than with amiodarone, especially in patients with a non-dilated left atrium. Both drugs did not differ in their impacts on the short- (ICU, hospital) and long-term (90-day, 12 months) outcomes.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000383

Introduction: Sepsis is known to severely alter arterial blood pressure (ABP) waveform and cardiovascular function (1, 2). Previous studies have shown that the recommended therapy is not able to restore the hemodynamic profile of ABP waveform, although resuscitation was considered successful on the basis of standard parameters (3), suggesting a persistent hidden vascular disorder leading to impaired pulse wave reflections (2).
Objectives: The objective of this study is to investigate the changes in ABP waveform and wave reflections during a long-term swine experiment of polymicrobial sepsis and resuscitation.
Methods: 9 pigs underwent a protocol of polymicrobial sepsis followed by standard resuscitation. 5 pigs were treated as sham controls. Septic animals were studied at baseline (T1), after sepsis development (T2), after 24 h (T3) and 48 h (T4) of therapy administration, and sham controls at the same time points. ABP and arterial blood flow (ABF) were measured in the left and right carotid artery, respectively. We estimated the arterial input impedance (Zin) and the carotid characteristic impedance (Zc) by using frequency domain techniques based on Fourier series decomposition. The first harmonic of normalized Zin modulus, computed as the ratio between the modulus of Zin and Zc, was taken as an indicator of the global amount of reflections in the system (4). Augmentation index (AIx) was computed on ABP as $AIx = \Delta P/PP$, where ΔP is the systolic augmented pressure and PP is the pulse pressure, and it was taken as another surrogate of wave reflections (5).
Results: Table 1 reports the values of Zc for both populations. At T2 septic pigs showed a significantly higher value than sham pigs, which gradually decreased afterwards to values similar to baseline and sham pigs. Zc depends on vessel size, wall stiffness and blood properties, i.e. the stiffer the vessel and the smaller its diameter, the higher Zc. We can hypothesize that carotid stiffening may have played a crucial role in Zc increase following sepsis (2); moreover, the increased blood viscosity due to capillary leakage may have also contributed.

Table 1 (abstract 000383) Characteristic impedance [mmHg/mL/s] values (Zc)

	T1	T2	T3	T4
Septic	0.07 (0.06, 0.08)	0.1 (0.08, 0.1)	0.07 (0.05, 0.08)	0.06 (0.04, 0.07) n = 8
Sham	0.07 (0.05, 0.08)	0.06 (0.05, 0.06)**	0.05 (0.05, 0.06) n = 4	0.05 (0.04, 0.06) n = 3

The values of AIx and the first harmonic of normalized Zin modulus are reported in Figure 1. Both indices were significantly reduced at T2 in septic pigs, highlighting a reduction of wave reflections probably due to the severe peripheral vasodilation induced by sepsis, as also reported in other studies (6). Accordingly, the shape of ABP waveform highly changed after sepsis development passing from a type A to a type C pulse (Figure 2). After therapy administration (T3 and T4), AIx was restored to values very similar to sham pigs and baseline; on the contrary, normalized Zin still showed significantly lower values in the septic population, hinting that a persistent arterial vascular disorder was still present despite the reaching of the overall hemodynamic targets according to guidelines (3). In support of this, an example of ABP waveform is shown in Figure 3: the ABP morphological characteristics in a sham pig after 72 h of resuscitation (T5) are similar to baseline, on the contrary, the ABP waveform in a septic pig is completely different from baseline and SH pig, despite the shape of the waveform has returned to a type A pulse as at baseline. This highlights some

weaknesses of AIx index when applied in critical care settings. Indeed, AIx reflects complex interactions: we know that it is influenced by HR changes (7), peripheral vasodilation (8), and pharmacological actions such as β1-adrenergic stimulation (9) or noradrenaline (10). In critical condition, such as sepsis, several factors are changing at the same time, and this may lead to erroneous interpretations of AIx values and trends. **Conclusions:** Despite resuscitation was able to restore the overall morphology of ABP pulse, the computed indices highlighted that wave reflections may be still altered after 48 h of successful hemodynamic resuscitation, suggesting a persistent alteration of the arterial vasculature. We propose that a complex pathological condition like sepsis mandates an extensive monitoring including additional important information from commonly measured signals like ABP.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000384

Introduction: Supraventricular arrhythmias (SVA) contribute to haemodynamic compromise in septic shock and associate with two to five times worse survival.
Objectives: To propose echocardiography parameters which may help in the decision on rhythm versus rate control approach.
Methods: Exploratory analysis of a prospective controlled randomized trial (1), ClinicalTrials.gov Identifier NCT03029169, performed in ICUs of two university hospitals. Included were adult patients in septic shock according to JAMA 2016 criteria with a new onset or known paroxysmal SVA, excluded were with severe LV systolic dysfunction (EF_LV < 35%) or on a continuous noradrenaline > 1.0 μg/kg min. Patients were assessed with echocardiography at the arrhythmia onset, + 1 h and + 4 h post cardioversion on an infusion of propafenone or amiodarone. There were no limits to electric cardioversions. The arrhythmia recurrences were analysed in relation to left atrial end-systolic diameter (LA_ESD), indexed biplanar volume (LAVI), left atrial active emptying (LA_emptying), transmitral A-wave and its velocity–time integral (Avti), transmitral E-wave and its deceleration time (DTe), pulmonary artery systolic pressure (PAPs) and a categorical parameter of a history of SVA.

Results: 209 patients were included between 2018 and 2022, of those 173 were analysed in sinus rhythm at 1 h and 187 at 4 h. With cardioversion, the heart rate slowed from a median of 130 (111; 146)/min to 84 (78; 100)/min at +1 h and 85 (77; 94)/min at +4 h, $p<0.001$, accompanied by an increase of stroke volume from 50 (42; 60) ml to 66 (58; 78) ml at +1 h and 69 (60; 79) at +4 h, $p<0.001$. The LA_ESD (40 (35; 44) mm) and LAVI (31 (26; 39) ml/m^2) did not change with cardioversion, the LA_emptying (35.07 (33.12; 37.02)% at +1 h vs 37.6 (35.7; 39.5)% at +4 h, $p=0.005$), a wave (0.67 (0.64; 0.71) m/s at +1 h vs 0.71 (0.67; 0.75)m/s at +4 h, $p=0.002$) and the Avti (7.17 (6.81; 7.54) cm at +1 h vs 8.03 (7.68; 8.39) cm at +4 h were stepwise rising between +1 h and +4 h. The E-wave decreased ($p<0.001$), DTe increased ($p<0.001$), PAPs did not change while the TAPSE and RV_FAC increased with cardioversion (all $p<0.001$). The best predictors of arrhythmia recurrences were LA_emptying at +4 h with the cut off 38.4%, AUC 0.69, $p<0.001$, and Avti at +4 h with the cut off 6.8 cm, AUC 0.65, $p=0.001$. The PAPs 51 mmHg at +4 h, AUC 0.63, $p=0.007$, predicted only multiple recurrences (>3) as well as the LA_ESD at arrhythmia onset ($p=0.04$). The LAVI ($p=0.06$) and arrhythmia history ($p=0.09$) were not useful.
Conclusions: Simple 2D left atrial and transmitral Doppler parameters at 4 h post cardioversion may help to decide on a rhythm control strategy in septic shock.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000385

Introduction: Serum ferritin is elevated during infectious diseases as part of normal host response. On the other hand, severe hyperferritinemia is a marker of injurious hyper-inflammation. Recent studies have investigated the connection between hyperferritinemic sepsis and multiple organ dysfunction syndrome (MODS).
Objectives: Our aim was to investigate the prognostic value of serum ferritin levels in COVID-19 ICU patients with septicemia. We also assessed the role of other inflammation markers such as procalcitonin (PCT), interleukin-6 (IL-6), c-reactive protein (CRP) and white blood cell count (WBC).
Methods: From January 2022 to February 2023, a total of 194 patients were admitted to our ICU. All patients with confirmed septicemia were included in our study. Ferritin, PCT, IL-6, CRP and WBC values were measured from samples collected within 24 to 48 h from the timepoint of a positive blood culture. We investigated all inflammation markers as prognostic markers for death and need for renal replacement therapy (RRT). We used t-test for parametrical data and Mann–Whitney U test for non-parametrical data. We also performed receiver operating characteristic (ROC) analysis for significant results. Statistical significance was set at $p=0.05$.
Results: Seventy-five patients were included in the analysis. Median age was 69 years (interquartile range—IQR = 58, 75) and 45 of the patients were male (60%). Twenty-one patients died in the ICU (28%) and 23 patients needed RRT. Patient characteristics are described in Table 1. Deceased patients presented with significantly higher ferritin and IL-6 ($p<0.0001$ and $p=0.018$ respectively). Serum ferritin was also higher in the RRT group ($p=0.049$) whereas CRP was lower ($p=0.037$). Regarding death, no significant differences were found for PCT, CRP and WBC. In ROC analysis for ferritin and the outcome of death the area under the curve (AUC) was 0.889 (confidence interval—CI: 0.783, 0.994) with $p<0.001$. For IL-6 the AUC was 0.785 (CI: 0.643, 0.927) with $p=0.002$. A cut-off value of 1514 ng/mL for ferritin yielded 92.9% sensitivity and 85.3% specificity for the prediction of death.

Table 1 (abstract 000385) Description of patient characteristics (non-parametrical data)

	Median	IQR (25th, 75th)	N
Age (years)	69	(58, 75)	75
Total days in ICU	17	(9, 32)	75
IL-6 (pg/mL)	93	(50, 1831)	52
PCT (ng/mL)	0.49	(0.18, 1.65)	75
Ferritin (ng/mL)	997	(432, 1927)	75
CRP (mg/dL)	9.05	(4.44, 17.49)	75
WBC (per µL)	13,500	(8800, 17,600)	75

Conclusions: Our study revealed that serum ferritin values within 24 to 48 h from the timepoint of a positive blood culture have a statistically significant relationship with mortality in COVID-19 ICU patients with septicemia. High ferritin could be an early indicator of worse outcome. IL-6 levels were the only other inflammatory marker with statistically significant relationship with mortality. Also, there is statistically significant relationship between high ferritin levels and the need for RRT.

Early rehabilitation: bridging the gap. Enhanced ward-based rehabilitation for survivors of critical illness

R. Corbett[1], E. Cairney[2], J. Coulbeck[2]
[1]Physiotherapy, University Hospital Southampton Foundation Trust, Southampton, United Kingdom; [2]Therapies, University Hospital Southampton Foundation Trust, Southampton, United Kingdom
Correspondence: R. Corbett
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000391

Introduction: An Early Mobilisation Project (EMP) was introduced at University Hospital Southampton (UHS) in 2012, consisting of two

therapy technicians delivering additional therapy sessions for medical patients who required mechanical ventilation for > 24 h and a preceding hospital stay < 1 week. In 2016 we successfully bid for a further two Band 4 generic therapy technicians to continue enhanced therapy on the medical wards; our programme began in 2017. Since then, the team have worked through the introduction of Post Intensive Care Syndrome (PICs) related outcome measures, staff vacancies, a pause during the pandemic and a relaunch in 2023.

Objectives: To reduce the ward length of stay (LOS) and collect PICs related outcome measures for patients enrolled on the ICU EMP.

Methods: Patients receive individually tailored daily rehabilitation programmes (Monday–Friday); in addition to usual ward therapy. Rehabilitation options include ward activities, gym sessions, home visits, hydrotherapy, wellbeing discussions and visits to shops or restaurants within the hospital. In addition to collecting ward length of stay data, we also record the following: Chelsea Critical Care Physical Assessment Tool (CPAx), Barthel, timed up and go (TUG) and the Intensive Care Psychological Assessment Tool (IPAT).

Results:

	(Baseline) January–March 2016	January–March 2017	January–March 2018	January–March 2019	January–March 2020		January–March 2023
Total number of patients	13	25	24	15	8	2021/22 EMP Data Not Collected (COVID/Staffing)	13
Male:female	7:6	15:10	16:8	10:5	4:4		6:7
Age	64.7	69	58	58	64.9		53
Ward LOS	27.2	11.5	12.2	9.5	19.8		6.8
Hospital LOS	33.6	25.6	24.8	26.7	29.2		14.3
Barthel improvement	–	–	49.8%	37.7%	35%		50.8%
CPAx improvement	–	–	–	42.8%	44.4%		19.2%
TUG improvement	–	–	–	–	–		6.2 Secs
IPAT average score	–	–	–	5.75	10.8		3.7

Conclusions: There has been a reduction in both ward and hospital LOS since the introduction of our ward-based rehabilitation program. The functional outcome measures utilised have demonstrated an improvement in scores and the IPAT results are below the threshold for concern. However, we are aware that we have no baseline data to compare. The start of the global pandemic in early 2020 may explain the elevated LOS and IPAT scores in Jan–March 2020. Employing generic therapy technicians means patients benefit from clinicians with both physiotherapy and occupational therapy skills. Our project has highlighted the need for a variety of outcome measures sensitive to identifying the signs and symptoms of PICs; beyond the physical and psychological. From 2023 we have begun using the Montreal Cognitive Assessment (MOCA); this will be recorded at ward admission and discharge home. All patients who were in employment prior to admission will receive follow-up calls at 1 week, 1 month and 3-month post hospital discharge to ascertain if they have returned to employment and if not—what the barriers are. We intend to investigate relevant treatment options for patients with PICs.

Risk factors associated with disability in patients with subarachnoid hemorrhage in a neurotraumatic ICU: a nine-year study

C. Sánchez Ramírez[1], C. F. Lübbe Vázquez[1], M. Cabrera Sánchez[1], M. San Martín Bragado[1], L. Lara Franco[1], F. J. Lapi Cerezo[1], A. Padrón Mujica[1], P. Saavedra-Santana[2], S. Ruiz-Santana[1]

Correspondence: C. Sánchez Ramírez
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000392

Introduction: Aneurysmal subarachnoid hemorrhage (SAH) is a global health burden with serious consequences such as permanent disability. It is important to know the risk factors for disability and to identify those that can be prevented in order to reduce them.

Objectives: To evaluate risk factors for disability in patients admitted with subarachnoid hemorrhage (SAH) admitted to a neurotraumatic ICU.

Methods: Prospectively collected data from patients admitted from October 2013 to December 2022 in a 10-bed Neurotrauma ICU. We analyzed: main diagnosis on admission; demographics, including sex and race; neurological data (clinical examination, pupil reactivity and size, and Glasgow Coma Score (GCS); aneurysm location and size; presence of intracranial hematoma (ICH); presence and volume of intraventricular hemorrhage; days to develop vasospasm; development of acute cerebral ischemia (ACI) and delayed cerebral ischemia (DCI); Fisher scale, modified Fisher scale, Hunt and Hess scale, World Federation of Neurosurgeons (WFNS) scale; presence of vasospasm on Doppler or arteriography; delayed ICU admission; treatment of the aneurysm; complications, including infections; Glasgow Outcome Scale (GOS) at ICU discharge and 6 months after ICU discharge and several other risk factors. Disability was defined as GOS ≤ 3. To identify those factors that maintained an independent association with disability, multivariate logistic regression analysis was performed. It was considered significant if $p \leq 0.05$. To determine the discriminatory ability of the Score, a receiver operating characteristic (ROC) analysis was performed. The diagnostic ability of the Score was assessed by the area under the ROC curve, which was estimated using a 95% confidence interval. For the chosen cutoff point, sensitivity, specificity, positive predictive value (PPV) and negative predictive value (NPV) were calculated.

Results: Among the 246 patients admitted for SAH, 90 (37.67%) had a GOS ≤ 3. DCI was not significantly different between the groups studied (Table 1). Fifty-one patients died, 36 at ICU discharge and 16 in hospital. Decompressive craniectomy was performed in 12 (5.4%) patients with SAH, all with GOS ≤ 3. Independent risk factors associated with disability were: mechanical ventilation (MV) > 7 days OR: 5.696 (2.535; 12.798). ACI OR: 5.012 (1.374; 18.286); Hunt and Hess score OR: 1.449 (1.099; 1.911) and Apache II on ICU admission per unit OR:1.164 (1.090; 1.243) (Table 2).

The following Score was derived from the logistic model: $0.152 \times \text{Apache II} + 1.740 \times \text{MV} > 7 \text{ days} + 1.612 \times \text{ACI} + 0.371 \times \text{Hunt and Hess score}$.

Here, MV > 7 days = 1/0 according to MV > 7 days or not.

The area under the curve (AUC) was 0.92 IC 95% IC (0.873; 0.951) (Figure 1). Cut-off point: 0.4757; specificity: 86.2 [79.7; 91.2]; sensitivity 83.3 [74.0; 90.4]; NPV: 89.7 [83.6; 94.1; PPV: 78.1 [68.5; 85.9] (Table 3).

Conclusions: In our study, 37.67% of SAH patients had severe disability at ICU discharge In SAH patients admitted to a neurotraumatic ICU, the risk factors that were independently associated with disability were: score: MV > 7 days, ACI, Hunt and Hess score and Apache II at ICU admission per unit. A predictive score was obtained.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000393

Introduction: Delayed cerebral ischemia (DCI) is a major contributor to the high morbidity and mortality rates of aneurysmal subarachnoid hemorrhage (SAH). About 30% of patients with SAH have DCI, but it is difficult to predict which patients will develop it.

Objectives: To prospectively assess risk factors for DCI in patients with SAH admitted to a neurotraumatic ICU.

Methods: Prospectively collected data of patients admitted from October 2013 to December 2022 to a 10-bed Neurotraumatic ICU. We analyzed: main diagnosis at admission; demographics, including sex and race; neurological data (clinical examination, pupil reactivity and size, and Glasgow Coma Score: GCS; aneurysm localization and size; presence of intracranial hematoma (ICH); presence and volume of intraventricular bleeding; days to develop vasospasm; development of DCI; Fisher scale, Modified Fisher Scale (MFS), Hunt and Hess scale (HHS), Word Federation of Neurosurgeons scale (WFNS); presence of vasospasm in doppler or arteriography; delayed ICU admission; aneurysm treatment; complications, including infections; Glasgow Outcome Scale (GOS) at ICU discharge and 6 months after ICU discharge and several other risk factors. A univariate analysis of DCI was performed. To obtain an DCI prediction rule, a prediction model was obtained using the classification and regression trees (CART) procedure [1]. CART classifies data using a sequence of if–then rules. The basis of decision tree algorithms is the recursive binary partitioning of the data. First the most discriminative variable is selected to split the data set into child nodes. The partitioning continues until some stopping criterion is reached. At each terminal node, the probability of DCI was estimated as the proportion of patients belonging to that node who developed the event. The tree was constructed according to the following algorithm: in the first stage, the tree grows until all cases are correctly classified, and in the second stage, we used the tenfold cross-validation method of successive pruning [1]. Finally, the tree that minimized the error measurement (deviance) was chosen. For this predictor, the corresponding ROC curve was obtained and the AUC was estimated using a 95% CI.

Results: A total of 246 patients with SAH were collected, of whom 55 (22.35%) developed DCI. Demographic data and types of admission are shown in Tables 1a and 1b. Anterior communicating artery (Aco) aneurysms were the most frequently encountered. The most frequent complications of patients with DCI were stroke 39 (70.9%) and hydrocephalus 28 (50.9%). Thirty-six (14. 6%) of the patients with SAH died at ICU discharge. Eleven (20%) of the patients with SAH and DCI died at ICU discharge. There was no statistically significant difference in mortality in patients with DCI vs. patients with SAH. The classification tree showed that: MFS ≤ 2 had 94.5% odds of no DCI (Figure 1). The AUC was 0.645 (0.577–0.713), a high negative prediction of DCI (Figure 2).

Conclusions: Our data show that 22.35% of the patients studied had DCI. The classification tree showed a high negative predictive value for DCI. Finally, mortality was not significantly higher in the patients studied than in the total patients with SAH.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000395

Introduction: Adequate sedation of critically ill patients receiving neuromuscular blocking agents (NMBA) is vital for preventing awareness (1).
Bispectral Index monitoring (BIS) is a method of assessing depth of sedation but data supporting BIS and target values comes from experience in the operating theatre and there is insufficient evidence about BIS in critically ill patients and whether this changes sedation use (2).
Objectives: To evaluate BIS use in critically ill patients receiving NMBA infusions in a large adult general critical care unit, evaluate compliance with BIS and assess sedation change in response to BIS values.
Methods: Data was collected retrospectively from patients admitted to the Adult Critical Care Unit at Manchester Royal Infirmary between 1st June 2020 and 31st December 2021. We extracted data on BIS, sedation, heart rate (HR), mean arterial blood pressure (MAP) and noradrenaline requirements. BIS values were grouped into >60, 40 to 60 and <40. We assessed differences between groups at set time points after commencing NMBA.
Results: 451 episodes of NMBA infusion were identified in 241 patient encounters. 224 episodes (49.7%) had BIS data recorded at least once in the five hours following NMBA infusion commencement. Of 756 BIS values recorded in $\leq$5 h, 96.7% were $\leq$60 of which 51.1% were between 40 and 60, and 45.6% were <40. Of 235 BIS values recorded at 12 h, 97.0% were $\leq$60 of which 48.1% were between 40 and 60, and 48.9% were <40.
During the first 5 h of NMBA infusion, in 46.4% (104/224) of episodes, the mean BIS value was <40, whilst in 53.6% (120/224) the mean BIS value was $\geq$40. There was no significant difference in the mean volumes of propofol, midazolam or alfentanil infused in this time between the two groups ($p=0.09$, $p=0.12$, $p=0.78$ respectively). Similarly, there was no difference in mean HR, MAP or noradrenaline dosing between the groups ($p=0.93$, $p=0.32$, $p=0.38$ respectively).
In episodes with BIS $\geq$40 in the first hour, the median change in BIS at 12 h was −7 (IQR −11 to 0) whilst episodes with BIS <40, the median change was +3 (IQR −2.5 to 11), ($p<0.001$). There was no difference in the rate of propofol, midazolam and alfentanil infusions between these groups at hour one and hour twelve ($p=0.08$, $p=0.85$, $p=0.98$, respectively).
Conclusions: We found BIS was only recorded in the first five hours for half of the patients receiving NMBA infusion. This may partly reflect insufficient resources, particularly during the COVID-19 pandemic when the need for NMBA infusions was high (3). Reassuringly, most patients had BIS $\leq$60 which provides some confidence of a lack of awareness in these patients.
Approximately half of the patients may have had excessively low BIS values (<40) which may represent unnecessary over sedation with a similar proportion still having BIS values <40 at 12 h. This may suggest insufficient adjustment of sedation in response to low BIS values, lack of awareness of appropriate BIS values or a lack of confidence in the output of BIS monitoring.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000396

Introduction: Patients with SARS-CoV-2 infection can express a broad spectrum of clinical manifestations, from asymptomatic to severe coronavirus disease 2019 (severe COVID-19) marked by a prominent acute respiratory distress syndrome (ARDS) [1]. Recently, it has been shown that both a daily positive fluid balance in the intensive care unit (ICU), as well as a positive cumulative fluid balance (CFB) at discharge from the ICU are associated with high mortality in patients with sepsis [2, 3]. Tissue edema due to fluid overload is a well-known mechanism of pulmonary function worsening [4].
Objectives: To evaluate the effect of two restrictive cumulative fluid balance (CFB) trends on 28-day survival in the Intensive Care Unit (ICU) in invasively ventilated patients with moderate and severe respiratory distress syndrome (ARDS) due to SARS-CoV-2.
Methods: Prospective observational single-center cohort study in the ICU of a tertiary hospital. The selected patients were older than 18 years old with confirmed infection due to SARS-CoV-2 who required endotracheal intubation and mechanical ventilation immediately at the admission at the intensive care unit. None of the patients included in this study was vaccinated against SARS CoV-2.
Results: It was enrolled 171 patients (Figure 1) in the study and divided according to their CFB trends during seven days of follow-up using model-based clustering, median restrictive CFB negative trend [n = 89] −279 ml (−664 to 203) and [n = 82] median restrictive CFB positive trend 1362 ml (619 to 2026). The group with CFB negative trend showed a higher chance of surviving 28-day in the ICU ([Figure 2 and 3] unadjusted Hazard Ratio: 0.62, 95% CI, 0.41–0.94, p = 0.038). Moreover, this group had a reduced length of stay in the ICU, 11 (8–19) days versus 16.5 (9–29) days, p = 0.004, and presented higher odds (OR = 0.22; 95% CI 0.09 to 0.52) of not being invasively ventilated after 28-days in the ICU. Length of mechanical ventilator stay was lower in CFB negative trend group 12 (9–19) versus 14.5 (9–25.5), p = 0.04.
Conclusions: In patients invasively ventilated with moderate-severe ARDS due to COVID-19, the collective who showed a negative trend inside the restrictive CFB after seven days of invasive ventilation had a higher chance of surviving 28 days in the ICU and lower length of stay in the ICU.

Introduction: Cerebral hypoxia is an important cause of secondary brain injury. Improving systemic oxygenation may increase brain tissue oxygenation ($PbtO_2$). The effects of PEEP on $PbtO_2$ and intracranial pressure (ICP) needs to be further elucidated.
Objectives: To study he effects of PEEP increments on brain tissue oxygenation and intracranial pressure.
Methods: This is a single center retrospective cohort study (2016–2021) conducted in the intensive care unit of Erasme University Hospital, Brussels, Belgium. All patients with acute brain injury under mechanical ventilation who were monitored with intracranial pressure and brain tissue oxygenation ($PbtO_2$) catheters and underwent at least one PEEP increment were included in the study. Primary outcome was the rate of $PbtO_2$ and ICP increases after PEEP increase.
Results: We included 115 patients who underwent 295 episodes of PEEP increase. Overall, PEEP increased form 6 (5–8) cmH_2O to 10 (8–12) cmH_2O, $PbtO_2$ increased from 21 (16–29) mmHg to 23 (18–30) mmHg while ICP remained statistically unchanged from 12 (7–18) mmHg to 12 (7–17) mmHg. ICP increased in 142/295 episodes of PEEP increments (58%) and no baseline variable was able to identify this response. Of 163 episode of PEEP increments with concomitant $PbtO_2$ monitoring, $PbtO_2$ increased in 102 (63%). A higher baseline PaO_2 (OR 1.02 [1.01–1.03]) and a lower baseline $PbtO_2$ (OR 0.92 [0.91–0.94)]) were associated with $PbtO_2$ increase.
Conclusions: The response in $PbtO_2$ and ICP to PEEP elevations in brain injury patients is highly variable. Lower $PbtO_2$ values and higher PaO_2 at baseline could predict an increase in brain oxygenation after PEEP increments.

Introduction: During the various waves of the COVID19 pandemic, a lot of biomarkers and inflammation markers, expensive or inexpensive, have been investigated in order to assess possible outcome in COVID-19 patients. There are few publications regarding eosinophil count or eosinophil to neutrophil ratio as a mortality prognostic marker.
Objectives: Our main aim was to assess the prognostic value of eosinophil count and eosinophil to neutrophil ratio in COVID-19 ICU patients.
Methods: We collected data from patients who were admitted to our COVID-19 ICU from April 2021 to March 2023. We recorded sex, age, ICU stay duration, outcome, maximum eosinophil count, day of maximum eosinophils (Dmax) and neutrophil count on Dmax. We tested the eosinophil to neutrophil ratio (E/N), multiplied by 1000 for readability, as a prognostic marker for death. We used the Mann–Whitney U test as we dealt with non-parametrical data. We performed receiver operating characteristic (ROC) analysis for significant results. We also performed logistic regression analysis for the outcome of death depending on age, sex, and E/N ratio. Statistical significance was set at $p = 0.05$.
Results: A total of 290 patients were included in the study. Ninety-nine of them were female (34%) and 149 of them died in the ICU (51.4%). We compared two groups of patients, those who died in the ICU and those who survived. Characteristics of the two groups are described in Table 1. Statistically significant differences were found for age, maximum eosinophil count, neutrophils at Dmax and E/N. In ROC analysis for E/N and the outcome of survival the area under the curve (AUC) was 0.854 (confidence interval—CI: 0.809, 0.898). A cut-off value of 19.23 for E/N yielded 85% sensitivity and 74% specificity for the outcome of survival. Logistic regression for the outcome of death depending on age, sex and E/N revealed that a higher value of E/N decreased the likelihood of the patient dying.

Table 1 (abstract 000398) Characteristics of the two groups of patients according to outcome

Outcome	Discharged alive (N = 141)		Died in ICU (N = 149)		
	Median	IQR	Median	IQR	p
Age (years)	66	(55, 75)	71	(62.5, 77)	0.007
ICU stay duration (days)	9	(2.5, 19)	9	(5, 20)	0.5
Maximum eosinophil count (cells/μL)	310	(165, 555)	90	(20, 270)	< 0.0001
Day of max eosinophils (Dmax)	7	(2, 15.5)	6	(2, 12)	0.278

Outcome	Discharged alive (N = 141)		Died in ICU (N = 149)		
	Median	IQR	Median	IQR	p
Neutrophils on Dmax (cells/μL)	6500	(4550, 9150)	13,800	(8500, 20,000)	< 0.0001
Eosino-philsX1000/ Neutrophils	49.5	(24.69, 92.28)	5.58	(1.27, 20.17)	< 0.0001

Conclusions: During a COVID-19 patient's stay in the ICU, the eosinophil to neutrophil ratio can prove to be quite useful as it is a sensitive marker for survival. Moreover, the absolute maximum eosinophil count is higher in COVID-19 ICU patients who are discharged alive from the ICU. Using a cheap test, such as complete blood count, we can predict the outcome of COVID-19 ICU patients.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000399

Introduction: In the beginning of the SARS-CoV-2 pandemic, patients with COVID-19 were treated with general supportive measures, as specific treatments were unknown [1]. National and societies guidelines released initially advised against the administration of systemic corticosteroids and limited the use of non-invasive ventilation to specific populations or clinical scenarios [1, 2]. The subsequent waves could be faced with new diagnostic and therapy tools (e.g., anti-viral medicaments and vaccines) [3, 4–9].
Objectives: Assess and describe differences in the clinical and demographic features, treatments and outcomes of COVID-19 adult patients admitted in the first and subsequent waves of the pandemic.
Methods: We performed a systematic review and meta-analysis with three databases. The primary outcome was in-hospital mortality. The secondary outcomes were intensive care unit (ICU) mortality, ICU length of stay (LOS), acute renal failure, extracorporeal membrane oxygenation (ECMO) implantation, mechanical ventilation time, hospital LOS, systemic thromboembolism, myocarditis and ventilator associated pneumonia.

Results: A total of 25 studies (Figure 1) with 126,153 patients were included. There was no significant difference for the primary endpoint ([Figure 2] OR = 0.94, 95% CI 0.83–1.07, p = 0.35). The first wave group presented higher rates of ICU LOS (SMD = 0.23, 95% CI 0.11–0.35, p < 0.01), acute renal failure (OR = 1.71, 95% CI 1.36–2.15, p < 0.01) and ECMO implantation (OR = 1.64, 95% CI 1.06–2.52, p = 0.03). The other endpoints did not show significant differences.
Conclusions: The analysis suggests that the first wave group when compared with the subsequent waves group presented higher rates of ICU LOS, acute renal failure and ECMO implantation, without significant difference in in-hospital or ICU mortality, mechanical ventilation time, hospital LOS, systemic thromboembolism, myocarditis or ventilator associated pneumonia (Figure 3).

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000401

Introduction: Chest CT scans of patients with Covid-19 most commonly show ground-glass lesions, consolidations or mosaic-type lesions (1–3), predominantly distributed in basal and peripheral regions and with bilateral involvement (4). The greater the pulmonary involvement, the greater the need for ICU admission and the use of invasive mechanical ventilation (5–7).

Objectives: To verify the association of the initial assessment of chest computed tomography in cases of COVID 19 infection with respiratory outcomes in the ICU, using the classification of the Radiological Society of North America and an automatic software.

Methods: A single-center, retrospective study that evaluated patients with positive RT-PCR for COVID-19, who underwent chest computed tomography and had a final COVID-19 clinical diagnosis. The visual tomographic classification was evaluated according to the Consensus of the Radiological Society of North America and software developed for detection of chance estimation of COVID-19. According to the percentage of pulmonary involvement in $>50\%$ and $\leq 50\%$, patients were compared regarding respiratory clinical and laboratory outcomes.

Results: A total of 121 patients were clustered into the $>50\%$ lung involvement group and 105 patients into the $\leq 50\%$ lung involvement group. Patients $\leq 50\%$ lung involvement group presented lower PEEP levels and FiO_2 values, respectively $P=0.09$ and $P=0.04$. The adjusted COX model found high hazard ratio for $>50\%$ lung involvement group HR: 1.69, 95% CI, 1.02–2.80, $p=0.042$ and the adjusted logistic regression model showed increased risk ventilator-associated pneumonia $OR=1.85$ 95% CI 101–3.39.

Conclusions: COVID-19 infection patient's with $>50\%$ lung involvement present association to longer mechanical ventilator time (Figure 1) and more ventilator-associated pneumonia rate.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000402

Introduction: Traumatic brain trauma (TBI) is one of the main causes of mortality and disability in patients, mostly youngs, admitted to intensive care units (ICU) and require early diagnosis and proper management to prevent secondary brain injury and treatment of intracranial hypertension (ICHT). In this study we will analyze the functional outcome and mortality in patients admitted after a severe ITB undergoing different lines of ICHT treatment.
Methods: Data was collected from a total of 182 patients admitted to the neurotraumatologic ICU after a pure TBI, with no other associated severe trauma, from 2019 to 2022, inclusive. Demographic variables, TBI prognostic assessment scales (APACHE II), treatment steps, functional outcomes (GOSE scale), and ICU mortality at 6 months and 1 year were analyzed. It was treated as a retrospective analytical study. Data were analyzed with the SPSS computer program, collecting descriptive data, frequency tables, normality tests, and statistical significance values.
Results: The 75% of the sample were men, with the mean age of the sample being 49 years. The mean APACHE was 14 points at the admission. Regarding the main injury mechanisms, 55% are made up of falls at own height and traffic accidents (16%) (Figure 1).
50% of the sample had a severe TBI (GCS < 9 points). 52% of the patients had an evacuated mass TBI (TCDB 6) and 27% type 2 (injuries less than 25 cc). Neuromonitoring was indicated in 38% (severe TBI with lesions on CT or normal CT in those over 40 years of age, abnormal motor response or hypotension).
Patients received three tiers of measures against intracranial hypertension (intracranial pressure > 22 mmHg), 50% with general measures (elevated headrest, sedation, normothermia); 38% with first tier measures (external ventricular drainage, hyperventilation, osmolar therapy and neuromuscular blockers) and 11% with second tier measures (barbiturates, decompressive craniectomy and hypothermia). In 9% of the patients (24% of those under neuromonitoring), decompressive craniectomy was performed.
Survival in the ICU was 80%. The factors that were associated with higher mortality with statistically significance were: being a man ($p < 0.012$), age over 60 years ($p < 0.001$), APACHE II > 20 ($p < 0.001$), GCS < 8 ($p < 0.009$), presence of unreactive anisocoria ($p < 0.001$) and progress to first tier measures ($p < 0.001$).
The 48% of the sample had a favorable functional outcomes (GOSE < 5) 1 year after de TBI.
The first tier measures were associated with both higher mortality and worse functional outcome ($p < 0.001$), probably since these patients intrinsically have poor prognostic factors such as GCS, APACHE II and TCDB (Figures 2 and 3). No significant differences were found in relation to mortality nor functional outcome among patients who underwent decompressive craniectomy (Figure 4).
The limitations of our study were that we could not complete mortality at 6 months and one year in patients who had not yet reached this estimated time. Likewise, despite the fact that we collected more than 180 patients over 4 years, finally the sample size of patients with decompressive craniectomy was insufficient in our hospital probably due to performing a good ABCDE strategy in emergency management, early control of extracranial factors and a proactive neurosurgery service with use of early neuromonitoring, external ventricular drainage or surgical evacuation, which decreases the volume of patients requiring barbiturate coma or decompressive craniectomy.

Conclusions:

- There is no relation between performing decompressive craniectomy and the functional outcomes and mortality, probably due to the small sample size.
- Patients treated with first tier measures have a worse outcomes.
- A good initial ABCDE strategy, good control of extracranial factors and a proactive neurosurgery service reduce the need for decompressive craniectomy.

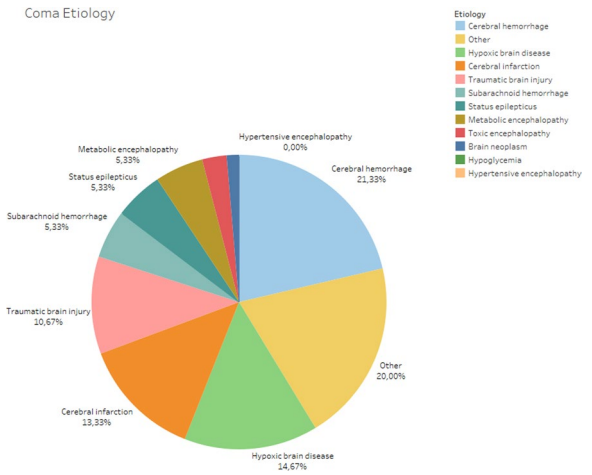
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000403

Introduction: Coma and associated disturbances in consciousness are significant challenges in neurocritical care. Understanding the prevalence of coma and its characteristics is essential for resource allocation and targeted interventions. This study aims to determine the prevalence of coma in critical and coronary care units in Chile and provide insights into demographics, etiology, complications, and support requirements of affected patients.
Chile, with a length of 4270 km (2653 miles) and an average width of 177 km (110 miles), has a mixed public and private healthcare system, presenting unique challenges when addressing treatment of coma and its associated complications.
Objectives: Our cross-sectional study aimed to investigate the prevalence of coma in critical care and coronary care units in Chile. Our primary objectives were to (1) determine the prevalence of coma within the Chilean population, (2) identify demographic data for these patients, and (3) determine the regional distribution of coma in Chile.
Methods: A cross-sectional study was conducted through a national survey of 105 out of 125 public and private hospitals with critical and coronary care units in Chile, representing 84% of such facilities. Data were collected via an online questionnaire, capturing bed occupancy, coma patient demographics, etiology, complications, and support requirements on March 22, 2023.
The definition of coma used in our study corresponds to the consensus definition established by the Neurocritical Care Society in the COME TOGETHER study.
Results: The total prevalence of coma in the surveyed units was 2.9%. The prevalence in intermediate care units was 0.7%, while it was 6.5% in intensive care units and 0.7% in coronary units. With an average response rate of 84%, no region reported data from less than 67% of its beds, and several regions even reported information from all of their facilities. The point prevalence of coma at the regional level ranged from 0 to 15.2% on the day of the survey, warranting further investigation.
Demographic data revealed a median age of 61 years, a male predominance of 66.2%, and a median coma duration of 5 days with interquartile ranges of 2 to 9 days.
Cerebral hemorrhage was the most frequent cause of coma (16%), followed by hypoxic cerebral disease (11%), cerebral infarction (10%), and traumatic brain injury (8%). At the time of the national survey, 48.1% of patients experienced coma-related complications, with 35.1% having coma-associated pneumonia. Support requirements were identified in 97.4% of patients, and the decision was made to adjust the therapeutic effort to 35% of the total number of patients.
Conclusions: This nationwide cross-sectional study provides valuable data on coma prevalence in Chilean critical care and coronary care units, highlighting the need for further research and targeted

interventions to improve patient outcomes in this unique healthcare context. The study's detailed information on coma etiologies offers insights into the causes of coma in Chile, which may inform targeted prevention and intervention strategies in the country's critical care and coronary care units.



Coma etiologies.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000405

Introduction: Approximately 15,000 tracheostomies are performed annually in the UK (McGrath et al., 2020). Historically, patients with a tracheostomy would be under the care of specialist teams such as ear, nose, and throat (ENT) or intensive care (ICU). But more recently, patients with a tracheostomy often have significant, complex medical conditions alongside their artificial airway, and are being cared for outside of critical care. Staff on general hospital wards may lack the knowledge and skills to care for this vulnerable population, resulting in significant patient harm (McGrath and Thomas, 2010). National guidance from groups such as the National Tracheostomy Safety Project, the Global Tracheostomy Collaborative and the Intensive Care Society all suggest the introduction of regular mandatory training for staff caring for patients with altered airways.
Methods: A multidisciplinary team consisting of staff from the critical care outreach team, physiotherapy and ENT devised a study day for staff on the wards who would be caring for patients with an altered airway. This included trained nurses and auxillary staff based on the ward as well as physiotherapists, occupational therapists and speech and language therapists.
The study day consisted of a mixture of theoretical and practical sessions with the opportunity to practice key skills. Pre course questionnaires were submitted to participants asking them to assess confidence levels on a scale of 1–5 on 12 subjects related to the care of patients with an altered airway. The questionnaire was repeated after the study day to assess effectiveness of the teaching and participants' confidence.
Questions asked included: define the term tracheostomy, discuss the difference between a tracheostomy and a laryngectomy, discuss the indications for a tracheostomy, identify the essential bedside equipment, discuss the different types of tracheostomy tube used within the trust, explain the function of the inner tube, explain the function of the cuff, explain why a patient with a tracheostomy may not be able to speak, discuss the methods of achieving effective communication, discuss the signs and symptoms of respiratory distress in a patient with a tracheostomy, identify complications that may occur immediately after insertion, identify complications that may occur within 3 days of insertion.
Results: Scores were obtained for each participant before and after the teaching session. The table below shows the mean score for each question.

	Sept Pre	Sept Post	Oct Pre	Oct Post	Nov Pre	Nov Post	Dec Pre	Dec Post	Jan Pre	Jan Post	Feb Pre	Feb Post	Mar Pre	Mar Post
1	2.18	4.54	3.25	4.92	2.33	4.67	2.75	4.5	1.86	4.71	3.0	4.71	3.00	4.79
2	1.63	4.45	2.67	5.0	1.56	4.67	2.63	4.63	1.71	4.57	2.57	4.71	2.93	4.86

10	1.55	4.73	2.42	4.83	1.56	4.56	2.38	4.88	1.71	4.71	3.00	4.86	2.57	4.79

	Sept Pre	Sept Post	Oct Pre	Oct Post	Nov Pre	Nov Post	Dec Pre	Dec Post	Jan Pre	Jan Post	Feb Pre	Feb Post	Mar Pre	Mar Post
11	1.18	4.73	2.42	4.67	1.22	4.44	1.25	4.88	3.00	4.86	1.00	4.43	2.43	4.64
12	1.18	4.64	2.17	4.75	1.22	4.44	1.00	4.75	2.71	5.00	1.00	4.43	2.00	4.5

Conclusions: All scores showed an improvement following the study day indicating an improvement in the knowledge and skills of the staff attending. There were a couple of areas where confidence was still slightly lower despite the study day, and these were the bedside equipment and the different types of tracheostomy rubes used within the trust. Changes were made to the study day to improve focus on these areas during the practical sessions. Scores will continue to be monitored after each study day to check that these areas are improving.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000406

Introduction: Critically ill patients often harbor risk factors for colonization and infection with multidrug-resistant (MDR) bacteria and are frequently exposed to antibiotics, leading to sustained selection pressure. Immunocompromised patients are particularly at risk of developing healthcare-associated infections (HAIs). We describe in this study the prevalence of infections by MDR microorganisms in hemato-oncology patients and their association with prognosis.
Objectives: To describe the multi- resistance profile of gram-negative germs in patients with septic shock admitted to a reference oncology ICU in Latin America.
Methods: We carried out an observational prospective cohort study in ICU of Center Treatment and Investigation in Cancer en Bogota-Colombia. All consecutive patients with an ICU stay > 24 h were included and followed for 28 days. Patients admitted exclusively with Immunosuppression for cancer or hematologic malignancy, neutropenia, solid-organ transplant, use of steroids or immunosuppressive drugs. The primary endpoint was the diagnosis of sepsis and the presence of infection in ICU for MDR microorganism.
Results: 210 patients were included, with 26 patients with shock septic for gram-negative MDR (12.3%). (58.9% males, median age 65 years) were included. The scores of severity its similar in groups of septic shock for MDR vs no- MDR.
The most frequently isolated germ was K pneumoniae with 46%, followed by *E. coli* with 30%. 46% of the isolates presented extended-spectrum beta-lactamase resistance, followed by 39% resistance to carbapenems, with 27% KPC and 12% NMD, and finally 15% with cAMP resistance. MDR isolation was more frequent in patients with hemato-oncology cancer (61%) vs solid organ cancer (39%), as well as secondary etiology to febrile neutropenia with bacteremia in 53%. Mortality in the ICU was higher in the gram-negative MDR group with 39% vs. non-MDR septic shock in 25%.
Conclusions: Cancer patients admitted to the ICU reported in this series in Latin America have a higher percentage of isolates due to MDR gram-negative germs than reported in other series. The highest percentage of these microorganisms are resistant to third generation cephalosporins with a significant increase in the isolates of germs resistant to carbapanemase. This finding points to the role of contact precautions and isolation measures, and could have important implications on antibiotic stewardship and treatment empirical antibiotics in this population.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000407

Introduction: High flow nasal cannula (HFNC) can reduce respiratory rate (RR) and work of breathing and increase end-expiratory lung volume with increasing flow rates. It is unclear these benefits can be related to increasing in expiratory resistance generated by high airflow.
Objectives: The objective of this study was to examine expiratory time constants using electrical impedance tomography (EIT) with increasing flow rates of HFNC. In addition, the associations between the expiratory time constant and RR, and end-expiratory lung volume were also investigated.
Methods: A prospective randomized cross-over study was performed in patients with acute hypoxemic respiratory failure (AHRF) and PaO_2/FIO_2 ratio of less than 300 were included. A standard non-occlusive facial mask (FM) and HFNC at rates of 10 L/min (LF) and 50 L/min (HF) were randomly applied for 15 min. At the end of each phase, RR, Borg dyspnea scale, and arterial blood gases were measured. EIT data were recorded at each phase and more than 20 recorded breaths were analyzed offline. Expiratory time constant in each pixel was determined from the expiratory flow-impedance curve and its average in the whole lung area (Tau) was calculated. In addition, impedance value at end-expiration (EELI) and impedance change during inspiration (TIV), which are corresponding to end-expiratory lung volume and tidal volume, were also examined. Changes in EELI during HFNC were expressed as a percentage of TIV at FM (ΔEELI%). The comparisons of measurements between each study phase were analyzed by one-way analysis of variance with repeated measures. Correlations were tested with Pearson's product moment correlation coefficient.
Results: Fourteen patients with AHRF (mean age 67, BMI 24) were included in this study. Mean RR and Borg dyspnea scale decreased with increasing flow rates (RR: FM 21 ± 5/min, LF 18 ± 4/min, HF 16 ± 4/min, $p = 0.007$, Borg scale: FM 4 ± 3, LF 3 ± 3, HF 2 ± 2, $p = 0.324$). Mean Tau was gradually elongated with increasing flow rates (FM 0.61 ± 0.17 s, LF 0.63 ± 0.19 s, and HF 0.73 ± 0.17 s). However, the results reached no significant differences between each study phase ($p = 0.168$). ΔEELI% were −4.8 ± 59% and −4.6 ± 45% in LF and HF respectively, indicating that EELI did not increase during HFNC compared to that of FM. On the other hand, TIV reduced with increasing flow rates. A weak correlation between Tau and RR ($R = -0.32$, $p = 0.04$) was found.
Conclusions: Delivered airflow during HFNC could prolong the expiratory time constant, indicating increased expiratory resistance with increasing flow rates. Elevated airway resistance during expiration might reduce respiratory rate and tidal volume leading to improvement of patient discomfort, regardless of increase or decrease in end-expiratory lung volume.

Longitudinal metabolic phenotypes in the critically ill: a metabolomics subtyping cohort study

H. Kobayashi[1], K. Amrein[2], J. Lasky-Su[3], K. Christopher[4]
[1]Department of Critical Care Medicine, Sunnybrook Health Sciences Centre, Toronto, Canada; [2]Division of Endocrinology and Diabetology, Medical University of Graz, Graz, Austria; [3]Channing Division of Network Medicine, Brigham and Women's Hospital, Boston, United States of America; [4]Division of Renal Medicine, Brigham and Women's Hospital, Boston, United States of America
Correspondence: H. Kobayashi
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000408

Introduction: Recent metabolomic studies demonstrated the different metabolomic profiles in patients with sepsis, trauma, and cardiac surgery. However, longitudinal metabolic phenotypes have not been described in the heterogeneous critically ill.
Objectives: To identify longitudinal metabolic phenotypes using unsupervised machine learning clustering method to the Vitamin D Deficiency in Critically Ill Patients (VITdAL-ICU) trial data and explore the relationships with outcome and meaningful biological pathways in phenotypes.
Methods: We determined the relative abundance of 659 metabolites in 1107 plasma samples from 369 patients on trial day 0, 3, and 7. We applied unsupervised longitudinal k-means clustering algorithm with joint trajectories to the metabolite abundance data. The optimal number of clusters was determined by Callinski and Harabatz criterion and biological plausibility. The primary outcome was 180-day mortality. To determine the association between longitudinal metabolic phenotypes and 180-day mortality we performed logistic regression adjusted for age, sex, Simplified Acute Physiology Score (SAPS) II, admission diagnosis, baseline 25(OH)D value, and absolute increase in 25(OH)D at day 3. Furthermore, we determined the associations between individual metabolites and phenotypes via logistic mixed-effects models with adjusting potential confounders.
Results: In the cohort, the median of age (IQR) was 66 (54, 75) years, 35% were female, 55% were surgical patients, the median SAPS II (IQR) was 30 (22, 42), and the median of baseline 25(OH)D (IQR) was 13.0 (9.5, 16.4) ng/mL. Eventually, 28-day, 90-day, and 180-day mortality were 18%, 28%, and 33%, respectively. We identified two distinctive longitudinal phenotypes: (A) amino acid-low-stable, lipid-low-stable, andxenobiotics-low-stable (65%); (B) amino acid-high-increase, lipid-high-increase, and xenobiotics-high-decrease (35%). Among the two phenotypes, major clinical characteristics were significantly different. Briefly, phenotype A was characterized by younger, high baseline 25(OH)D, low bilirubin, low creatinine, low procalcitonin, and low pro b-type natriuretic peptide (BNP). Patients with phenotype B were characterized by a high proportion of cardiac surgery patients, low baseline 25(OH)D, high bilirubin, high creatinine, high procalcitonin, and high pro-BNP. Phenotype B was significantly associated with higher 180-day mortality compared to metabotype A (adjusted odds ratio, 6.14; 95% CI, 3.12–12.09; $p < 0.001$). In the logistic mixed-effects models, 153 metabolites had significant associations with phenotype B. The metabolites were dominated by increases in glutamate metabolism, histidine metabolism, branched-chain amino acid metabolism, tyrosine metabolism, tryptophan metabolism, acylcarnitine metabolism, dicarboxylate metabolism, and polyamine metabolism. These metabolites were lower abundance and had decreasing trend in phenotype A, though the same metabolites were higher and trend increasing in phenotype B.

Conclusions: In this post-hoc metabolomic cohort study of the VITdAL-ICU trial, we identified two distinct biological longitudinal metabolic phenotypes using clustering analysis of longitudinal plasma metabolome data. The two longitudinal phenotypes have significant differences in 180-day mortality and distinct individual metabolite abundance patterns. Our findings are the first step towards identifying specific longitudinal phenotypes with optimal long term responses to critical illness.

Prognostic value of a biomarker in ARDS—a prospective study

U. Jithendran[1], T. P. Madhusudanan[1]
[1]Critical Care Medicine, GG Hospital, Thiruvananthapuram, India
Correspondence: U. Jithendran
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000410

Introduction: ARDS is common in patients admitted to ICU and is associated with multi-organ dysfunction and mortality. It is diagnosed based on a combination of clinical and physiological variables. The lack of a specific biomarker for ARDS is arguably one of the main obstacles to developing novel treatments for ARDS. It is anticipated that shortly, using biomarkers for defining ARDS, or for determining those patients who are more likely to benefit from a given therapy will have a major effect on clinical practice. B-type natriuretic peptide (BNP) was first described in the porcine brain, but BNP in humans originates primarily from the heart's ventricular myocardium. The biologically active BNP and the remaining part of the prohormone, N-Terminal-proBNP (76 amino acids) can be measured by immunoassay in human blood. Both BNP and NT-proBNP are secreted in response to ventricular muscle stretch. These are well validated as prognostic markers in heart failure. Recently, several studies have reported that BNP or NT-proBNP was elevated in patients with ARDS. We investigated whether the level of NT-proBNP is a precise predictor of the prognosis in patients with ARDS.
Objectives: The primary objective was to estimate the 28 days mortality rate and new organ dysfunction in patients presenting with ARDS in ICU and to determine plasma NT-proBNP levels in patients presenting with ARDS in ICU. The secondary objectives were to determine whether elevated plasma NT-proBNP level is associated with 28 days mortality and new organ dysfunction and to get a cut-off plasma NT-proBNP value to prognosticate mortality in patients presenting with ARDS.
Methods: A prospective observational study including all adult patients (18 years) with clinically confirmed ARDS (as per Berlin Definition) consecutively admitted in the ICU of a tertiary care hospital in Thiruvananthapuram between February 2022 and December 2022.
Results: Out of 80 ARDS patients included in the study, 38 died during the study period. The 28-day mortality rate was 47.5%. Non-survivors had higher APACHE II and SOFA scores than the survivors.
Non-survivors had a strong association with severe ARDS. They were also associated with comorbidities like Type 2 diabetes mellitus and CKD.
The median NT-proBNP of survivors was 995.50 with IQR 654–2729.25, and that of non-survivors was 4330.50 with IQR 3140.25–8240.75. The NT-proBNP levels were significantly higher among non-survivors ($p < 0.001$). The results of the ROC analysis demonstrated an area under the curve (AUC) of 0.868 with 95% confidence intervals of 0.790–0.947 (p-value < 0.001). The optimal NT-proBNP cut-off point for predicting mortality was 2491.50 pg/ml. It had 86.5% sensitivity and 76.7% specificity. New onset cardiovascular and renal dysfunctions were significantly associated with 28-day mortality ($p < 0.001$).
Conclusions: Our study was a prospective observational study of 80 ARDS patients admitted to ICU whose NT-proBNP levels were measured within 24 h. The 28-day mortality rate was 47.5%. New onset of cardiovascular and renal dysfunctions had significant association with elevated NT-proBNP. The optimal NT-proBNP cut off point for predicting 28-day mortality was 2491.50 pg/ml. It had 86.5% sensitivity and 76.7% specificity. A value of serum NT-proBNP above the optimal value was seen strongly associated with 28-day mortality.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000411

Introduction: Predictive equations in measuring energy expenditure (EE) in the critically ill patients have been associated with over or underfeeding [1]. Major guidelines recommend Indirect Calorimetry (IC) to determine EE [2]. With proprietary metabolic cart modules in the GE Carescape R860 invasive ventilators, an IC-guided nutritional protocol was implemented in Tan Tock Seng Hospital, Singapore.
Objectives: The objectives were to compare EE measured by IC versus the Harris-Benedict Equation (HBE) and the implementation of the IC-directed nutritional protocol in a retrospective observational cohort.
Methods: The study included all adult patients of age at least 21 years old admitted to the Neuroscience Intensive Care Unit (NICU) of Tan Tock Seng Hospital, Singapore, between 1 June 2020 and 30 June 2021 with an IC reading.
We excluded patients who were likely to be extubated within 24 h, imminent death within 24 h, known pneumothorax, presence of a chest tube, fraction of inspired oxygen requirements 30.6 and those on renal replacement therapy, which could entail peritoneal dialysis, haemodialysis or continuous renal replacement therapy.
The IC readings were obtained by the dieticians as part of their routine clinical work and the HBE was chosen as a comparison.
Results: A total of 108 patients admitted to the NICU had an IC measurement during the study period. Of these, their median age was 62 years and they were predominantly male (60.2%). The median BMI was 23.2 kg/m^2. The median APACHE II score was 18.0, SOFA score was 5.0 and NUTRIC score was 1.0. The most common admission diagnosis is that of an intracerebral haemorrhage (37%). The median NICU stay was 10 days with a mortality of 10.2%.
The median time from admission to an IC reading was 3 days. On the day of the IC assessment, 35.2% of the patients had fever and the recorded median GCS was 6 and median RASS was −4. The median daily calories based on HBE and IC reading was 1722.4 kcal and 1278 kcal respectively.
Analysis of the daily calories prescribed based on HBE versus IC reading demonstrated a significant difference of mean 465.3 kcal (95% CI 408.1–522.5, p = 0.000). There is a positive correlation between HBE and IC with coefficient r = 0.565 (p-value < 0.001).
Conclusions: Using predictive equation to estimate EE will confer significant overfeeding in the patients. With an IC-directed nutritional protocol, intensive care units will be able to deliver appropriate calories to the critically ill patients.

Association between out-of-hospital resuscitation duration and outcomes in children with cardiac arrest caused by drowning

A. Komori[1], H. Iriyama[1], T. Abe[1]
[1]Department of Emergency and Critical Care Medicine, Tsukuba Memorial Hospital, Tsukuba, Japan
Correspondence: A. Komori
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000412

Introduction: As little useful information is available to aid in the decision to discontinue resuscitation efforts, clinicians often perform prolonged cardiopulmonary resuscitation (CPR) in children who have drowned [1].
Objectives: We aimed to describe the association between CPR duration and outcomes in children with cardiac arrest caused by drowning using a national database in Japan.
Methods: This retrospective cohort study was conducted between 2013 and 2017 using the All-Japan Utstein Registry. We included patients (aged ≤ 18 years) with cardiac arrest caused by drowning. To investigate the association between CPR duration and outcomes, we calculated the dynamic proportion of 1-month outcomes as a function of CPR duration as follows: dynamic proportion of 1-month outcomes = ([{number of all patients who had the outcome} − Nx] 100)/ number of patients. Nx was the number of patients who underwent CPR from 0 to x min and had the outcome. CPR duration was defined as the time from CPR initiation by emergency medical service (EMS) personnel to the time of return of spontaneous circulation (ROSC) or, when patients did not achieve ROSC at prehospital EMS-initiated CPR, it was defined as the time from CPR initiation by EMS personnel to the time of hospital arrival. Additionally, we calculated the sensitivity, specificity, and positive predictive value of CPR beyond 30 min, which was the time that predicts unfavorable neurological outcome [2]. The primary outcome was favorable neurological outcome (Cerebral Performance Category score of 1 or 2) at 1 month.
Results: Of 8629 children in the registry, 611 patients with cardiac arrest caused by drowning were identified. Of these, 53 (8.7%), 185 (30.3%), 146 (23.9%), and 227 (37.2%) patients were aged < 1, 1–5, 6–11, and 12–18 years, respectively, and 418 (68.4%) were boys. The median duration of out-of-hospital CPR was 20 (13–28) min, and 137 (22.4%) patients received CPR by EMS personnel beyond 30 min. One-month favorable neurologic outcomes and survival were detected in 30 (4.3%) and 101 (16.5%) patients, respectively. After 19 min of out-of-hospital CPR, the rate of favorable neurologic outcomes decreased to < 1% of the total patients. After 30 min of out-of-hospital CPR, the rate decreased to 0.3%. After 34 min of out-of-hospital CPR, no patients with favorable neurological outcomes were noted. After 144 min of out-of-hospital CPR, 1-month survival decreased to 0%. For predicting unfavorable neurologic outcomes, CPR beyond 30 min provided a sensitivity of 0.23 (95% CI: 0.23–0.24), specificity of 0.93 (95% CI: 0.89–0.98), and positive predictive value of 0.99 (95% CI: 0.96–1.00).
Conclusions: In pediatric patients with cardiac arrest caused by drowning, the duration of prehospital EMS-initiated CPR that decreased the likelihood of favorable neurological outcome was 34 min. At 30 min, these patients may still have a chance to survive with a favorable outcome.

The performance of SOFA score as a predictor of 30-day mortality over time and in different patient groups, a retrospective cohort study

J. Helleberg[1], A. Sundelin[2], J. Martensson[3], O. Rooyackers[4]
[1]Perioperative Medicine and Intensive Care, Karolinska University Hospital, Stockholm, Sweden; [2]Perioperative Medicine and Intensive Care, Nya Karolinska, Stockholm, Sweden; [3]Departmen of Clinical Science and Education, Sodersjukhuset, Karolinska Institute, Stockholm, Sweden; [4]Department of Clinical Science, Intervention And Technology, Karolinska Institute, Stockholm, Sweden
Correspondence: J. Helleberg
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000413

Introduction: SOFA score is commonly used to quantify severity of illness in the ICU and as outcome parameter in clinical trials. Furthermore, it has been suggested to be used to guide clinical decision making. However, the standard of care has changed since SOFA was developed, both in the ICU in general but also in specific patient groups such as Sepsis, Trauma and Acute Respiratory Distress syndrome. It is also known that the predictive performance of other scoring systems such as APACHE II decrease over time in the ICU. Thus, whether SOFA score accurately reflects illness severity equally in these patient groups, and if SOFA score is equally valid as measurement throughout the stay in the ICU remains uncertain.
Methods: A computer algorithm for calculating SOFA score accurately and objectively according to recent guidelines directly from data extracted from a Patient Data Management System (PDMS) was developed and validated. In a separate cohort, consisting of 5076 adult patients admitted to any ICU at the Karolinska University Hospital between 2015 and 2018, SOFA score was calculated using the algorithm for each ICU day. The SOFA score on each day from admission to day 7 was used as predictor in a univariable logistic regression analysis with 30-day mortality as outcome parameter, and ROC-curves were constructed. DeLong's test was use for pairwise comparison of the area under ROC-curves. R version 4.2 was used for all analyses.
Results: In the 5076 patients, SOFA score could be calculated on a total of 30,883 out of 31,889 ICU days. Overall, 953 patients (18.7%) died within 30 days.

Patient characteristics at admission

Age (years)	62 (47–72)
Female/male (N/%)	2000 (39.4%)/3076 (60.6%)
SAPS3 points (mean/SD)	57.87 (± 17.38)
Surgery prior to admission (N/%)	1752 (34.5%)
Invasive mechanical ventilation (N/%)	2810 (55.4%)
Vasoactive therapy (N/%)	1320 (26.0%)
Death at 30 days (N/%)	953 (18.77%)

The AUC was highest on ICU day 2 at 0.786 (95% confidence interval 0.769–0.803) (Figure 1). In pairwise testing of day 2 vs all other days, the difference in AUC was significant in every test except vs day 1 (p = 0.12).
In a subgroup analysis of some common causes for admission in this patient population [Intracranial mass effect (n = 876), Trauma (n = 807), Acute Respiratory Failure (n = 376) and Septic Shock (n = 360)], the AUC of SOFA on the second ICU day ranged from 0.692 (0.633–0.751) in acute respiratory failure, 0.751 (0.712–0.790) in Intracranial volume effect, 0.762 (0.707–0.818) in septic shock, to 0.817 (0.775–0.859) in Trauma (Figure 2).
Conclusions: SOFA score can be used for risk stratification in the ICU, with the best performance on ICU day 2. The predictive performance differs significantly across patient groups and decreases as time progresses in the ICU. This suggests that other factors than the level of multiorgan failure as described by SOFA score could be useful to stratify the severity of illness later in the ICU stay and in specific patient groups.

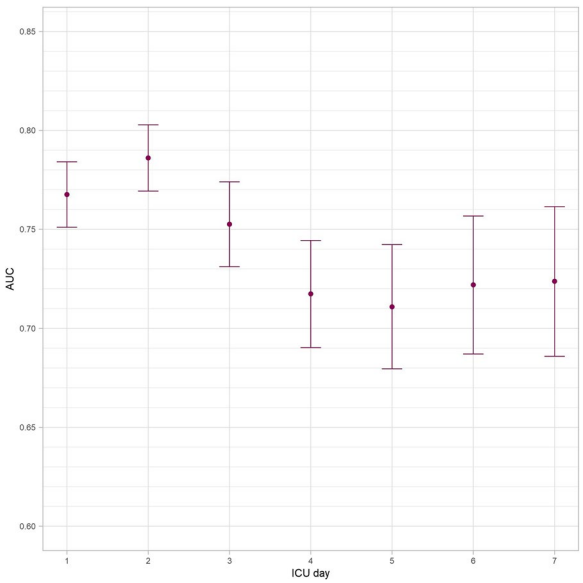

Figure 1 (abstract 000413) AUC (with 95% CI) of SOFA score as predictor for 30-day mortality, per ICU day

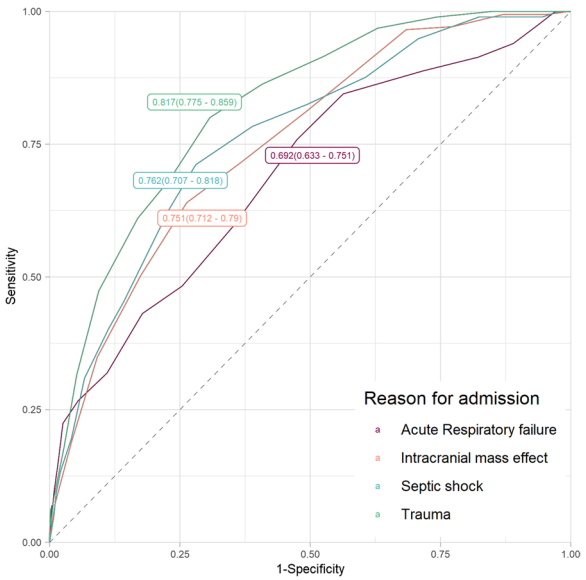

Figure 2 (abstract 000413) ROC curves of SOFA score on day 2 versus 30-day mortality, by subgroup

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000414

Introduction: Chimeric antigen receptor-modified T (CAR-T) cells are a targeted treatment for patients with advanced haematological malignancy. A proportion of these patients will develop significant CAR-T-related toxicity, namely cytokine release syndrome (CRS) and Immune Effector Cell Associated Neurotoxicity Syndrome (ICANS), with some requiring intensive care unit (ICU) admission [1]. There are limited data and consensus on the management of critically ill patients with CAR T-cell therapy toxicities in ICU, especially in the UK [2, 3].
Objectives: To describe our experience with managing patients admitted to ICU after CAR-T CD19 administration.
Methods: A retrospective analysis between January 2019 and December 2022 of patients who received CAR-T cell therapy in our tertiary hospital, one of the largest immune cell centres in the UK. Patients with diffuse large B cell lymphoma, transformed follicular lymphoma, primary mediastinal B-cell lymphoma, acute lymphoblastic leukaemia or mantle cell lymphoma, who required ICU admission after treatment were included. Patient demographics, disease characteristics and ICU management information were collected.
Results: CAR-T therapy was administered to 137 patients during the study period, with 35 (25.6%) requiring ICU admission. Patient information and the reason for ICU admission are shown in Table 1 and *Fig.* 1. Grade 2 CRS was documented in 19/35 patients (54.3%) for a median duration of 1.5 (range 0–6) days. Grade 3 CRS was seen in 9/35 patients (29%). Grade 4 CRS was documented in 1 patient. Neurological toxicity was documented in 20/35 patients (57.1%), with the majority (65%) having grade 2 ICANS.
During their ICU stay, 14/35 patients (40%) required vasopressors for a mean duration of 2.9 (1–12) days. 7 patients (20%) needed mechanical ventilation with a mean duration of 5 (4–9) days and 2 patients needed renal replacement therapy. Siltuximab was administered to 4/35 (11.4%) and anakinra to 13 (37.1%) ICU patients. Four patients (11.4%) died in ICU, all in multi-organ failure. A further 8 patients who were discharged from ICU, died before hospital discharge, all from disease progression (34.3% hospital mortality for this ICU cohort).
Conclusions: A significant number of patients receiving CAR-T therapy needed ICU admission, requiring various levels of organ support, mainly for neurotoxicity. Observed ICU mortality (11.4%) was in accordance with that reported in international literature (2, 3) and no deaths were attributed to treatment toxicity. The expanding use of CAR-T therapy in other malignancies may increase the need for ICU admissions and close collaboration between haematology and ICU is warranted for the optimal management of these patients.

Table 1 (abstract 000414) Patient information

Parameter	
Age median (range)	56 (21-69)
Gender (% female)	31.4
Median Length of stay (range) (days)	4 (1-49)
Haematological Malignancy (%)

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000417

Introduction: COVID vaccines were phased out for use among general population as early as March 2021. Vaccine hesitancy however remains the hurdle which India as a nation struggles to overcome. Although data from the World Health Organization supports COVID vaccines for preventing severe COVID, data from India is limited and almost negligible.
Methods: This retrospective cross sectional study was conducted at a tertiary care COVID center in Chennai, Tamilnadu—South India from March 2020 to March 2022. Data of all COVID inpatients confirmed by Reverse Transcriptase Polymerase Chain Reaction (RT PCR) were analyzed for clinical outcomes. All severe COVID 19 patients were admitted to the Intensive Care Unit based on the ICU admission criteria and managed appropriately using national as well as institutional guidelines. Patients` demographic details, category of COVID 19, vaccination details, comorbidities were generated real time upon patient admission and tabulated on an Excel sheet. Patients who succumbed to the disease were further categorized based on vaccination status and dose of vaccine administered. Mortality rate analysis was done for patients after segregating as pre-vaccination and post-vaccination period.
A comparative analysis among deceased patients with available data was done between vaccinated and unvaccinated individuals. Among vaccinated deceased individuals, details about type of vaccine, doses of vaccine received, mean age among vaccinated and unvaccinated individuals were analyzed. Among vaccinated deceased individuals, further analysis was performed to determine time to positivity after receiving vaccination. The cause of death among these patients along with comorbidities and contributing factors to their mortality were determined.
Results: A total of 4512 RT-PCR confirmed COVID 19 positive cases were admitted to our hospital since the beginning of the COVID pandemic; of which 4167 recovered and 345 COVID 19 positive deaths were reported. Therefore the overall mortality rate was 7.6% in our study. Mean age of all individuals who succumbed to the infection was 63.3 years. Out of 2387 patients in post vaccine era, 197 patients (8.2%) who had severe COVID 19 pneumonia and respiratory distress succumbed to the infection. Among these 197 patients, 146 (74.1%) were not vaccinated, 51 (25.8%) were vaccinated [Figure 1]. Mean age of vaccinated individuals who succumbed to the virus was 70.2 years.
Upon analysing vaccine eligibility of deceased individuals, all 197 patients were eligible for vaccination. Date of vaccination and time to positivity were analysed. During second wave, the median time to positivity after receiving vaccine was 28 (9–90) days. Whereas, during third wave, the median time to positivity was 171.6 (8–328) days. Major comorbidities among vaccinated individuals were systemic hypertension (94.2%), type II diabetes mellitus (82.7%), heart disease (40.4%), chronic kidney disease (23%), and lung diseases (28.8%) [Figure 2]. Many patients succumbed to the disease complicated by sepsis and septic shock. Few patients suffered from conditions such as acute kidney injury, pyelonephritis, chronic liver disease, Parkinsonism and rheumatoid arthritis.
Conclusions: This study showed that in spite of vaccine availability and eligibility, many COVID deaths in India could not be prevented during the second wave. This catastrophic effect was contributed by the huge pool of unvaccinated population. Although available, hesitancy and reluctance are major stumbling blocks for vaccine coverage among Indian population. Therefore, data from such studies can be used as awareness tools to delineate major differences in outcome of vaccinated and unvaccinated COVID infected patients. The next hurdle for our nation is compliance to precaution/booster doses by fully vaccinated individuals to tackle newer evolving variants and sub variants. Good vaccine coverage will help in reducing ICU admissions and burnouts among healthcare workers caring for COVID patients in ICUs.

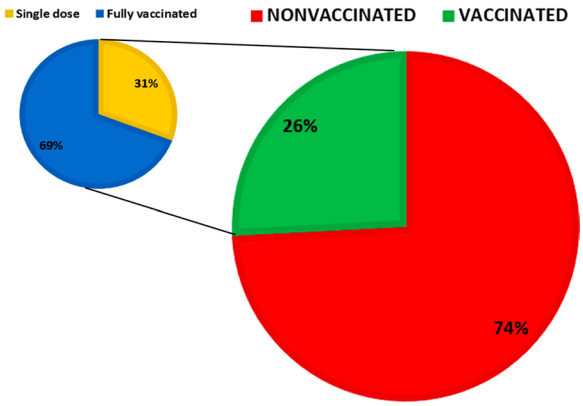

Figure 1 (abstract 000417) Distribution of vaccine status of deceased COVID patients (n = 197)

Comorbidities	Percentage of vaccinated patients
Systemic hypertension	94.2%
Type II Diabetes mellitus	82.7%
Heart disease	40.4%
Chronic Kidney Disease	23.0%
Airway diseases (Bronchial Asthma/COPD)	17.3%
Interstitial lung disease	11.5%

Figure 2 (abstract 000417) Contributing factors to mortality among vaccinated individuals (n = 52)

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000418

Introduction: Optimal anticoagulation strategies for COVID-19 patients with the acute respiratory distress syndrome (ARDS) on veno-venous extracorporeal membrane oxygenation (VV ECMO) remain uncertain. A higher incidence of intracerebral hemorrhage (ICH) during VV ECMO support compared to non-COVID-19 viral ARDS patients has been reported, with increased bleeding rates in COVID-19 attributed to both intensified anticoagulation and a disease-specific endotheliopathy (1). We hypothesized that lowering the intensity of anticoagulation during VV ECMO would reduce the risk of ICH.
Methods: In a retrospective, multicenter study from three academic tertiary intensive care units, we included patients with confirmed COVID-19 ARDS requiring VV ECMO support from March 2020 to January 2022. Patients were grouped by anticoagulation exposure into higher intensity, targeting anti-factor Xa activity (anti-Xa) of 0.3–0.4 U/mL, versus lower intensity, targeting anti-Xa 0.15–0.3 U/mL, cohorts. Mean daily doses of unfractionated heparin (UFH) per kg bodyweight and effectively measured daily anti-factor Xa activities were compared between the groups over the first seven days on ECMO support. The primary outcome was the rate of ICH during VV ECMO support.
Results: 141 critically ill COVID-19 patients were included in the study. Patients with lower anticoagulation targets had consistently lower anti-Xa activity values over the first 7 ECMO days ($p < 0.001$). ICH incidence was lower in patients in the lower anti-Xa group: 4 (8%) vs 32 (34%) events. Accounting for death as a competing event, the adjusted subhazard ratio for the occurrence of ICH was 0.28 (97.5% CI 0.1–0.8, $p = 0.023$) for the lower anti-Xa compared to the higher anti-Xa group (Figure 1). 90-day ICU survival was higher in patients in the lower anti-Xa group, and ICH was the strongest risk factor associated with mortality (odds ratio [OR] 6.62 [CI 2–21.4], $p = 0.002$) (Figure 2).
Conclusions: For COVID-19 patients on VV ECMO support anticoagulated with heparin, a lower anticoagulation target was associated with a significant reduction in ICH incidence and increased survival.

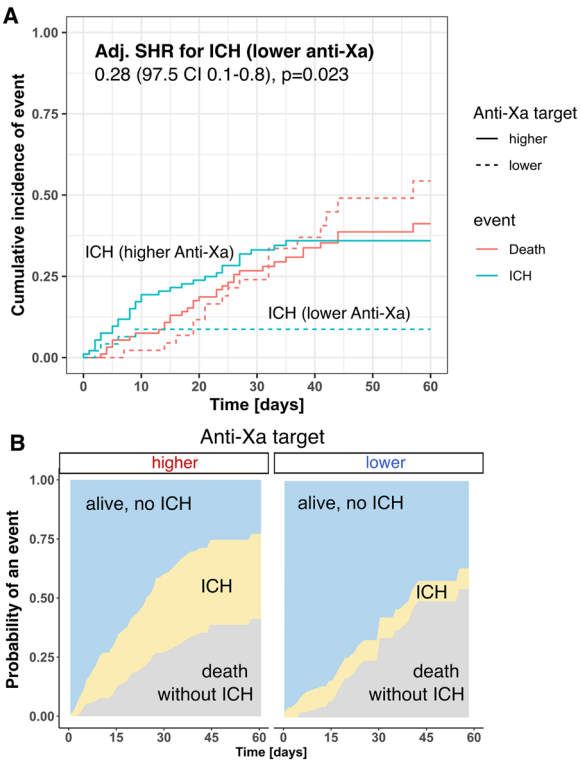

Figure 1 (abstract 000418) Competing risk regression model demonstrating incidences of intracranial hemorrhages (ICH) according to anticoagulation target group (A). Cumulative incidence of ICH and death as multistate comparison is shown in (B)

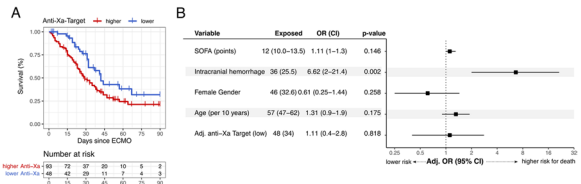

Figure 2 (abstract 000418) Generalized linear mixed effects model. Introduction: Families' preference and knowledge about end of life care may act as important factors in intensive care unit (ICU).
Objectives: We performed a randomized trial to find out the effects of video education materials on preference and knowledge of on life sustaining treatment among families of ICU patients in Korea.
Methods: Family members of ICU patients aged > 18 years were randomized into to either verbal arm listening to a recorded verbal narration or the video arm watching video regarding life-sustaining treatments.
Results: Among a total of 209 participants, 168 participants enrolled, and were randomly assigned to the verbal (n = 84) or the video arm (n = 84). The proportion of participant in the verbal group and video group wanting to receive each life sustaining treatments was similar before randomization. Each 84 participants want to receive the life sustaining treatment after intervention as follows; CPR [30 (35.7%) vs. 31 (36.9%), p = 1.000]; intubation [26 (31.0%) vs. 29 (34.5%), p = 0.7425]; tracheostomy [20 (23.8%) vs. 20 (23.8%), p = 1.000]; CRRT [18 (21.4%) vs. 20 (23.8%), p = 0.8539]. When analyzing all participants, the preference for life-sustaining treatment also did not change after education except tracheostomy (16.9% vs. 24.1%, P = 0.014). The mean of life-sustaining treatments assessment questionnaire scores (range 0–10) were significantly increased after intervention in all participants (8.46 vs. 7.55, P < 0.0001).
Conclusions: Our study suggests that the preference of life sustaining treatments was not impacted by each intervention. However, total of participants who viewed video and listened verbal narration more likely desire to undergo tracheostomy after intervention. Moreover, participants were more informed after intervention.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000424

Introduction: As a measure of preload responsiveness, change in the corrected flow time of the carotid artery (ccFTΔ) is a surrogate for stroke volume change (SVΔ). However, the reported optimal threshold and accuracy of ccFTΔ to detect SVΔ are inconsistent. Conflicting data likely have 3 sources: (1) human measurement variability, (2) temporal discordance between carotid Doppler and the reference standard and (3) sampling too few cardiac cycles.
We hypothesized that the area under the receiver operator curve (AUROC) for ccFTΔ to detect a + 10% SVΔ would improve with synchronization between the carotid artery and left ventricular outflow tract (LVOT) with temporal resolution of a single cardiac cycle and as a function of consecutively-averaged cardiac cycles.
Objectives: (1) Describe sources of error when comparing hand-held Doppler SVΔ surrogates with a reference standard.
(2) Describe a paradigm where human measurement variability and temporal discordance between peripheral Doppler and SVΔ reference standard are minimized.
(3) Explore the effect of cardiac cycle sample size on the diagnostic accuracy of ccFTΔ for detecting a + 10% SVΔ
Methods: The Research Ethics Board of Health Sciences North approved the study. A convenience sample of adult patients comprise this analysis. Exclusion criteria were history of severe carotid stenosis, lack of informed consent and contraindication to transesophageal echocardiography (TEE).
Anesthesia was induced with 0.5 mg/kg propofol, 1.2 mg/kg rocuronium, 1.0 µg/kg sufentanil and maintained with sevoflurane of 0.5 to 0.7 minimum alveolar concentration and 0.2 µg/kg/h sufentanil IV. Ventilation was volume-controlled with tidal volume 8 mL/kg of lean body weight, respiratory rate 15 breaths/min, PEEP 5 cmH_2O and FiO_2 0.5.
The wearable Doppler patch (Flosonics Medical, Sudbury, ON, Canada) is a continuous-wave 4 MHz ultrasound placed over the carotid artery and calculates ccFT by Wodey's equation. LVOT velocity time integral (VTI) from TEE was measured by a cardiac anesthesiologist using a Phillips Epiq (Cambridge, MA, USA) 2.9 MHz probe in the trans-gastric window; the insonation angle was 0 degrees and sample window 4 mm.
Synchronized Doppler data from the carotid artery and TEE were recorded during a 60 s baseline and throughout an entire 90 s Trendelenburg maneuver following CABG with the chest open.
For each subject, both ccFTΔ from the ultrasound patch and LVOT VTI change (LVOTΔ) from TEE were calculated using 1-to-30 consecutively-averaged, synchronous cardiac cycles between supine and Trendelenburg positions. Consecutive beats were selected randomly for 1000 iterations per patient. Comparisons were dichotomized into LVOTΔ (i.e., SVΔ, assuming constant LVOT diameter) of ≥ + 10% or < + 10%. From the 1000 iterations, distributions of optimal ccFTΔ and its sensitivity, specificity and AUROC were determined for each of 1-to-30-cycle averages. The mean and standard deviations of the distributions were calculated.
Results: Data from 23 patients and preload challenges comprising 2310 cardiac cycles are included. Figure 1 shows the baseline patient characteristics and results.
When 1 cardiac cycle was compared from baseline to Trendelenburg position, the mean AUROC, sensitivity, specificity and optimal ccFTΔ threshold were: 0.65, 76%, 67% and 8.2 ms (ms), respectively. For 6 and 24 consecutively-averaged cardiac cycles, these values were 0.76, 85%, 73%, 8.6 ms and 0.84, 91%, 84% and 7.2 ms, respectively.
Conclusions: The clinical relevance of our findings are as follows: (1) ccFTΔ obtained by wireless, wearable Doppler ultrasound accurately detects TEE-measured SVΔ when synchronized with single-beat temporal resolution, (2) the accuracy of ccFTΔ to detect SVΔ depends on the number of consecutively-averaged cardiac cycles. (3) the optimal ccFTΔ threshold is less influenced by the number of averaged-beats but the standard deviation decreases with more cardiac cycles (i.e., confidence increases). (4) AUROC plateaued at 0.84 with 24 consecutively-averaged cardiac cycles (sensitivity 91%, specificity 84%); the optimal ccFTΔ to detect a 10% SVΔ with this number of beats was 7.2 ms.

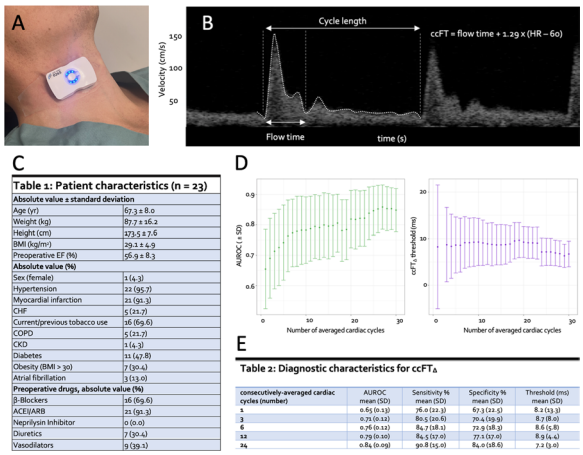

Figure 1 (abstract 000424) (A) Wearable Doppler ultrasound on a volunteer. (B) Carotid Doppler spectrogram, flow time and equation of Wodey. (C) characteristics of patients. (D) relationship between number of averaged cardiac cycles (x-axis) and the area under the receiver operator curve (AUROC) and optimal corrected flow time change (ccFT?) threshold for identifying a + 10% change in stroke volume (SV?). Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000426

Introduction: Ventilator associated pneumoniae (VAP) is defined as a nosocomial pneumonia that develops 48 h after intubation in patients receiving mechanical ventilation (IMV). VAP is the second most common nosocomial infection in ICU, affecting 5–40% of patients with an incidence ranging from 5 to 20 cases per 1000 ventilator days. It increases the duration of hospitalization and mortality, with a VAP-related mortality of 30–50%. During the last decades there have been great scientific concern about implementing the best strategies to reduce its incidence and it is consensual that general preventive measures, if implemented together—as bundle, might result in better outcomes.
Objectives: The aim of this study was to describe the epidemiological evolution of VAP and to evaluate bundle compliance during the last 5 years.
Methods: We performed a retrospective analysis of sociodemographic, clinical data and VAP-bundle compliance of patients admitted to our ICU between march 2019 and march 2023.
Results: A total of 61 patients were diagnosed with VAP, corresponding to a prevalence of 16.5% (24 per 1000 ventilator days), with an increasing pattern from 2019 to 2021 (16.7% *vs* 17.1% *vs* 20.2%) and decreasing since then (13% *vs* 4.35% in 2023). Table 1 summarizes the baseline sociodemographic and clinical data of the overall VAP population and the particular analysis through the 5 years of study. There were no significant differences between years in the 24-h SOFA, SAPS II and APACHE II scores. The mean age was 64.9 ± 11.8, with significant older patients in 2020 (F (4, 56) = 2.98; ***p* = 0.03**). 39 patients (63.9%) were male, with no differences regarding gender between years (χ^2 (4) = 3.03; $p = 0.55$). The mean ICU length of stay was 21.9 ± 14.8 days and 28-days mortality 39.3%. The time of onset of VAP was 9.61 ± 5.66 days since intubation. 29 patients (47.5%) had COVID-19 at admission and the peak of cases occurred in 2020, despite there were no significant differences between years (χ^2 (4) = 9.20; $p = 0.06$). Data regarding bundle compliance are reported in Table 2. Stress ulcer prophylaxis was performed in every patient (all considered high risk)—in 55 patients (90.2%) with i.v. pantoprazol and in 6 (9.84%) with omeprazol. 41 patients (67.2%) started enteral feeding in the first 48 h and readiness to wean and early spontaneous breathing trial (SBT) was performed in 57 patients (93%).
Conclusions: The prevalence of VAP was coincident with the reported in the literature. Regarding the evolution along the years, the peak of cases in 2020 and 2021 might be related with the reported increased incidence of COVID-19 cases in those years and the absence of significant differences might be explained by the small sample size. To date there is an increasing number of studies reporting a higher incidence of VAP in COVID-19 patients. Besides that, the compliance of SBT was also lower in 2020, which might also have predisposed to the increased risk to VAP. It is consensual that the implementation of measures among ICU personnel regarding to VAP preventive strategies is fundamental to reduce its incidence. Some standard measures included in the VAP bundle, as early SBT and restriction of stress ulcer prophylaxis to the high-risk patients appear to be consensual in the scientific community. However, there are measures that are still not certain such as oral care with chlorhexidine or the increased risk of VAP with the early initiation of enteral nutrition. In this context it is fundamental that randomized controlled trials are performed to compare different measures efficacy and find the best combination of interventions to create a gold standard VAP bundle.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000427

Introduction: The decision on the initiation of enteral nutrition therapy in patients admitted to the ICU who require oxygen therapy with high-flow nasal oxygen therapy (HFO) and/or noninvasive mechanical ventilation (NIV) is currently the subject of debate. Despite the benefits associated with this practice, the scarcity of clinical studies with sufficient methodological quality, as well as the absence of specific recommendations on enteral nutrition therapy in this type of patient generates controversy.
Objectives: Prospective, observational, multicenter study to analyze: 90-day mortality, tolerance and side effects of trophic enteral nutrition (TEN) in a cohort of critically ill patients with HFNO and/or NIV.
Methods: Patients requiring 24 or more hours of oxygen therapy with HFNO and/or NIV with expected ICU stay and survival greater than 72 h. BMI < 18 and absolute contraindication to start TEN or non-functioning GI tract were excluded.
Energy target: 20–30% caloric needs (oral: decaffeinated coffee flavored diet or NG tube); protein intake: corresponding diet used: hyperproteic (100 g/1000 ml); caloric intake 1.2 kcal/ml and ratio non-protein kcal/g nitrogen: 52:1 (Fresubin Intensive. Fresenius-kabi, Germany).
Variables: age, sex, weight, height, BMI, severity scales, reason for admission, type of patient, days HFNO/NIV; days of stay and ICU/hospital mortality: 90 days. Protein levels, renal and liver biochemistry: admission/discharge. Nosocomial infectious complications. Variables related to efficacy and safety of TEN, including gastric residuals (> 500 ml/day). Follow-up: from start of oxygen therapy until 3 days after the end of TEN.
Categorical variables are expressed as frequencies and percentages and continuous as mean and standard deviation (SD) when data followed a normal distribution, or as median and interquartile range (IQR = 25th–75th percentile) when distribution departed from normality. The percentages were compared, as appropriate, using the Chi-square () test or the exact Fisher test, the means by the t-test, and the medians by the Wilcoxon test for independent data. Data were analyzed using the R package, version 4.2.1 (R Development Core Team, 2022). (clinicaltrials.gov: NCT03728452).
Results: One hundred and seven patients were recruited. Mean age, Apache II and Sofa score, tracheobronchitis, UTI and antibiotic treatment were significantly higher in dead versus alive patients. There were no significant differences in the volume of diet administered and kilocalories between alive and dead. However, the dead received significantly less protein than the alive. Episodes of feeding intolerance were scarce, but feeding interruptions were significantly higher in death versus alive patients. None of them had aspiration episodes, but 15.6% received prokinetics. Mortality was 14.9%, but at 90 days was 43.8% (Table 1).
Conclusions: Trophic enteral nutrition appears feasible and safe in this cohort of ICU patients. Sixteen patients died, although nearly half of them between 60 and 90 days.

Introduction: Following cardiac arrest and return of spontaneous circulation, persistent brain hypoxia leads to ongoing hypoxic-ischemic brain injury (HIBI). Red blood cell (RBC) transfusions have been explored as a method to improve brain oxygenation, but studies from the neurocritical care setting have not demonstrated a consistent ability for RBC transfusion to improve brain oxygenation.
Objectives: Determine the impact of RBC transfusion on brain oxygenation in post-cardiac arrest patients with HIBI.
Methods: We performed a single center prospective interventional study on 23 post-cardiac arrest patients with HIBI that were enrolled into one of two groups: (1) invasive neuromonitoring of the intraparenchymal partial pressure of brain tissue oxygen ($PbtO_2$; n = 9), and (2) non-invasive neuromonitoring with jugular venous oximetry and near-infrared spectroscopy (NIRS; n = 14). Pre-transfusion and 12–24 h following transfusion, paired arterial and jugular venous blood samples were collected to determine the arterial-to-venous differences of brain injury biomarkers. These markers included glial fibrillary acidic protein (a marker of astroglial injury and activation) as well as neurofilament light (a marker of axonal injury).
Results: Neither the NIRS-derived regional saturation of oxygen (P = 0.08) or $PbtO_2$ (P = 0.19) were altered by RBC transfusion. Following RBC transfusion there was cerebral release of glial fibrillary acidic protein (− 91.0 [− 325.9–20.9] pg/mL; P = 0.045) and neurofilament-light (− 39.5 [− 499.3–7.1] pg/mL; P = 0.040) indicating ongoing neuroglial injury.
Conclusions: RBC transfusions may lack efficacy in mitigating secondary brain hypoxia in post-cardiac arrest patients with HIBI. Future work investigating the physiologic consequences of RBC transfusion is needed to determine the mechanisms underlying this potential lack of efficacy.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000433

Introduction: Patients with long-term critical illness, after a period of intensive care, deterioration of heart failure, or arrhythmias in need of implantable cardioverter-*defibrillator* often have an impaired physical function, decreased health-related quality of life (HRQoL) and symptoms of anxiety and depression. Yoga, as a mind–body intervention, may improve these outcomes. Further a tele-yoga intervention can potentially increase accessibility and facilitate participation for highly symptomatic patients that have problems leaving their home.
Objectives: To determine effects of tele-yoga on exercise capacity and patient-reported outcome measures.
Methods: Participants were recruited from four hospitals (university and county hospitals) in Sweden. Inclusion criteria were patients > 18 years, hospitalised at intensive care units (ICU) or cardiology units > 48 h during the last 36 months and now clinically stable. The participants were randomised to a control group receiving individual exercise advice or to the intervention group (tele-yoga). The intervention included performing live-streamed group-yoga for 60 min twice/week for 3 months and practicing yoga individually for a minimum of 10 min/day using an application. The group-sessions were led by certified mediyoga-instructors via a virtual video-platform. The yogaform was Kundalini adapted to individuals with health conditions (mediyoga) including different postures, breathing exercises and meditations. The primary endpoint of the study was a combined endpoint consisting of minimal clinically important difference in functional capacity measured by 6-min walk test (6MWT), HRQoL (EQ-5D index/VAS) and symptoms of anxiety and depression (HADS). The used cut offs for comparison between baseline and follow-up after 3 months were > 30 m for 6MWT, a score > 0.08/> 11 for EQ-5D index/VAS and ≥ 8 for HADS. The primary combined end-point analysis after 3 months follow-up compared the change in the combined endpoint between the participants in the tele-yoga and control group. Secondary endpoints included separate analysis of functional capacity, HRQoL and symptoms of anxiety/depression.
Results: A total of 311 participants were randomized to tele-yoga (n = 156) and control (n = 155), mean age 65,8 years, 30% women, 16% being cared for in an ICU. There was a significant improvement in favour of the tele-yoga group in the combined primary endpoint (p = 0.006). When analysing them separately, there was a significant improvement in 6MWT (p = 0.008) and HRQoL in EQ-5D VAS (p = 0.014), but not in EQ-5D index (p = 0.12), and a significant difference between the groups in symptoms of anxiety and depression (p = 0.03).
Conclusions: The tele-yoga intervention showed a significant improvement in the combined endpoint consisting of physical function, HRQoL and mental health. Tele-yoga may be a promising new form of rehabilitation for patients with long-term critical illness.

Introduction: Extremely low lipid levels are considered a sign of debilitation and illness. Previous reports on the association between lipid levels and mortality in critically ill patients have been inconsistent, and there have been few detailed reports for critically ill children.
Objectives: The objective of the study was to characterize the longitudinal, dynamic high-density lipoprotein (HDL) trajectory in critically ill children admitted to the pediatric intensive care unit (PICU) and explore the relationship between the groups stratified by different trajectories and clinical outcomes.
Methods: All critically ill children admitted to PCIU between 2016 and 2021 were included. Group-based trajectory modeling was applied to characterize the HDL trajectories in days 0–6 post-PICU admission and develop HDL trajectory subgroups. Then, multivariate logistic regression and multiple linear regression were used to compare clinical outcomes across distinct groups. In addition, a sensitivity analysis was performed in critically ill children with the age less than 1 year. The primary outcome indicator was in-hospital mortality; the length of stay (LOS) in the PICU was the secondary outcome.
Results: A total of 4384 eligible critically ill children were ultimately enrolled in the study, and 6 HDL trajectory subgroups were developed by GBTM analyses, differing in the initial HDL, evolution pattern. Group 1 (n = 758), "the lowest HDL subgroup", was characterized by starting with the lowest HDL and maintaining stable after slightly declining. Group B (n = 1413), the "lower HDL subgroup", was the same trend as Group 1 but the whole trajectory was higher than Group 1. Group 3 (n = 74), the "low-to-high subgroup", was characterized by starting with low HDL (lower than Group 2 but higher than Group 1), then rose slowly to the highest. Group 4 (n = 621), "the medium HDL subgroup", was the same trend as Group 2, but the whole trajectory was higher than Group 2 and lower than Group 5. Group 6 (n = 147), the highest HDL subgroup, started with the highest HDL and then slowly descended. Group 5 (n = 1371), the "higher HDL subgroup", was the same trend as Group 6, but the whole trajectory was lower than Group 6. Compared with critically ill children in Group 1, those belonging to Group2, Group 3, Group 4, Group 5, and Group 6 were at lower risks of in-hospital mortality with (odds ratio[OR] 0.475; 95% confidence interval [CI] 0.352–0.641, P < 0.001), (OR 0.093; 95% CI 0.013–0.679, P = 0.019), (OR 0.322; 95% CI 0.208–0.479, P < 0.001), (OR 0.263; 95% CI 0.185–0.374, P < 0.001), (OR 0.142; 95% CI 0.044–0.454, P = 0.001), respectively. Multiple linear regression analysis was performed to evaluate the effect of HDL trajectory subgroups on the LOS of PICU. Compared with critically ill children in Group 1, those belonging to Group2, Group 3, Group 4, Group 5, and Group 6 had the trend of shorter LOS of PICU, and the β value and 95% CI were (β −0.744; 95% CI −1.494 to −0.007, P = 0.052), (β −1.497; 95% CI −3.530–0.537, P = 0.149), (β −4.332; 95% CI −5.238 to −3.426, P < 0.001), (β −3.053; 95% CI −3.809 to −2.297, P < 0.001), (β −6.28; 95% CI −7.842 to −4.721, P < 0.001), respectively. Similar results performed by sensitivity analysis were observed in critically ill children with the age less than 1 year.
Conclusions: This study developed six HDL trajectory subgroups for critically ill children with distinct clinical outcomes. GBTM is a granular method for describing HDL evolution, which may add to the current knowledge of lipid metabolism in critically ill children.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000435

Introduction: Electrical impedance tomography (EIT) can detect collapsed and overdistended lung regions and is currently used for PEEP titration. We hypothesized that the results of ventilation distribution on EIT during PEEP titration would be different between pressure control ventilation (PCV) and volume control ventilation (VCV) mainly because of heterogeneity in time-constant among lung regions in a same patient and the difference between individual alveolar inflation as a result of a preset airway pressure and time with less interaction among lung regions, and that as a result of a preset flow rate and volume as a whole lung with more interaction among different lung regions.
Objectives: The aim of this study is to investigate the hypothesis that the transition point of anterior to posterior ventilation ratio (A/P ventilation ratio) from less than 1.0 to greater than 1.0 would be different between PCV and VCV on EIT during PEEP titration.
Methods: Mechanically ventilated patients with ARDS were enrolled in the study. We performed decremental PEEP titration with PCV, VCV with constant flow rate of 50 L/min and/or VCV with decelerating flow with a peak flow rate of 50 L/min during intensive care unit admission. We compared the transition point of A/P ventilation ratio from less than 1.0 to greater than 1.0 detected by EIT with each ventilation mode.
Results: So far, a total of 6 mechanically ventilated patients with ARDS were included. Median age was 71.5 [IQR 68.3–77.6] and median BMI was 24.7 [IQR 23.9–25.9]. Median P/F ratio was 159 [IQR 99.0–213] and median respiratory system compliance was 30.0 [IQR 27.0–40.5] ml/cmH_2O before PEEP titration. Decremental PEEP titration was performed with PCV in all patients, 4 with VCV-constant flow and 3 with VCV-decelerating flow in addition. The transition point was 7.00 [7.00–9.25] cmH_2O with PCV, 10.0 [9.30–11.50] cmH_2O with VCV-constant flow and 7.00 [7.00–8.50] cmH_2O with VCV-decelerating flow. Mean difference of the transition point between PCV and VCV-constant flow was −3.0 cmH_2O (p value = 0.07) and 0 cmH_2O (p value = 1.0) between PCV and VCV-decelerating flow.
Conclusions: This interim report indicates that ventilation distribution with VCV-constant flow might be more ventrally at the same PEEP compared to PCV in ARDS patients and that the "Best PEEP" determined by EIT might vary among ventilation modes.

Long-term outcomes of patients who received extracorporeal cardiopulmonary resuscitation (E-CPR) following in-hospital cardiac arrest—an analysis of EXCEL registry data

G. Pound[1], D. Jones[1], G. Eastwood[1], E. Paul[1], C. Hodgson[1]
[1]School of Public Health and Preventive Medicine, Monash University, Faculty of Medicine, Nursing and Health Sciences, Clayton, Australia
Correspondence: G. Pound
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000437

Introduction: The estimated frequency of in-hospital cardiac arrests (IHCA) in Australia and New Zealand is 1.3–6.0 per 1000 hospital admissions [1]. Despite treatment advances, survival rates have only marginally improved, and in-hospital mortality is approximately 75–80% [2]. As such, there is growing interest in the use of novel therapies to improve outcomes of patients who experience IHCA. There has been a tenfold increase in the utilisation of extracorporeal cardiopulmonary resuscitation during cardiac arrests (E-CPR) that are refractory to conventional CPR [3]. Although E-CPR may be associated with increased survival and improved neurological outcomes at hospital discharge [4], there is limited data regarding the long-term outcomes of patients who receive E-CPR following IHCA.
Objectives: To evaluate the functional outcomes of patients who received E-CPR following IHCA at 180-days.
Methods: Secondary analysis of prospectively collected EXCEL registry data. EXCEL is a high-quality, prospective, binational registry of adult

patients who receive extracorporeal membrane oxygenation (ECMO) in Australia and New Zealand. Patients reported to the EXCEL registry who were ≥ 18 years old, received E-CPR following an IHCA and who have 180-day outcome data available were included in this study.
Results: Between 15th February 2019 and 31st August 2022, 113 patients received E-CPR following IHCA (mean age 50.7 ± 13.7 years; 79/113 [69.9%] males). Approximately one third had a shockable arrest rhythm (39/113 [34.5%]), and almost all were witnessed (110/113 [97.3%]) with resuscitation commencing immediately (median no flow time 0 [0, 0] minutes). The median time from IHCA to E-CPR implementation was 40 (29, 56) minutes. Thirty-nine (34.5%) patients survived to hospital discharge and 36 (31.9%) to 180-days. At follow-up, most patients were living at home (29/36 [80.6%]) and had a good functional outcome (modified Rankin Scale (mRS) score ≤ 3; 25/36 [69.4%]). However, patients reported higher levels of disability and a worse health-related quality of life (HRQoL) at 180-day follow-up compared to baseline (median WHODAS total disability % score 0.0 [0.0, 8.3] vs. 20.0 [6.0, 35.0], p < 0.0001; median EQ5D index 1.000 [0.787, 1.000] vs. 0.773 [0.623, 0.893], p = 0.003; median EQ5D VAS 85 [75, 90] vs. 70 [60, 85], p = 0.027). In addition, there was a high prevalence of complications reported at 180-days, including reduced lower limb sensation (23/26 [63.9%]), lower limb weakness (19/36 [52.8%]) and memory problems (18/36 [50.0%]).
Conclusions: Approximately one third of patients who received E-CPR following IHCA were alive at 180 days, and most had a good functional outcome. However, patients reported higher levels of disability and a worse HRQoL at 180-days compared to baseline and complications were highly prevalent.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000438

Introduction: In recent years, there is an active automation of processes in medicine and robotic (Intellectual) ventilation modes are being actively introduced into the daily practice of intensive care units. These modes allow for automated respiratory support, minimizing clinician's involvement. Currently, the most automated mode is INTELLiVENT-ASV (Adaptive Support Ventilation)®.
Objectives: To compare the effect(s) and safety of full closed loop ventilation and oxygenation Intellivent-ASV mode with closed loop ASV mode and conventional ventilation modes during respiratory support after uncomplicated cardiac surgery.
Methods: In this randomized controlled trial 40 adult patients were ventilated with Intellivent-ASV®, 40 with ASV mode and 40 with conventional ventilation modes. Hamilton G5 ventilators were used and 8 physicians were involved into the study. Care of groups were standardized, except modes of postoperative ventilation.
We compared: (1) the physician's workload, through accounting number of manual ventilator settings and time they spent near the ventilator in every group;
(2) evaluation of ventilation safety by considering driving pressure (ΔP), mechanical power, PEEP, tidal volume (Vt) and FiO_2 level;
(3) duration of tracheal intubation in the ICU.
Results: In Intellivent-ASV® group the number of manual ventilator settings and physician's time spent near the ventilator before tracheal extubation were significantly lower: 0 (0–0) vs 2 (2–3) (ASV) and 4 (3–5) (control group), and 35 (27–45) sec vs 99 ± 35 s (ASV) vs 164 ± 69 s (control group) respectively (median (25%-75% quartile), p < 0.0001 in all cases).
Duration of respiratory support in the ICU were significantly shorter in the Intellivent-ASV group: 226 ± 31 vs 259 ± 66 (ASV) and 271 ± 78 min (control) (mean ± SD, p = 0.0042) and time on spontaneous ventilation (without any mandatory breaths) were significantly longer in Intellivent-ASV® group: 90 (75–103) vs 80 (60–110) (ASV) vs 60 (60–105) (control) min (p = 0.0462).
Intellivent-ASV® provided a significantly more protective ventilation through reduction in the driving pressure, tidal volume, FiO_2 and PEEP levels, but without differences between paO_2/FiO_2 ratio and mechanical power. ΔP and Vt on mechanical ventilation were significantly lower in Intellivent group: ΔP was 6 (6–7) cmH_2O vs 6 (6–7) (ASV) and 7 (7–9) (control) cmH_2O (p < 0.0001 in all cases); Vt was 6 (6–7) vs 7 (6–7.7) (ASV) and 7 (7–8) (control) ml/kg/PBW (p < 0.0001 in all cases). PEEP and FiO_2 level on mechanical ventilation were also significantly lower in Intellivent group: PEEP was 5 (5–7) cmH_2O vs 8 (7–10) (ASV) and 7 (6.5–9) (control) cmH_2O and FiO_2 level was 26 (24–30) vs 34 (30–35) (ASV) and 34 (30–38) (control) %, respectively (p < 0.0001 in all cases).
There were no significant differences between the groups in paO_2/FiO_2 ratio during all the phases of respiratory support and after extubation of trachea, and also there were no differences in mechanical power level, frequency of undesirable events (patient–ventilator asynchrony, patient's anxiety) during respiratory support and duration of ICU stay.
Conclusions: Application of intellectual technologies after uncomplicated cardiac surgery gives the opportunity for interactive personalization of respiratory support and provides more protective mechanical ventilation and reduces the physician's workload without compromising the quality of respiratory support and safety of patients.

The role of CD39-A2aR pathway in mediating the crosstalk between endothelial cells and natural killer cells in sepsis-associated lung

Y. Tang[1]

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000440.

Introduction: Sepsis is a common clinical critical care disease, and the lung is the most vulnerable organ during sepsis. How to reduce sepsis-associated lung injury is a clinical problem that needs to be solved urgently. While the contribution of neutrophils or macrophages to sepsis is well documented, the role of NK cells, which are critical innate immune cells, remains controversial. Some studies demonstrated that increasing the number of NK cells or enhancing their function was beneficial for controlling infection and reducing mortality in sepsis, while other studies showed that removing NK cells could reduce septic mortality. Furthermore, the function of NK cells in sepsis-associated lung injury needs exploration.
Objectives: Our study aimed to confirm the role of NK cells in sepsis-associated lung injury and the underlying mechanisms.
Methods: We conducted a monocentric, retrospective, and observational study to clarify the impact of NK cell count on the prognosis of sepsis. Mice were administrated with αNK1.1 (PK136) to deplete NK cells. Single-Cell RNA Sequencing was used to explore the interaction between each cell type and NK cells in septic mice. Mouse pulmonary microvascular endothelial cells were stimulated with LPS or not to produce inflammatory extracellular vesicles (LPS-EVs) or control extracellular vesicles (Con-EVs). A lentiviral vector selectively expressing NTPDase-1 (CD39) (LV-*Entpd1*) and its control (LV-Con) were generated. Mouse pulmonary microvascular endothelial cells were treated with LV-*Entpd1* or LV-Con to produce CD39-overexpressing EVs or Control EVs. Mice were intravenously injected with LPS-EVs/Con-EVs or CD39-overexpressing EVs/Control EVs. Western blot or qRT-PCR was applied to assess the expression level of CD39. Multicolor flow cytometry was used to evaluate the amount of activating receptors or inhibitory receptors on NK cells. The lung injury was scored by hematoxylin–eosin (H&E) staining.
Results: Septic patients with low NK cell counts had significantly higher mortality than those with high NK cell counts, and that patients with sepsis associated acute respiratory distress syndrome (ARDS) had significantly lower NK cell counts than those without ARDS, suggesting that low NK cell counts in sepsis may aggravate lung injury. To confirm the role of NK cells in sepsis, we applied αNK1.1 (PK136) to deplete NK cells 24 h after cecum ligation and puncture (CLP). Depletion of NK cells after CLP significantly reduced survival rate. Then, we used single cell sequencing to explore the interaction between each cell type and NK cells in sepsis, and found that the NTPDase-1 (CD39)-A2aR pathway between lung endothelial cells and natural killer cells was significantly upregulated after CLP. Further studies showed that the septic pulmonary microvascular endothelial cells could release CD39+ small extracellular vesicles (sEVs) to target NK cells and damage their functions.
Conclusions: In conclusion, we found that pulmonary vascular endothelial cells could release CD39+ sEVs to target A2aR of NK cells, thus damage the functions of NK cells to aggravate lung injury in sepsis-associated lung injury. Our studies discover a crosstalk between endothelial cells and natural killer cells, and provide prospective approaches for evaluating the prognosis of sepsis and exploring therapeutic strategies of sepsis-associated lung injury.

Pendelluft in patients with acute respiratory distress syndrome during trigger and reverse triggering breaths

C. W. Chen[1], W. C. Lin[1]
[1]Division of Critical Care Medicine, Department of Internal Medicine, National Cheng Kung University Hospital, Tainan, Taiwan
Correspondence: C. W. Chen
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000443

Introduction: Pendelluft occurs in patients with acute respiratory distress syndrome (ARDS) during spontaneous breaths. Quantifying pendelluft in ARDS patients has not been performed before. We combined electrical impedance tomography (EIT) and respiratory mechanics monitoring to quantitatively examine pendelluft in trigger and reverse triggering breaths in mechanically ventilated patients with ARDS.
Methods: EIT and respiratory mechanics measurements were analyzed in 20 mechanically ventilated patients with ARDS during transitioning from controlled to spontaneous breaths following discontinuance of neuromuscular blocking agents under volume-cycled ventilation. Breath selection was based on 4 levels of esophageal pressure swing (ΔPes). These were rest (0 cmH_2O, breaths = 200), low (< 5 cmH_2O, breaths = 471), moderate (≥ 5, < 10 cmH_2O, breaths = 906), and high effort (≥ 10 cmH_2O, breaths = 565). A total of 2142 breaths were analyzed (around 20% of a total of 5155 trigger breaths and 3518 reverse triggering breaths counted besides rest breaths). Quantitation of pendelluft was calculated according to the method proposed by Coppadoro et al*.
Results: The pendelluft response to breathing efforts varied and was significantly greater in trigger versus reverse triggering breaths (3.9 ± 6.8 vs 1.9 ± 2.8 ml, respectively, $p < 0.0001$). There were two distinct patterns of effort-related pendelluft (high vs. low pendelluft group) in trigger and reverse triggering breaths based on pendeluft-ΔPes slope (ml/cmH_2O). For trigger breaths, high pendelluft group (n = 9, slope 0.7 to 2.4 ml/cmH_2O) was significantly associated with lower peak airway/plateau pressure (30.5 ± 3.2 vs 36.5 ± 1.8/ 20.8 ± 2.6 vs 25.2 ± 2.0 cmH_2O; $p < 0.01$) and lower lung elastance (19.4 ± 7.9 vs 31.8 ± 8.6 cmH_2O/L; $p < 0.01$) than low pendelluft group (n = 11, slope −0.1 to 0.3 ml/cmH_2O). For reverse triggering breaths, there was no difference in respiratory mechanics between high (n = 4, 0.49 to 2.53 ml/cmH_2O) and low pendelluft (n = 12, −0.22 to 0.25 ml/cmH_2O) groups. The prediction of pendelluft by ΔPes was characterized by a low positive predictive value. ARDS cases with high effort-related pendelluft were uncommon. The prediction of pendelluft was not significant in reverse triggering breaths.
Conclusions: Effort-related pendelluft should be individualized. Pendelluft is higher in trigger breaths than reverse triggering breaths. For trigger breaths, high pendelluft is likely to occur in ARDS patients with lower lung elastance and lower peak airway/plateau pressure. However, ARDS cases with high effort-related pendelluft were uncommon in our study population.

Introduction: The incidence of Acute Kidney Injury (AKI) among trauma patients ranges from 15 to 50%. Hence, early identification of trauma patients who are at risk of developing AKI and implementation of appropriate reno-protective strategies may improve their outcomes. Urinary TIMP-2 and IGFBP7 have been studied in varying clinical scenarios to predict AKI with reasonable accuracy. However, their role has not been validated in critically ill trauma patients. Hence, this study was designed to evaluate the product of urinary markers (TIMP-2) × (IGFBP7) to accurately detect the sub-group of critically ill trauma patients at high risk for developing AKI.
Methods: This trial was designed as a prospective observational study at JIPMER, India. All critically ill trauma patients admitted to the critical care unit (CCU), with age > 18 years and < 65 years were screened for eligibility. Patients who met eligibility were observed for the occurrence of AKI throughout the hospital stay. Injury severity score (ISS), Acute Physiology and chronic health evaluation score (APACHE II) of all patients were calculated at admission and noted. At admission, and 24 h post CCU admission, urine samples were collected for analysis. The urinary levels of TIMP-2 and IGFBP-7 were estimated using commercially available ELISA-based kits (Abbkine Scientific Co; Ltd. China, and BioAssay laboratory technology, China). These values were used to predict AKI within 12 h of the last measurement and the need for RRT in those patients. During the first 24 h, details regarding total fluid intake, blood product transfusions, blood loss, and urine output were collected. Lowest blood pressure (systolic, diastolic, and mean arterial pressure), the need for vasopressors, mechanical ventilation, cardiopulmonary resuscitation (CPR), co-morbidities within the first 24 h were also noted.
Results: A total of 79 patients were enrolled in the study, of them 14 developed AKI (as per KDIGO criteria). The median APACHE II scores for those with AKI and without AKI were 11 (7–18) and 9 (7–11), respectively. While ISS score for AKI and without AKI were 34 (25–34) and 25 (25–34), respectively. The ROC-AUC for urinary (TIMP-2) × (IGFBP-7) were 0.49 (95% CI: 0.32 to 0.67) and 0.57 (95% CI: 0.42 to 0.71) at 0 and 24 h, respectively. As only the levels at 24 h showed discriminating power, a cut-off of 0.008 (ng/ml) 2/1000 was chosen, which had a sensitivity and specificity of 85.71% (95% CI: 57.19% to 98.22%) and 27.69% (95% CI: 17.31% to 40.19%), respectively. (Figure 1) The negative predictive value (NPV) and positive predictive value (PPV) were 90% (95% CI: 70.17% to 97.18%) and 20.34% (95% CI: 16.43% to 24.90%), respectively. All other variables were similar in patients with or without AKI.
Conclusions: We hereby conclude that Urinary [TIMP-2] × [IGFBP7] measured 24 h post admission in critically ill trauma patients can predict patients at risk of AKI with sufficient sensitivity.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000447

Introduction: The United Kingdom (UK) National Poisons Information Service (NPIS) is a 24-h service led by consultant clinical toxicologists, offering advice and guidance for healthcare professionals on the management of poisoning including access to the poisons information database, TOXBASE. (1) The diagnosis of death has important medical, legal and societal implications, making it imperative that its determination is accurate, reliable and certain. The Academy of the Medical Royal Colleges (AoMRC) Code of Practice for the Diagnosis of Death requires that when confirming death according to neurological criteria the exclusion of reversible causes of apnoea and coma prior to undertaking clinical tests to determine if brainstem function is present is required (2). Specifically, it requires the exclusion of any clinical effect attributable to a wide range of drugs including narcotics, hypnotics, sedatives and tranquilisers. Data summarising enquiries made to NPIS relating to the diagnosis of death in poisoned and non-poisoned patients has previously been published. (3) We undertook a retrospective analysis of the NPIS database to examine as to why the NPIS was contacted with reference to confounding factors affecting the ability to undertake neurological death testing.
Objectives: To examine the reasons why the NPIS was contacted for guidance where neurological death testing was being planned in poisoned and non-poisoned patients.
Methods: Using the database, enquiries to the NPIS in the preceding 10 years (01/01/2013–31/12/2022) were collated retrospectively using the search terms 'brain dead', 'brain death', 'brain stem', 'brainstem' or 'stem testing'. The data was analysed and any duplications or incongruous cases were deleted from the data set. Toxicological injury was defined as a case where the exposure to a xenobiotic was the cause of the current morbidity. This included direct effects of the xenobiotic and sequelae of the poisoning such as hypoxic ischaemic encephalopathy (HIE). Non-toxicological injury was defined as a case where the primary cause was not due to exposure to a xenobiotic; contact with the NPIS was made in regard to medications being used therapeutically and their potential effect on brain-stem function.
Results: The original search retrieved 136 enquiries of which 96 were deemed relevant. Enquiries were toxicological in 85 patients and non-toxicological in 11. Reasons for consulting the NPIS (more than one were allowed per case) were regarding: how the presence of agents affected brainstem reflex tests (n = 37); kinetics and metabolism of drugs (n = 26); toxicological causes of brainstem signs (n = 17); requests for laboratory analysis (n = 14); interpretation of quantitative analytical results (n = 4); suitability for organ donation (n = 4); and advice regarding withdrawal of active treatment (n = 4). The median age of the toxicological group was 35.5 years (IQR 24–44), 49% were male. Agents involved were: single drug of abuse (n = 12), single

prescribed drug (n = 18), mixed prescription drugs (n = 16), toxic alcohol (n = 12), multiple drugs of abuse (n = 7), combination of prescription drugs and drugs of abuse (n = 6), other (n = 7), and unknown (n = 7). Cocaine (n = 7), and Heroin (n = 5) were the most commonly implicated drugs of abuse, whilst in the prescribed drug group, antidepressants: Amitriptyline (n = 8), Citalopram (n = 4), Sertraline (n = 3), Venlafaxine (n = 2), and Mirtazepine (n = 2) were the most common. The median age of the non-toxicological group was 43.5 years IQR (25.25–57.5); 44% were male. The causes of brainstem injury were: traumatic brain injury (n = 5), stroke (n = 1), subarachnoid haemorrhage (n = 1), status epilepticus (n = 1), hypoxic ischaemic encephalopathy (n = 2), and meningitis (n = 1).

Conclusions: The NPIS remains a valuable centralised resource of expert advice regarding management of the poisoned and non-poisoned patient in the context of severe neurological injury and in the diagnosis of death using neurological criteria. The frequency and nature of such enquiries varied over time. The reasons for this are likely multifactorial and may take into account a number of socioeconomic, legal and health care related factors.

The introduction of cerebral CT angiography as an ancillary investigation to support the diagnosis of death using neurological criteria may change the nature of interactions between clinicians and NPIS in the future (4).

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000448

Introduction: Awake prone position has been proposed for nonintubated patients with acute hypoxemic respiratory failure to improve oxygenation [1–4]. Although two studies showed that awake prone positioning in patients with hypoxemia due to COVID-19 reduces intubation rate and possibly mortality [5, 6], other data did not confirm these findings, highlighting possible risks related to intubation delays due to only transient oxygenation improvements [7].

Objectives: Few studies address the physiological effects of prone position in spontaneously breathing humans with acute hypoxemic respiratory failure [8–10]. We conducted a sequential, cross-over trial to comprehensively evaluate the physiological effects of awake prone positioning in patients with moderate-to-severe acute hypoxemic respiratory failure receiving high-flow nasal oxygen (HFNO).

Methods: Fifteen patients with moderate-to-severe hypoxemia ($PaO_2/FiO_2 < 200$ mmHg) received HFNO for 1 h in supine position and 2 h in prone position, followed by a final 1-h supine phase. For each study phase the following parameters were measured: arterial blood gases; inspiratory effort (ΔPES), transpulmonary driving pressure (ΔPL), respiratory rate and esophageal pressure simplified pressure–time product per minute (sPTPES) by esophageal manometry; tidal volume (VT), end-expiratory lung impedance (EELI), lung compliance, dynamic strain (VT/EELI), airway resistance, expiratory time constant and pendelluft extent through electrical impedance tomography.

Results: Results concerning comparisons between supine, prone and supine after proning are displayed in Figure 1, 2 and 3. Compared to supine position, prone position improved PaO_2/FiO_2 (median [interquartile range] 104 mmHg [76–129] vs. 74 [69–93], $p < 0.001$), reduced respiratory rate (24 breaths/min [22–26] vs. 27 [26–30], $p = 0.05$) and increased ΔPES (12 cmH_2O [11–13] vs. 9 [8–12], $p = 0.04$) with similar sPTPES and ΔPL. Airway resistance and expiratory time constant were higher in prone vs. supine position (9 cmH_2O*sec*arbitrary units-3 [4–11] vs. 6 [4–9], $p = 0.05$; 0.53 s [0.32–61] vs. 0.40 [0.37–0.44], $p = 0.05$). Prone position increased EELI (3887 arbitrary units [3414–8547] vs. 1456 [959–2420], $p = 0.002$) without affecting VT and lung compliance: this yielded lower dynamic strain (0.21 [0.16–0.24] vs. 0.38 [0.30–0.49], $p = 0.004$). Pendelluft was not different between study phases.

Conclusions: Prone position improves oxygenation, increases EELI and does not affect VT, ΔPL, lung compliance and pendelluft extent: this yields reduced dynamic strain. Prone position reduces respiratory rate but increases ΔPES because of higher airway resistance with prolonged expiratory time.

Introduction: COVID-19 emerged in 2020 as a novel disease associated with a high morbidity and mortality generating a overload in most ICUs around the world. It is necessary to analyze clinical and epidemiological characteristics of these patients to define risk factors and their outcome. We analyzed epidemiological and clinical features of all critically ill COVID-19 patients hospitalized in Spain along the first three pandemic waves, as well as risk factors predictors of hospital mortality.
Methods: Analysis of the National Hospital Discharge Records Database (NHDRD) of patients hospitalized with diagnosis of COVID-19 who required ICU admission. Demographic and clinical features and their relationship with clinical outcomes were analyzed. We performed a descriptive and a multivariated analysis to identify those risk factors related with fatal evolution in this population. Statistical package STATA v16.1 was employed.
Results: 22,957 critically ill patients were registered. ICU mortality was 31%, 62% of these patients were over 60 years old (mortality rate 41%). The main comorbidities were hypertension (45%, 38% mortality rate), dyslipidemia (31%, 34% mortality rate), DM (24%, 37% mortality rate) and obesity (19%, 28% mortality rate). Charlson Comorbidity Index ≥ 2 showed a mortality rate of 48%. Mechanical ventilation (MV) was required in 59% and SDRA were present in 28% with 39 and 40% of mortality respectively. Sepsis was presented in 14% (mortality rate 63%) and AKI was present in 25% (mortality rate 56%). Multivariate analysis identify age as independent risk factor for mortality along with comorbidities related to endothelial dysfunction and immunosupression such as obesity, diabetes, artery disease, HIV, cancer, hematological malignance. Finally multivariate analysis identified presence of sepsis, AKI or need of MV were too independent risk factor associated with mortality. Combination of these last variables predicted mortality with an AUROC > 0,90.
Conclusions: Mortality rate in critically ill COVID-19 Spanish patients in 2020 was very high. Age, states of immunosuppression and cardiovascular risk factors were the main risk factors associated with mortality. The need for MV and the presence of sepsis or AKI were independently conditions associated with a fatal prognosis.

Table 1 (abstract 000449) Risk factors associated with mortality in critically ill COVID-19 patients

	HR	IC 95%	P
AGE	1,57	1,53-1,62	0,000
OBESITY	1,18	1,10-1,27	0,000
HIV	2,22	1,36-3,64	0,001

Lung ultrasonography can predict responsiveness to prone positioning in COVID19 ARDS

S. Patsilinakou[1], E. Bourgani[1], C. Merkouri[1], M. Poulou[1], E. Dikoudi[1], V. Karaouli[1], M. Karagianni[1], A. Aiginitou[1], E. Kourtelesi[1], M. Daganou[1], A. Flevari[1]
[1]New ICU Department, Sotiria Thoracic Diseases Hospital, Athens, Greece
Correspondence: A. Flevari
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000450

Introduction: Prone positioning is a well validated therapeutic strategy in the treatment of Acute Respiratory Distress Syndrome (ARDS) in adults. Its application leads to improvement in PaO_2/FiO_2 (P/F) ratio and mortality reduction. Moreover, lung ultrasonography (LU) in critically ill patients is a useful point-of-care imaging method for the assessment of various thoracic pathologies.
Objectives: To examine if LU is able to predict prone positioning responsiveness in COVID19—associated ARDS (C-ARDS).
Methods: This prospective study was conducted in a 13-bed capacity ICU. Age, sex, Body Mass Index (BMI), disease severity scores APACHE II and SOFA were recorded on admission day. Alterations in FiO_2, Driving Pressure (DP), static Compliance (Cst) and Lung Ultrasound Score (LUS) between supine and prone positions were recorded at bedside. The effectiveness of the strategy was also recorded. Kolmogorov–Smirnov test checked normality. Paired two-sample t-test examined equality of the means. Multiple linear regression tested for differences in the means between categorical and continuous variables.
Results: Fifteen (15) intubated patients (8 male) with P/F ratio < 150 were included. Mean Age was 62.18 (± 16.68) years, mean BMI was 30,82 (± 5,93), mean APACHEII score was 15.64 (± 7.24) and mean SOFA was 6.09 (± 2.77). Table 1 states that there was significant improvement of all parameters examined in prone position compared to supine. We investigated whether all 4 variables stated in Table 1 could predict success of proning. The model explained 62% of variance and was a significant predictor of proning success [F(4,10) = 4.06, p = 0.033]. Among variables, only ΔLUS could effectively predict proning success (B = − 0.07, p = 0.027), while others could not (ΔFiO_2 p = 0.43, Δcst p = 0.02, ΔDP p = 0.54).

Table1 (abstract 000450) Paired sample T-test results between supine and prone position

	T (14)	p-value
ΔFiO_2	6.97	0.000
ΔCst	− 4.06	0.001
ΔDP	2.86	0.013
ΔLUS	3.40	0.004

Conclusions: Bedside LUS, a point-of-care imaging tool, seems to have predictive value in the success of proning in patients with CARDS.

Tracheostomy in mechanically ventilated patient with ARDS by SARS CoV2: outcomes in reference center in Mexico City

M. Vidals-Sánchez[1], J. C. Gasca-Aldama[1], N. V. Alva-Arroyo[2], L. Mayo-Hernandez[1], M. A. Amezcua-Gutiérrez[1], J. Garduño-López[1], M. Mendoza-Martinez[1], F. Ordoñez-Hernandez[1]

Correspondence: M. Vidals-Sánchez
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000451

Introduction: Percutaneous tracheostomy is one of the most frequently performed techniques in the intensive care unit (ICU), with great relevance during the SARS CoV2 pandemic. The most common indication remains the need for prolonged ventilation.
Objectives: To determine mortality in patients undergoing percutaneous tracheostomy vs. patients undergoing the Weaning protocol.
Methods: Non-randomized, descriptive clinical trial, 179 patients divided into 2 groups: tracheostomy group and non-tracheostomy group. The sample size was calculated with the formula for the estimation of two means, power of 80%, an error of 0.05, with a CI 95%. Variables with statistical significance were subjected to Cox correlation, ending with a Kaplan Meier curve or graph, calculating the Long Rank. Assigning a value of p < 0.05 as statistically significant. SPSS v25 was used for data analysis.
Results: Lower mortality, statistically significant, in patients with tracheostomy with the following risk factors: body mass index (BMI) and days of stay in the ICU. In a timely manner, patients with a higher BMI had a 60% higher risk of dying than non-obese patients. A total of 179 patients were analyzed, since there was no randomization due to bias in favor of the maneuver, n = 80 remained in the tracheostomy group, vs. n = 99 non-tracheostomy group. When comparing the relationship of both groups, the variables with statistical significance stood out: 1) days of Hospitalization 95% CI 16–31 p = 0.034, 2) days of stay in the ICU 95% CI 3.7–12.7 p = 0.027 and 3) days mechanical ventilation 95% CI 3.1–5.8 p = 0.003.
Conclusions: According to this study, there was lower mortality in the intervention group compared to the non-tracheostomy group (Figure 1). The risk factors associated with mortality are: BMI, ICU stay-reaching a median survival of 23 days-, the median survival for mechanical ventilation was 22 days (Table 1). However, other factors that could influence patient mortality regardless of the intervention would also have to be recognized.

Table 1 (abstract 000451) Cox proportional hazards or Cox regression

	B	HR	95% CI	p value
BMI > I	1.85	6.36	0.994–40.7	**0.021***
ICU length of stay	1.94	7.01	1.07–45.6	**0.002***
Mechanical ventilation duration (days)	1.77	2.93	0.141–3.80	**0.001***
Hospital length of stay	1.38	3.22	0.412–9.71	**0.028***

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000452

Introduction: In November 2020, the Community of Madrid decided to implement a system of VV ECMO mobile teams (two hospitals on a one week-on, one week-off roster) so ECMO technology could reach all of its citizens.
Objectives: The objective of this study is to describe the population and the results of one of this mobile teams.
Methods: Retrospective study (Nov-2020 to April-2023). We recorded all patients referred to our VV ECMO mobile team and transferred to our center. We analyzed: number of referrals and transfers; age, gender, respiratory failure etiology, VV ECMO use, ICU length of stay (ICU-LOS) and mortality of all the transferred cases. Results are shown as mean ± SD or median (IQ25-IQ75) for quantitative variables and as absolute value (%) for qualitative variables.
Results: In the 30-month period studied a total of 96 patients were referred to our VV ECMO mobile team. Forty-nine of them fulfilled relocation criteria and were transferred from 19 different hospitals (public and private centers). In 30 cases, the VV ECMO team was mobilized and ECMO cannulation was performed at the referring center. The other 19 were transferred without ECMO and 10 of them were finally cannulated upon arrival to our center. There were no complications during transfer. In the same time frame, our ICU admitted 12 local cases of VV ECMO, so the ECMO mobile program accounted for 77% (40) of all the ECMO cases of our department for that period of time.
Mean age of the transferred patients was 48 ± 12 years and 29 (59.2%) were males. Regarding respiratory failure etiology there were 48 (98%) cases of ARDS (40 secondary to SARS-CoV-2, one Influenza A, three cases each of community acquired and ventilator associated pneumoniae and one ARDS of unknow origin in an hematological patient) and one case (2%) of status asthmaticus. Median ECMO run was 14 (11–22) days.
Median ICU-LOS of the transferred patients was 27.5 (15.5–35) days. Overall mortality was 24.5% (12) with a VV ECMO group mortality of 30% (12). There were no casualties amongst the patients that were transferred that didn´t require VV ECMO support.
Conclusions: ECMO mobile teams are a reality in the Community of Madrid. ECMO retrievals are our main source of ECMO patients nowadays which stresses the importance of referral centers. ECMO mobile teams bring equipoise across our population with good clinical results.

Volatile sedation in veno-venous ECMO patients. Impact on mechanical ventilation, ECMO parameters and sedation practices

S. Alcántara Carmona[1], N. Martinez Sanz[1], M. Pérez Redondo[1], B. Balandín Moreno[1], M. Valdivia De La Fuente[1], P. Matía Almudévar[2]
[1]Intensive Care, Hospital Puerta de Hierro-Majadahonda, Majadahonda, Spain; [2]Intensive care, Hospita Puerta de Hierro-Majadahonda, Majadahonda, Spain
Correspondence: S. Alcántara Carmona
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000453.

Introduction: Volatile sedation (VS) might be an acceptable practice for patients on veno-venous ECMO (VV ECMO).
Objectives: To describe VS use in a small cohort of VV ECMO patients together with changes in mechanical ventilation (MV), sedation and neuromuscular blockade (NMB) practices before and after 24 h of VS.
Methods: Retrospective single-center study (Jan-2021/March-2023). We included all patients on VV ECMO with concomitant VS. Demographics; MV and ECMO parameters, vasoactive drug usage and sedation and NMB practices before and 24 h into VS; VS characteristics and ECMO run duration together with hospital length of stay and survival were recorded.
Results: Six patients were included. Mean age 34.3 ± 12.3 years. Four (66.6%) males. One patient was immunocompromised, and one suffered from COPD. There were no other comorbidities. Median BMI: 28.5 (26–39) kg/m^2. SOFA score 6.5 (3.75–7). All patients were admitted to ICU due to respiratory failure and global respiratory failure (5 patients) was the main indication for VV ECMO. In three patients VS was started at the same time as VV ECMO and in the other three cases VS started a median of 6.3 ± 3.5 h after VV ECMO commencement. Four patients received VS for difficult sedation and two for bronchospasm. Sevoflurane was the only agent used.
Before VS, MV parameters were: 235 (215–240) ml of tidal volume and 13 (10.5–14) bpm. Mean ECMO flow was 3.5 ± 0.23 lpm with a sweep gas flow of 5.4 ± 2.7 lpm. Three patients were receiving

norepinephrine. Regarding IV sedatives propofol was used in all patients, four received also ketamine, three midazolam and three clonidine. Four patients (66.6%) were treated with three sedatives at the same time and two were receiving two before VS was initiated. All patients were under continuous NMB. Mean BIS values were 50 ± 12.2. Twenty-four hours after VS, tidal volume decreased to 195 (152.5–245) ml and respiratory frequency increased to 18 (14.5–21.5) bpm. ECMO flow was kept steady at 3.5 ± 0.53 lpm and sweep gas flow decreased to 4.1 ± 1.9 lpm. Two patients were receiving norepinephrine. Propofol, clonidine and midazolam were used in four patients each while three patients were treated also with ketamine. Half of the cohort was receiving three sedatives and two the other half. Four patients were still under continuous NMB. Mean BIS values were 40.2 ± 9.8.
Total dose of sevoflurane for the first 24h was 137.5 (133.5–228.5) ml with a mean exhaled concentration of 0.59 ± 0.29%. Median duration of VS: 228.5 (77.2–335.5) h. No complications associated with this therapy were reported.
ECMO run duration was 13.5 (9.5–16.7) days. Median hospital length of stay was 73 (43.7–98.5) days. Five patients survived (83.7%).
Conclusions: VS in this small cohort of patients did not prompt major changes in MV or ECMO parameters and was not associated with hemodynamic instability. VS led to lower BIS values and decreased NMB needs but did not spare the use of IV sedatives. Long-term sedation with sevoflurane seems to be safe.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000454

Introduction: Feed intolerance in critically ill patients may be associated with adverse outcomes. Yet, risk factors associated with enteral feeding intolerance are poorly described especially in SARS-Cov2 ARDS patients.
Objectives: To identify risk factors associated with enteral feeding intolerance in SARS-Cov2 severe ARDS patients.
Methods: We prospectively included SARS-Cov2 ARDS patients hospitalized due to severe ARDS in the ICU of a tertiary hospital during thepandemic period (2020–2021).
Enteral feeding intolerance (EFI) was defined asevents that included at least one the following: episode of high gastric residual volume (which was set based on previous studies, > 500 ml), recorded in patients' ICU chart and/or emesis.
Results: A total of 75 patients with severe SARS-Cov2 ARDS, median (IQR) PaO_2/FIO_2 was 211.8 (201.5; 231.2), median APACHE II score of 17.31 (15.9; 18.7) and median SOFA score of 8.32 (7.7; 8.9) were included. Fifty six of them (74.67%) died within 28 days. Median length of ICU stay was 14.79 (12.61; 16.96). EFI was documented at least once during hospitalization in 50 patients. Patients with EFI had more days in control modes of mechanical ventilation, received higher dose of propofol, midazolam (mg/kg/h) and of corticosteroids (mcg of hydrocortisone equivalent/kg/day) during their hospitalization compared to patients without EFI: (13.6, 11.7; 15.5 vs 7.5, 5,2; 9.8, $p < 0.0001$), (0.09, 0.07; 0.11 vs 0.05, 0.03; 0.06, $p = 0.0009$), (0.18, 0.14; 0.22 and 0.07, 0.05; 0.09, $p < 0.0001$) and (1.5, 1.2; 1.8 and 1.3, 0; 2.7 respectively, $p = 0.001$). Midazolam was independently associated with EFI ($p = 0.01$).
Conclusions: Sedative medication and more specifically the excessive use of midazolam may be a risk factor of increased EFI in SARS-Cov2 ARDS.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000455

Introduction: Controlled donation after the determination of circulatory death (cDCD) has established itself as a fundamental source of organs in the last decade in Spain. The objective of this study is to review the cDCD donors and the validity of the organs retrieved under normothermic regional perfusion (NRP) of a third level hospital with a NRP-cDCD program.
Methods: Retrospective observational study (2017–2022) including all NRP-cDCD donors. Data were obtained from the e-medical records and the paper files of the NRP-cDCD process. General demographic and descriptive variables were collected as well as those associated with the NRP-cDCD technique. Functional warm ischemia time (f-WIT) was defined as the time from systolic arterial pressure < 60 mmHg to the onset of NRP. Organ success rate was defined as number of organs retrieved/total of organs evaluated in the cDCD–NRP × 100. Quantitative variables are expressed as mean ± SD for normal distribution, and median (IQR 25–75) for non-normal. Qualitative variables are expressed as % (absolute value).
Results: Twenty-nine NRP-cDCD were performed in the period studied. Mean age of the donors was 58 ± 13 years. Males accounted for 52% (n = 15) of the sample. Twenty-five (86%) donors were local while four (14%) were transferred from other centres for the sole purpose of donation under NRP. The reasons for hospital admission were: recovered cardiorespiratory arrest (55%; n = 16), stroke (28%; n = 8), severe brain injury (10%; n = 3) and respiratory failure (7%; n = 2). Mean ICU stay was 11 ± 6 days.
All cannulations were premortem. The median f-WIT was 14 (9–18) minutes. Seventy-one organs were retrieved; 16 livers (55% success rate), 39 kidneys (63% success rate), 14 lungs (24% success rate) and two hearts (3.4% success rate).
NRP-cDCD accounted for 25.3% of the total of organs transplanted in our centre during the study period. According to organ NRP-cDCD provided: 27.6% of livers, 28.9% of kidneys, 18.9% of lungs and 14.3% of hearts of the total pull.
Conclusions: NRP-cCDC has contributed to an increase in the total number of donors, and is responsible for one out of every four donations performed in our centre. Organs obtained through PAN-DAC show acceptable success rates that are comparable to those described in other series.

Diagnostic accuracy of point-of-care ultrasound for shock: a systematic review and meta-analysis

T. Yoshida[1], T. Yoshida[2], H. Noma[3], T. Nomura[4], A. Suzuki[5], T. Mihara[2]
[1]Intensive Care Unit, Department of Emergency Medicine, Jikei University School of Medicine, Minato City, Japan; [2]Department of Health Data Science, Graduate School of Data Science, Yokohama City University, Yokohama, Japan; [3]Department of Data Science, The Institute of Statistical Mathematics, Tachikawa, Japan; [4]Department of Perioperative Medical Support, Tokushukai Medical Corporation, Tokyo, Japan; [5]Department of Anesthesiology and Critical Care Medicine, Jichi Medical University, Shimotsuke, Japan
Correspondence: T. Yoshida
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000456

Introduction: Circulatory failure is classified into four types of shock (obstructive, cardiogenic, distributive, and hypovolemic) that must be distinguished as each requires a different treatment [1]. Point-of-care ultrasound (POCUS) is widely used in clinical practice for acute conditions [2, 3], and several diagnostic protocols using POCUS for shock have been developed [4–6].
Objectives: This study aimed to evaluate the diagnostic accuracy of POCUS in identifying the etiology of shock.
Methods: We conducted a systematic literature search of MEDLINE, Cochrane Central Register of Controlled Trials, Embase, Web of Science, Clinicaltrial.gov, European Union Clinical Trials Register, WHO International Clinical Trials Registry Platform, and University Hospital Medical Information Network Clinical Trials Registry (UMIN-CTR) until June 15, 2022. We followed the Preferred Reporting Items for Systematic Reviews and Meta-Analyses guidelines and assessed study quality using the Quality Assessment of Diagnostic Accuracy Studies 2 tool. Meta-analysis was conducted to pool the diagnostic accuracy of POCUS for each type of shock. The study protocol was prospectively registered in UMIN-CTR (UMIN 000048025).
Results: Of the 1553 studies identified, 36 studies were full-text reviewed, and 12 studies with 1132 patients were included in the meta-analysis. Pooled sensitivity and specificity were 0.82 [95% confidence interval (CI): 0.68–0.91] and 0.98 [95% CI: 0.92–0.99] for obstructive shock, 0.78 [95% CI: 0.56–0.91] and 0.96 [95% CI: 0.92—0.98] for cardiogenic shock, 0.90 [95% CI: 0.84—0.94] and 0.92 [95% CI: 0.88–0.95] for hypovolemic shock, and 0.79 [95% CI: 0.71–0.85] and 0.96 [95% CI: 0.91–0.98] for distributive shock, respectively. The area under the receiver operating characteristic curve for each type of shock was approximately 0.95. The positive likelihood ratios for each type of shock were all greater than 10, especially 40 [95% CI: 11–105] for obstructive shock. The negative likelihood ratio for each type of shock was approximately 0.2.
Conclusions: The identification of the etiology for each type of shock using POCUS was characterized by high sensitivity and positive likelihood ratios, especially for obstructive shock. These findings should be considered in future diagnostic protocols for shock using POCUS.

Introduction: Maternal death in the UK is rare. Therefore, efforts to improve quality of care have focussed on reducing the risk of life-threatening perinatal illness [1]. Identifying women at highest risk of perinatal critical care admission may enable clinicians to risk stratify women antenatally so that enhanced care or elective admission to critical care may be considered in birthing plans.
Objectives: We aimed to develop a statistical model for the prediction of risk of perinatal critical care admission.
Methods: We studied 762,918 pregnancies between 2005 and 2018. Predictive models were constructed using multivariable logistic regression. The primary outcome was admission to critical care, i.e., an intensive care unit (ICU) or general high dependency unit (gHDU). Additional analyses were performed for: (a) admission to either ICU, gHDU or obstetric HDU in the subgroup these data were available, and (b) primary outcome occurring either on or after day of delivery to allow study of delivery-related factors. Predictors were selected following expert consultation and reviewing literature, resulting in 13 variables being included in the primary analysis: demographics, prior health status (e.g., comorbidities, smoking status), obstetric history (e.g., parity, previous C-section) and pregnancy factors (e.g., multiple gestation) A complete case analysis was done. K-fold cross validation was used to adjust for overfitting.
Results: Complete data were available for 578,310 pregnancies, of whom 2121 were admitted to critical care (0.37%). Model performance with respect to discrimination and calibration was fair (Figure 1; area under the ROC curve [AUC] = 0.65; Brier score = 0.0036). The negative predictive value (NPV) of the model was high across a range of predicted probability thresholds. A comparatively high cut-point of 2.8% or more for risk of critical care admission resulted in NPV of 99.6% and specificity 99.9% but positive predictive value (PPV) of just 3.95% and sensitivity of 0.896%.
Models produced from subgroup analyses also performed favourably. Complete data pertaining to delivery-related factors were available for 553,164 pregnancies, 1497 of which involved admission to critical care. A model containing an additional five variables relating to delivery achieved an AUC 0.77 and Brier score 0.0027. Among 68,553 for whom data on obstetric HDU admission were available, 1890 were admitted to either ICU, general HDU, or obstetric HDU. A model to predict risk of admission to critical care in this group achieved an AUC of 0.77 with Brier score of 0.026.
Conclusions: We have identified multiple independent risk factors for perinatal critical care admission. Our primary model has an acceptable discriminative ability, with an AUC of 0.65. While the NPV of the model is high, its low PPV indicates that implementation of the prediction model would be most useful as a "rule-out" test, to exclude women from pre-emptive consideration of critical care admission.

Introduction: The mortality rate for resuscitated patients after out-of-hospital cardiac arrest (OHCA) remains high, and prompt identification of the precipitating cause of OHCA is crucial for implementing cause-specific treatments and improving patient outcomes. We propose a protocolized diagnostic algorithm to quickly differentiate the exact etiology of OHCA.
Methods: We conducted a retrospective cohort study at a tertiary medical center between 2006 and 2020. We excluded pediatric cases, traumatic cases, cases with ROSC before hospital arrival, and cases without sustained ROSC ($\geq$ 20 min). Emergency physicians reviewed medical records and followed the proposed diagnostic algorithm to determine a single most likely etiology of OHCA. The presumptive diagnoses during CPR and final diagnoses in post-ROSC period during hospitalization were listed and compared. The survival rate until hospital discharge was compared among the determined causes of OHCA.
Results: We included 584 cases, with 46% presumed cardiac etiology, 35% non-cardiac etiology, and 19% undetermined etiology during CPR. After extensive workup during the post-ROSC period, final etiology was determined to be cardiac in 52%, non-cardiac in 42%, and unknown in 6% of cases. Compared to cardiac etiology, non-cardiac etiology was linked to younger age, lower rates of established survival predictors, and lower rates of all survival outcomes. Among non-cardiac etiology, respiratory causes accounted for 64% of cases, followed by infection (15%), neurology (9%), toxicology (4%), non-traumatic massive bleeding (3%), metabolic derangement (3%), and other (2%). Overall, 72.5% of initially undetermined cases had a final diagnosis deemed responsible for OHCA. Among these cases, 49% had cardiac causes and 51% had non-cardiac causes. Coronary angiogram and CT scan provided contributory causes of OHCA in 88% of initially undetermined cases. After exclusion of undetermined cases, only 29 cases (0.05%) received an incorrect presumptive diagnosis compared to the final diagnosis, and 70% of these cases required a CT scan to make the correct diagnosis responsible for OHCA.
Conclusions: Our protocolized diagnostic algorithm demonstrated high diagnostic rate and accuracy in determining the specific etiology of OHCA. Coronary angiogram and CT scan provided contributory causes of OHCA in most of the initially undetermined cases. Prospective studies are warranted to determine if protocolized OHCA diagnosis can lead to prompt cause-specific treatments following successful resuscitation and improve survival.

Introduction: Previously, we have shown that the mitochondrial transplantation in sepsis model has immune modulation effects. The mitochondrial function could have different characteristics dependent on cell types.
Objectives: We investigated the effects of mitochondrial transplantation on sepsis model could be different depending on the cell type, from which mitochondria was isolated.
Methods: We isolated mitochondria from L6 muscle cells, clone 9 liver cells, and mesenchymal stem cells (MSC). We tested the effects of mitochondrial transplantation with in-vitro and in-vivo sepsis model. We used LPS stimulation of THP-1 cell as in-vitro model. First, we saw the mitochondrial function in mitochondrial transplantation. Second, we compared anti-inflammatory effects of mitochondrial transplantation. Third, we investigated the immune enhancing effects with endotoxin tolerance model. With in-vivo polymicrobial fecal slurry sepsis model, we investigated the survival and biochemical effects of each type of mitochondrial transplantation.
Results: In in-vitro LPS model, mitochondrial transplantation from all three cells improved mitochondrial function measured by oxygen consumption using XF analyzer. Of those 3 cell types, L6-mitochondrial transplantation enhanced mitochondrial function more significantly. Mitochondrial transplantation with each cell type reduced hyper-inflammation in acute phase of in-vitro LPS model. It also enhanced immune function in late immune suppression phase, shown by endotoxin tolerance. These functions were not significantly different between 3 cell types-origin mitochondrial transplantation. However,

only L6-mitochondrial transplantation significantly improved survival than control in polymicrobial in-vivo sepsis model.
Conclusions: The effects of mitochondria transplantation on both in-vitro and in-vivo sepsis models were different from cell types of origin of mitochondria. L6-mitochondrial transplantation might be more beneficial in sepsis model.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000462

Introduction: Sepsis-induced cardiomyopathy (SICM) is increasingly recognized as an important factor contributing to poor outcomes in septic patients, and it was confirmed in left ventricular diastolic dysfunction and right heart dysfunction [1–3]. However, the association between left ventricular systolic dysfunction (LVSD) and mortality of septic patients is to be determined.
Left ventricular ejection fraction (LVEF) is inconsistent with the mortality in septic patients [4, 5]. Some studies have reported that global longitudinal strain (GLS) was an independent risk factor for sepsis while other researchers have reached the opposite conclusion, which limited the potential application of GLS in septic patients [6, 7]. And this study aimed to assess the prognostic clinical value of GLS in septic patients.
Methods: We included patients who met the criteria for sepsis-3 from the Surviving Sepsis Campaign: International Guidelines for Management of Sepsis and Septic Shock 2016 were screened. And patients with history and/or potential cardiac dysfunction in this prospective study were excluded. All echocardiographies were performed within 24 h of enrollment according to the recommendations from the European Association of Cardiovascular Imaging and the American Society of Echocardiography. And speckle tracking echocardiography was analyzed offline. Full clinical data of patients were collected. According to modified Simpsons' rule, LVEF was measured with the biplane method. LVEF was defined as depressed (LVEF < 45% or requiring inotrope infusion), moderate (45–60%) and hyperdynamic (> 60%).
Results: We recruited125 subjects in the final analysis. The age of all septic patients was 62.7 years old, and the28-day and 90-day mortality were 24.8% (n = 31) and 31.2% (n = 39), respectively. The non-survivors with 28 days had higher Arterial blood lactates (3.1 pg/ml vs 2.1 mmol/L, $p < 0.05$), Troponin I (0.03 ng/ml vs 0.01 pg/ml, $p < 0.05$), NT-proBNP (2980 pg/ml vs 1590 pg/ml, $p < 0.05$) than survivors. Non-survivors had lower absolute GLS than that of survivor group (− 17.2% vs − 19.3%, $p = 0.045$), however, GLS was not an independent risk factor for mortality of sepsis after adjusting for clinical variables. And GLS has been demonstrated poor accuracy in predicting 28-day and 90-day outcomes of all septic patients with AUROC of 0.633 and 0.638, respectively. While GLS has good accuracy in predicting both 28-day and 90-day mortality in hyperdynamic patients (area under the receiver operating characteristic curve were 0.865 and 0.851, respectively). Cox regression analyses showed that less negative GLS was an independent predictor of mortality for septic patients with hyperdynamic LVEF.
Conclusions: GLS is an independent risk factor associated for mortality in patients with hyperdynamic left ventricular ejection. The clinical implications of this finding should be investigated in future larger studies.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000463

Introduction: Systemic corticosteroids have been frequently used in COVID-19 pandemic. As there are many reports that demonstrated beneficial effects of corticosteroids on COVID-19, guidelines recommend the use of corticosteroids for COVID-19 patients requiring oxygen therapy (1, 2). However, optimal dose and duration of corticosteroids are not established. In a recent study (CIBERESUCICOVID), long-term use (≥ 10 days) of corticosteroid was associated with lower risk of 90-day mortality (3).
Objectives: To compare the clinical outcomes according to duration of systemic corticosteroid treatment for hospitalized patients with COVID-19.
Methods: This multicenter, retrospective study was conducted between January 2020 and August 2021 at 22 Korean hospitals. COVID-19 patients aged ≥ 19 years who were treated with more than high-flow nasal cannula were included in this study. This study is supported by Grant No. (KATRD-S-2021-2) from the Korean Academy of Tuberculosis and Respiratory Diseases.
Among 1114 patients, 982 patients whose hospital length of stay (LOS) was longer than 10 days were included in the analysis. Patients were divided into two groups according to duration of corticosteroid treatment: long-term (> 10 days) and short-term (≤ 10days). Propensity score matching (PSM) was performed using age, initial Sequential Organ Failure Assessment (SOFA) score, initial arterial partial pressure of oxygen (PaO_2) to fractional inspired oxygen (FiO_2) ratio, underlying diseases such as cardiovascular disease and hematologic disease, use of mechanical ventilation, and treatment with tocilizumab as confounding variables. Baseline characteristics and clinical outcomes were compared between the two groups of PSM cohort.

Results: Each group of PSM cohort consisted of 376 patients with no significant difference in demographic characteristics between the two groups (Table 1). Long-term group had longer time to negative conversion of COVID-19 polymerase chain reaction (PCR) test and longer hospital LOS. However, short-term group showed higher intensive care unit (ICU) mortality than long-term group (Table 2; 22.6% vs. 16.1%, p = 0.033). In Kaplan–Meier curve, long-term group exhibited better survival probability than short-term group (Figure1; p = 0.0025). Though short-term group was associated with shorter hospital LOS (Table 3A; B ± SE, −5.194 ± 2.031; p = 0.011), this group was associated with higher risk of in-hospital and ICU mortality (Table 3B; HR, 1.539; 95% CI, 0.123–0.739; p = 0.006 and HR, 1.598; 95% CI, 0.129–0.808; p = 0.007, respectively).

Conclusions: Short-term use of systemic corticosteroid for hospitalized patient with COVID-19 was associated with increased risk of in-hospital and ICU mortality.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000464

Introduction: The progression of acute respiratory failure (ARF) in patients with lung pathology of various etiologies is a common reason for urgent transfer of patient to the intensive care unit. The use of non-invasive ventilation (NIV) in intensive care units significantly improves patient outcomes, prevents intubation and increases survival (1). Therefore, the expansion of indications for the use of NIV outside the ICU is gaining momentum. The widespread use of non-invasive positive pressure ventilation is observed not only in wards, but also in a number of countries, NIV is successfully used at home, for example, in the treatment of chronic obstructive pulmonary disease. There is a good evidence base for the use of NIV in COPD. (2, 3). NIV also showed better results treating ARF in immunocompromised patients. (4) However, there is also meta-analytic evidence of a beneficial effect in ARF regardless of etiology (5).
Objectives: Improving respiratory care outside the intensive care unit through the use of early non-invasive ventilation of lungs for treating mild to moderate respiratory failure.
Methods: Patients included in the study were randomized into 2 groups: early NIV and standard treatment. Patients in the early NIV group received non-invasive ventilation procedures. The standard treatment group received the usual best therapy. Daily monitoring of vital functions, arterial blood gas composition, other laboratory and instrumental research methods was carried out. In patients of both groups, the progression of ARF to a severe degree was monitored, sufficient for the transfer of ICU, 28-day survival, length of stay in the hospital, safety of NIV, and all respiratory complications during the hospitalization period.
Results: The study involved 24 participants. There were 16 patients in the NIV group and 8 patients in the control group. Progression of ARF and subsequent transfer to ICU—9 (56%) patients in the NIV group and 5 (62.5%) patients in the control group. The 28-day survival was in the early NIV group—12 (75%) patients, in the control group—8 patients (75%). The average length of stay in the hospital was 17.2 ± 10 days in the early NIV group and 11.8 ± 8 days in the control group. There were no respiratory complications associated with the use of NIV among patients who underwent non-invasive ventilation of the lungs.
Conclusions: Interim results of the study showed no NIV-related respiratory complications using NIV outside ICU. The efficacy of early NIV in respiratory failure requires further study.

Comparison the performance of the Simplified Mortality Score for the Intensive Care Unit and Sepsis Severity Score for predicting 90-day mortality in sepsis patients

B. Khwannimit[1], N. Sathaporn[2], R. Jomsuriya[3]
[1]Prince of Songkla University, Hat Yai, Songkhla, Thailand, Department of Internal Medicine, Faculty of Medicine, Hat Yai, Thailand; [2]Internal medicine, Prince of Songkla University, Hat Yai, Thailand; [3]Internal Medicine, Prince of Songkla University, Tambon Kho Hong, Thailand
Correspondence: B. Khwannimit
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000465

Introduction: The commonly use severity scores were developed to predict in-hospital mortality. Recently, the Simplified Mortality Score for the Intensive Care Unit (SMS-ICU) was devised as a new model for predicting 90-day mortality in critically ill patients. The aim of this study was to compare the performance of the SMS-ICU with the Sepsis Severity Score (SSS) and standard severity scores in predicting 90-day mortality in patients with sepsis.
Methods: A retrospective study was conducted in a medical ICU of a tertiary university teaching hospital in Thailand over a 4-year period. The primary outcome was all cause 90-day mortality, and the secondary outcome was in-hospital mortality.
Results: A total of 1161 sepsis patients were enrolled, 641 (55.2%) patients were classified to septic shock. The 90-day mortality and in-hospital mortality were 42.4% and 41.5%. Community-acquired infection was classified in 750 patients (64.6%). Hemocultures were positive for 318 patients (27.6%), and micro-organisms were isolated from 941 patients (81%). The most common source of infection was respiratory tract infection (58.6%). Most patients (89.2%) needed mechanical ventilator support. Our sepsis patients had the SMS-ICU score ranges from 3 to 35 and SSS ranges from 13 to 138. The 90-day mortality gradually increased correlate with increasing the range of each score. The SMS-ICU had moderate discrimination for predicting 90-day mortality with an AUC 0.71 (95% CI 0.680–0.740) in contrast, the SSS present a good discrimination with an AUC 0.876 (95% CI 0.856–0.896). The AUC of SSS was significantly higher than that of the SMS-ICU ($p < 0.001$). However, the APACHE IV score provided the highest AUC for predicting 90-day and in-hospital mortality followed by SAPS II, APACHE II, SSS and was lowest for SMS-ICU. The AUCs of 90-day and in-hospital mortality of SMS-ICU and SSS were significantly lower than that of other standard severity scores (Figure 1). The SMS-ICU underestimated predicting 90-day and in-hospital mortality with SMR 1.36 (95% CI 1.24–1.48) and 1.33 (95% CI 1.22–1.46). The SSS presented appropriate estimating 90-day and in-hospital mortality with SMR 1.01 (95% CI 0.93–1.11) and 0.99 (95% CI 0.91–1.09). Similar with other standard severity scores, both SMS-ICU and SSS provide poor calibration for predicting 90-day mortality (Figure 2) and in-hospital mortality. The SSS had better overall performance than the SMS-ICU (Brier score 0.169 vs. 0.222 for 90-day mortality and 0.168 vs. 0.224 for in-hospital mortality, respectively).

Conclusions: The SSS had better discrimination and overall performance than the SMS-ICU. However, both scores poorly calibrated. The SMS-ICU score needs to be modified or we need to make a new specific model to predict 90-day mortality in patients with sepsis.

Effects of low positive end-expiratory pressure and pressure support on regional ventilation assessed by electrical impedance tomography during spontaneous breathing trials in specific patient populations. An interim report

M. Konaka[1], Y. Shimotani[1], T. Nakazawa[1], T. Santanda[2], M. Nabeshima[1], N. Yasuhiro[2]

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000466

Introduction: Although positive end-expiratory pressure (PEEP) of 5 mmHg and/or pressure support (PS) of 5 mmHg have been frequently used as "minimal or no ventilator support" in daily practice, it is physiologically expected that even low PEEP and/or PS can be beneficial and possibly lead to overestimation of breathing abilities in specific populations such as patients with chronic obstructive pulmonary disease (COPD), reduced left ventricular function and obesity. There are few studies investigating the effects of low PEEP and PS on regional ventilation using Electrical impedance tomography (EIT) during SBT in such populations.
Objectives: This study aimed to examine the effects of PEEP and PS of 5 cmH_2O on regional ventilation during SBT in various groups of patients.
Methods: Patients on mechanical ventilation who were planned to be extubated were included in this study and classified into 4 groups (group 1: COPD, group 2: reduced left ventricular function, group 3: obesity, group 4: others). Patients who belong to more than one groups were excluded. A 30-min SBT was divided into three 10-min phases to assess changes in ventilation distribution on supine position. Phase 1 with a PEEP and PS of 5 mmH_2O; Phase 2 with a PEEP of 0 mmH_2O and PS of 5 mmH_2O; and Phase 3 with T-piece. Respiratory impedance changes in ventral and dorsal regions were recorded on EIT throughout the trials. All participants were extubated within 10 min after passing the SBT.
Results: So far, a total of 49 patients have been enrolled in this study. Statistical analyses have not been conducted yet with this sample size. Only patients in group 3 showed a tendency that the elimination of PEEP (shift from phase 1 to 2) reduces ventilation in ventral regions (median change in ΔZ: −3.5 AU). Patients in group 3 and 4 showed a tendency that the elimination of PEEP (shift from phase 1 to 2) reduces ventilation in dorsal regions (median change in ΔZ: −1.04 AU and −1.78 AU, respectively). All patients had the tendency that the elimination of PS (shift from phase 2 to 3) reduces ventilation in both ventral and dorsal regions.
Conclusions: This interim report indicates that even low PEEP and PS of 5 cmH_2O affect regional ventilation during SBT and may vary among specific patient populations.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000467

Introduction: Cardiac surgery with cardiopulmonary bypass is associated with microcirculatory derangements that are often transient, but associated with significant patient morbidity and mortality in small observational studies [1, 2]. Current resuscitation markers used to

assess tissue perfusion include systemic hemodynamics, lactate, and blood gas derived biomarkers, but these measurements may not adequately reflect tissue perfusion after cardiac surgery. Inadequate postoperative resuscitation efforts may lead to prolonged impairments in tissue perfusion, leading to multiorgan injury and poor clinical outcomes [3, 4].

Objectives: To examine the relationship between microcirculatory blood flow, organ dysfunction, and traditional physiologic measures of tissue perfusion after surgery.

Methods: Consecutive adult patients undergoing elective cardiovascular surgery were consented and enrolled in the study. Preoperative sublingual microcirculation measurements were obtained, followed by repeated measurements immediately upon ICU admission, then 4- and 24-h later. Clinical data, hemodynamics, and blood samples were obtained at each time point. Microcirculation videos were analyzed manually using ESICM 2nd consensus recommendations [5]. Patients who were weaned from vasopressors and mechanical ventilation within 48-h of their index operation were used as controls. Prolonged postoperative organ dysfunction was defined as ≤ 28 vasopressor and ventilator free days (VVFDs) at postoperative day 30.

Results: A total of 142 subjects were enrolled in the study, 131 were included in the final analysis. Mean age was 66 ± 11 years, 68% were male, and EuroSCORE II was 2.81 ± 3.8. A total of 36 subjects (27%) had ≤ 28 VVFDs at day 30. Compared to controls, patients with prolonged organ dysfunction had lower postoperative perfused vessel density (22.5 ± 4.7 vs. 20.4 ± 3.9 mm/mm^2; $p < 0.05$; Figure 1), prolonged capillary refill time (4.5 ± 1.3 vs. 5.1 ± 1.3 s; $p < 0.05$), and lower central venous pressure (11 ± 4 vs. 9 ± 4; $p < 0.05$) on ICU admission. There was no difference in ICU admission cardiac index and mean arterial pressure between the two groups. Arterial lactate, mixed venous oxygen saturation, and venous-to-arterial PCO_2 difference were also similar at ICU admission. Baseline (23.8 ± 5.2 vs. 22.8 ± 4.9; $p = 0.32$), 4-h (22.6 ± 5.2 vs. 21.1 ± 3.9; $p = 0.16$), and 24-h (23.9 ± 4.3 vs. 22.3 ± 5.0; $p = 0.1$) PVD were similar between control and prolonged organ dysfunction groups (Figure 2).

Conclusions: After cardiac surgery, early microcirculatory blood flow abnormalities after cardiac surgery are associated with significant cardiovascular and pulmonary dysfunction. Microcirculatory perfusion could thus prove to be an early therapeutic target for resuscitation.

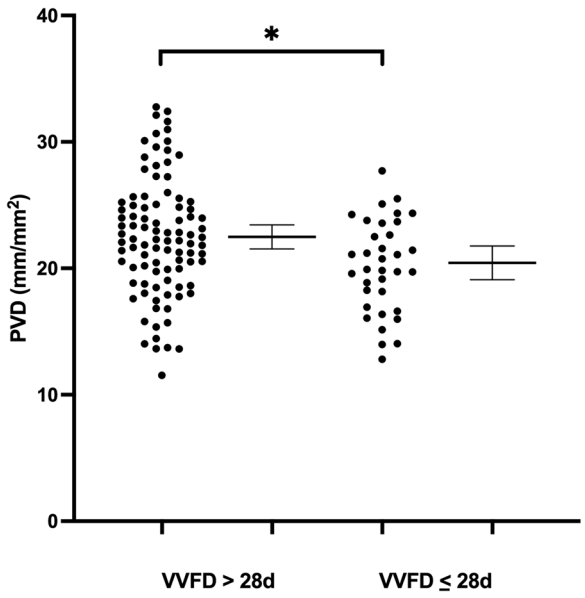

Figure 1 (abstract 000467) Perfused vessel density is lower in patients with prolonged vasoactive and mechanical ventilation requirements after cardiac surgery. Bars represent sample mean and 95% confidence interval

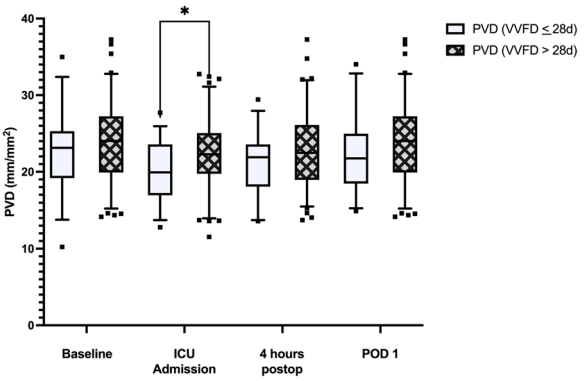

Figure 2 (abstract 000467) Changes in microcirculation perfused vessel density (PVD) over time. Patients with prolonged vasopressor and mechanical ventilation requirements had reduced microcirculatory flow on ICU admission, but similar values at baseline, 4-h after admission, and on postoperative day 1

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000468

Introduction: Diagnosing frailty in ICU patients can help plan interventions to improve outcome.1

Objectives:

1. To determine the prevalence of frailty in ICU patients based on Clinical Frailty Scale (CFS) within 24 h of admission.

2. To study effect of frailty on organ support requirement & clinical outcome.

Methods: After IEC approval & written informed consent, a prospective observational study was conducted in patients admitted to ICU from Feb2021 to Feb2022. Patients dying or getting discharged within 24 h and admitted for organ donation were excluded. The patients were categorized as Frail & Non-Frail, defining frailty as CFS $\geq$ 5, two weeks before index admission.2 The groups were compared for organ support requirment (vasoactive support, MV and RRT) & clinical outcomes (hospital & ICU LOS; hospital, ICU & 30-day mortality; HAI).

Results: The statistical analysis was done on Jamovi version 2.2.5. Out of 358 admissions to ICU, 317 were enrolled with 17 lost to follow up after ICU discharge.

Table 1 (abstract 000468) Demographic characteristics

Variable	All patients (n = 317)	Frail (n = 78)	Non-Frail (n = 239)	p-value
Age	41.6 ± 18.7	56.8 ± 17.3	36.7 ± 16.4	< 0.001
Gender				0.017
Male	154 (48.6)	47 (60.3)	107 (44.8)	
Female	163 (51.4)	31 (39.7)	132 (55.2)	
Level of education				0.091
Less than high school	183 (57.7)	43 (55.1)	140 (58.6)	
Undergraduate	111 (35.0)	25 (32.1)	86 (36.0)	
Postgraduate/ doctorate	23 (7.3)	10 (12.8)	13 (5.4)	
Marital status				0.072
Single	63 (19.9)	10 (12.8)	53 (22.2)	
Married	254 (80.1)	68 (87.2)	186 (77.8)	
Family income	39.7 ± 54.1	62.5 ± 64.9	32.3 ± 47.9	< 0.001

The prevalence of frailty (CFS $\geq$ 5) was 24.6%. A significantly higher number of frail patients required vasoactive support. (Table 2)

Table 2 (abstract 000468) Organ support

Variable	Frail (n = 78)	Non-frail (n = 239)	Relative risk (95% CI)	p-value
MV	71 (91)	203 (84.9)	1.07 (0.98–1.62)	0.173
Vasoactive support	55 (70.5)	125 (52.5)	1.34 (1.11–1.61)	0.006
RRT	19 (24.4)	36 (15.1)	1.62 (0.98–2.62)	0.060

The median ICU LOS was 7 days [IQR, 3–7] in frail compared to 6 days [IQR, 3–10] in non-frail group. The median hospital LOS in frail patients was 18 days [IQR, 10–32] compared to 15 days [IQR, 8.25–26] in non-frail

ICU, hospital and 30-day mortality were significantly higher in frail patients (Table 3)

Table 3 (abstract 000468) ICU, hospital and 30-day mortality

Mortality	Frail	Non-frail	Relative risk (95% CI)	p-value
ICU	39/78 (50.0)	54/239 (22.6)	2.21 (1.60–3.06)	< 0.001
Hospital	41/76 (53.9)	60/224 (26.8)	2.01 (1.49–2.72)	< 0.001
30-day	46/76 (60.5)	68/224 (30.4)	1.99 (1.52–2.61)	< 0.01

Incidence of HAI in frail group was significantly higher (48.7%) as compared to non-frail group (20.9%) (p < 0.001).

Conclusions: The prevalence of frailty in ICU patients was 24.6% and a higher number of frail patients had requirement of vasopressor support, incidence of HAI and ICU, hospital and 30-day mortality.

The impact of BioFire FilmArray pneumonia panel results on mechanical-ventilated pneumonia patients

H. T. Chang[1], Z. H. Zhang[1], C. J. Lin[2]
[1]Department of Critical Care Medicine, Far Eastern Memorial Hospital, New Taipei City, Taiwan; [2]Department of Industrial Engineering and Management, Yuan Ze University, Taoyuan, Taiwan

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000473

Introduction: The Biofire Filmarray Pneumonia Plus panel (FA-PP) has been proposed as a tool that can aid in the timely diagnosis and treatment of pneumonia but little evidence focus on its impact on mechanically-ventilated patients in real world. Also it is still unclear whether the use of FA-PP will improve the mortality rate of severe pneumonia patients in the intensive care unit. We evaluated the impact of FA-PP result on severe pneumonia patients who need mechanical ventilation in the intensive care unit.

Objectives: To evaluate the impact of Biofire Filmarray Pneumonia Plus panel (FA-PP) result on pneumonia patients who received mechanical ventilation in medical ICU.

Methods: This retrospective cohort study was conducted in medical ICU in northern Taiwan. From July 1, 2021 to Oct 31, 2022, all of the patients received mechanical ventilation in intensive care units were collected, while those who had clinical diagnosis of pneumonia and acute respiratory failure were enrolled. Demographic data, laboratory examinations, management records, timing of FA-PP and clinical outcomes were collected for analysis.

Results: During the study period, total 136 patients were enrolled for analysis. Among them, mean age was 66.87 (22–97) y/o, 95 patients (70%) were male, 58 patients (42.6%) had community-acquired pneumonia. Mean APACHE II score was 30.55 ± 8.47, and all of them received mechanical ventilation while enrollment. Fifty-two patients (38.2%) had disconcordant results between FA-PP and conventional sputum culture result, 28 patients (20.6%) received inappropriate antibiotics while FA-PP result available, and 33 patients (24.3%) escalated the antibiotics according to FA-PP result. 71 patients (52.2%) were nonsurvivors, they had higher APACHE II score (32.17 ± 8.572 vs. 28.78 ± 8.055, p = 0.019), had more malignant diagnosis (27 vs.11, p = 0.007), and the interval between ICU admission and FA-PP implementation was longer (2.90 ± 6.27 vs. 0.97 ± 6.28, p = 0.016) as compared to survivors.

Conclusions: In the present study, in evaluation of impact of FA-PP on pneumonia patients with mechanical ventilation, late initiation of FA-PP after ICU admission is associated with mortality in addition to higher APACHE score and malignancy diagnoses. Application of FA-PP result may decreased inappropriate antibiotics and increased the opportunity of precise antibiotics to treat severe pneumonia patients who need mechanical ventilation.

Critically ill cirrhotic patients admitted to ICU. What is the benefit?

R. Yébenes[1], J. Vejo[1], A. Agrifoglio[1], J. Rábano[1], J. Soto[1], L. Cachafeiro[1], E. Graciani[1], B. Guzmán[1], M. Lavara[1]
[1]Intensive Care Unit, Hospital Universitario La Paz, Madrid, Spain, Spain
Correspondence: R. Yébenes
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000474

Introduction: Cirrhotic patients requiring intensive care have higher morbidity and mortality compared to other critically ill patients. Their prognosis is influenced by both the severity of the underlying liver disease and the worsening of extrahepatic organ function. Since intensivists need objective prognostic measurements when making decisions, such as triage or treatment limitations, we conducted a retrospective study over a five-year period to reassess the prognosis of cirrhotic patients admitted to ICU.
Objectives: To evaluate the hospital mortality of cirrhotic patients admitted to our ICU as well as the development of organ failure during their admission.
Methods: All patients with clinical and/or histological diagnosis of liver cirrhosis admitted to ICU between January 2018 and December 2022 were retrospectively included. Liver transplantations were excluded and the following data were collected: demographic and epidemiological data, reason for admission to ICU, developed organ failure, need for organ support (Mechanical Ventilation MV, Continuous Renal Replacement Therapy CRRT and vasoactive drugs) and mortality in ICU.
Results: During the study period, 4790 patients were admitted to ICU. The mean APACHE II score was 17 points. Of these, 170 patients had liver cirrhosis diagnosis at admission, with mean APACHE II score of 19 points. The mean age was 51.5 ± 11 years and 70% were men. The mean length of stay for that subgroup was 7.5 days. Among the reasons for admission, 12% were related to complications directly associated with liver disease and 88% due to common causes of admission to ICU such as community and nosocomial sepsis, polytrauma, postoperative patients, neurocritically ill patients, exacerbation of COPD, intoxications, acute pulmonary edema or cardiac arrest. Cirrhotic patients, compared to the total number of patients admitted to ICU, required MV in 38% vs. 39%, CRRT in 18% vs. 10%, and shock needing vasoactive drugs in 75% vs. 40%. The mortality of cirrhotic patients was higher than expected for their APACHE II (40% vs. 17–27%) and, in relation to subgroups, mortality was 99% if CRRT was required, 83% for those requiring vasoactive drugs and 70% if they were on MV for more than 48 h.
Conclusions: The cirrhotic status of our patients resulted in a high mortality in ICU admission, higher than expected for their APACHE II, even if the reason for admission was for extrahepatic causes in 88% of them. The prognosis was poor if the patient developed organ failure on admission. Among the patients who survived their ICU stay, 48% died within a year. Therefore, after obtaining these data in our center and needing more studies about cirrhotic patients, we consider that the risk/benefit of ICU admission for patients with these characteristics should be individualized to make rational use of resources.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000475

Introduction: Intensive care patients often need sedation to better tolerate stressful life-sustaining measures (e.g. endotracheal intubation, mechanical ventilation). Impairment of thermoregulation by inhaled and intravenous anesthetics has been extensively studied and essentially all anesthetics blunt thermoregulatory responses [1]. Interestingly, isoflurane—unlike propofol—exhibits a non-linear dose–response, suggesting largely preserved thermoregulatory responses within low sedative doses [2, 3].
Objectives: We therefore hypothesized that an infection-associated increase in body temperature differs between isoflurane and propofol sedation.
Methods: According to STROBE guidelines, we performed a (retrospective) observational study over a period of one year. Patients needed to be ventilated for at least 96 h and received isoflurane or propofol for at least 48 h. Core temperatures were measured via urinary catheter temperature probes, collected digitally, and validated by an intensive care nurse. Prevalence of fever ($\geq$ 38,5 °C) and temperature increases on fever days were assessed and adjusted for age, sex, body mass index, opioid intake, sedation day, SAPS II, and SOFA scores using logistic or linear generalized estimating equations regression.
Results: 97 patients were included; they received isoflurane ($n = 13$), propofol ($n = 21$), or both sedatives ($n = 63$). Across a total of 725 sedation days, patients were given isoflurane on 257 (35%) days and propofol on 468 (65%) days. Fever was twice as common in patients receiving isoflurane: 41/257 days (16%) vs. 41/468 days (9%); adjusted odds ratio [95% CI]: 2.4 [1.1, 5.1], $p = 0.021$.
Temperature increases on fever days were more rapid in patients receiving isoflurane, in whom both the fever threshold ($\geq$ 38.5 °C) and peak temperatures were reached more quickly: average difference [95% CI]: -320 [-454, -187] min, $p < 0.001$; and -302 [-465, 138] min, $p < 0.001$ (Figure 1). Maximum increases observed within 1 or 2 h were significantly greater under isoflurane than propofol sedation, respectively: 0.13 [0.02, 0.23] °C/h, $p = 0.019$; and 0.17 [0.05, 0.29] °C/2 h, $p = 0.006$ (Figure 1). Baseline temperatures were slightly higher in isoflurane-sedated patients: 0.33 [0.07, 0.59] °C, $p = 0.012$; but peak temperatures were similar: 0.07 [-0.09, 0.23], $p = 0.407$. Procalcitonin and leucocyte count on fever days were indicative of infection and did not differ between the two groups. Symptoms of malignant hyperthermia (e.g., unexplained increases in end-tidal carbon dioxide, muscle rigidity, increased laboratory markers of muscle damage) did not occur.

Conclusions: Faster and steeper temperature rises were observed with isoflurane compared to propofol sedation, most probably due to better-preserved thermoregulatory responses with isoflurane sedation. The clinical significance of our findings remains to be determined.

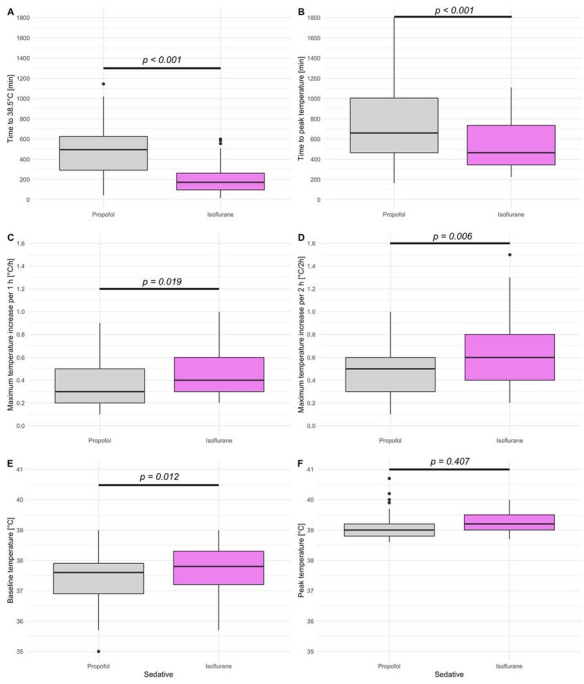

Figure 1 (abstract 000475) Body temperature increases—isoflurane versus propofol sedation
Differences in the characteristics of core temperature increases between patients receiving isoflurane (pink) or propofol (grey) were assessed by linear generalized estimating equations regression adjusted for age, sex, body mass index, opioid intake, sedation day, SAPSII, and SOFA scores. Boxplots show median, quartiles, 95-percentiles and outliers

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000476

Introduction: Central venous catheters (CVCs) are the lifelines of the critically ill, as they enable the co-administration of life-saving medications, fluids, blood products, and parenteral nutrition (Lee et al., 2018). At the same time, in situ CVCs are associated with a high risk of bloodstream infections that increase morbidity, mortality, and cost of care (Bearman et al., 2005; Allen et al., 2014; Ziegler et al., 2014). In 2011 (edited 2017), the Centers for Disease Control and Prevention (CDC) issued global recommendations on CVCs care and the prevention CVCs related infections (O'Grady et al., 2011). However, their implementation is hampered by gaps in ICU professionals' knowledge and training (Koutzavekiaris et al., 2011; Bianco et al., 2013; Dedunska and Dyk, 2015; Dyk et al., 2021). Several studies, recently reviewed by our team (Foka M et al., 2021) have shown that education and training programs can reduce the risk of CVCs-related infections, however, the ICU environment poses significant, escalating, time and physical presence-related educational constraints. e-Learning/distance learning in various formats has been extensively used in healthcare training (Vaona et al., 2018), however, effectiveness data, particularly in demanding environments like ICUs are scarce.
Objectives: This study aimed to assess the impact of an e-learning platform-based training program, on ICU professionals' knowledge regarding the prevention of CVC-related infections. The primary outcome was the improvement in participants' knowledge. Secondary outcomes included ICU professionals' satisfaction and the time they spend completing the interactive, distance learning education.
Methods: A prospective, quasi-experimental questionnaire-based study, to assess attitudes and theoretical knowledge of ICU nurses regarding the prevention of CVCs-related infections, before and after an e-Learning platform facilitated educational intervention. CREDEPTH guidelines were used for intervention development. The study was conducted in a twenty-three beds, multidisciplinary Intensive Care Unit/High Dependency Unit in a tertiary referral Hospital, and the participants were all nurses and intensivists working in both units during the study. An interactive, distance learning e-course was developed and delivered by TELEPROMETHEUS educational platform. To assess ICU professionals' attitudes and theoretical knowledge regarding the prevention of CVCs related infections, before and after education, a Greek version of the questionnaire originally developed by Labeau et al. (2008) and modified by Dedunska et al. (2015) was used. The questionnaire assesses health professionals' knowledge of evidence-based guidelines for preventing infections associated with central venous catheters. The questionnaire was translated into the Greek language (Brislin Richard, 1070), and the translation's semantic, idiomatic, experiential, and conceptual equivalence was checked by an expert committee. Furthermore, participants were asked about their view of the interactive, distance e-course and the time they spent completing the education, through a questionnaire specifically designed for this study. For checking the reliability of the questionnaire, a pilot study was conducted.
Results: Prior to the online, interactive, distance education, the mean total knowledge score was $\bar{x} = 4.8$ (SD = 2.46) while after, the mean total knowledge score increased to $\bar{x} = 8.9$ (SD = 2,38) ($p < 0.001$). Physicians had a higher mean total knowledge score ($\bar{x} = 10.20$) than nurses ($\bar{x} = 8.75$) after the intervention. There was no correlation between years of experience in ICU with the level of knowledge ($r = 0.048$). The interactive, distance education was positively evaluated by the participants.
Conclusions: The current study demonstrated that nurses and physicians had a good level of knowledge regarding the CDC guidelines for preventing CVC-related infections before the education. It is very important though, that even starting from a higher level of pre-intervention knowledge, significant improvement can be observed using

an eLearning platform-based, unsupervised training program. Our results showed that in high–intensity work environments, such as ICUs, adopting innovative solutions seems today more necessary than ever.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000477

Introduction: The Starling system (Baxter, Deerfield, IL, USA) is a non-invasive hemodynamic monitoring device that measures cardiac output through bioreactance. Through bioimpedance, it also measures the mean transthoracic electric impedance (Z0), from which the thoracic fluid content (TFC) can be derived, which should reflect extravascular lung water, fluid in the large thoracic vessels and the cardiac cavities. We compared TFC to the extravascular lung water indexed for ideal body weight (EVLWI) and the global end-diastolic volume index for body surface (GEDVI) estimated by transpulmonary thermodilution (TPTD).
Methods: A group of patients with shock and another one with acute respiratory distress syndrome (ARDS) were included. All the patients were equipped with calibrated TPTD device ($PiCCO_2$, Getinge, Sweden) and the Starling system. Variables measured by TPTD and by the Starling system were collected at the same time before and after volume expansion (500 mL saline) for shock patients, and once a day during the course of the disease for ARDS patients.
Results: In the 42 patients receiving a fluid bolus, TPTD-derived cardiac output increased by 0.44 [−0.16–1.06] (22.5%) L/min/m^2 and bioreactance-derived cardiac output by 0.22 [−0.72–1.16] (11.8%) L/min/m^2. GEDVI increased by 43.8 [−11.9–99.5] (7.6%) ml/m^2 and TFC by 2.4 [−0.3–5.1] (3%). EWLVI decreased by 0.02 [−1.83–1.79] (0.25%) ml/kg. There was no correlation between the fluid-induced changes in GEDVI or in EWLVI on the one side and in TFC on the other ($p = 0.95$ and $p = 0.58$).
In the 23 patients with ARDS, 124 measurements were performed. Between two successive measurements, EVLWI changed by −0.1 (6.3%) ml/kg and the TFC by −0.4 (4.6%). There was no correlation between the changes in EVLWI and in TFC between successive time-points ($p = 0.42$).
Considering all measurement together ($n = 166$), there was no correlation between the absolute values of GEDVI and TFC ($p = 0.16$), EVLWI and TFC ($p = 0.06$) and the sum of GEDVI and EVLWI on the one side and TFC on the other ($p = 0.19$). Still considering all measurements, there was no correlation between the bias between the sum of GEDVI and EVLWI vs. TFC on the one side and the bias between TPTD- and bioreactance-derived cardiac output on the other ($p = 0.29$).
Conclusions: In patients with shock or ARDS, there is no significant relationship between TFC measured by bioimpedance and GEDVI or EVLWI measured by TPTD, neither in absolute values, nor in relative changes.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000478

Introduction: The rise in the elderly patient population increases the frequency and percentage of intensive care unite (ICU) admissions.
The World Health Organization (WHO classification) set a chronological limit of 65 years of age human lifespan in 2007. While the age range of 66–79 is expressed as middle age, the age range between 80 and 100 expressed as old.
Before the WHO classification (BWHO), aging classes were 65–74 years as young old age, 75–84 years as advanced old age, 85 years and over as very advanced old age.
Objectives: Our aim is to retrospectively scan the hospitalization rates and characteristics of these age groups and to investigate the differences between the groups in terms of survival.
Methods: Patients who were hospitalized for longer than 48 h at Vehbi Koç Foundation in the American Hospital and Bakırköy Sadi Konuk Training and Research Hospital between 2005 and 2019, whose ethics committee approval was obtained, were retrospectively screened from electronic recording systems (ERS, Metavision). Demographic characteristics of the patients, age, place of admission to the ICU (emergency unit, service, external center, nursing home, etc.), ICU length of stay (LOS), admission APACHE II and SOFA scores, and survival were examined. The differences between the age groups were analyzed by the Kruskal Wallis and Mann Whitney-U test, which were statistically analyzed on SPSS. The difference between their mortality was examined by X-Square test. Analyze was performed according to four different age groups of BWHO.
Results: Data of 4754 patients were analyzed retrospectively and demographic data according to both classifications are shown in Table 1. Mortality, ICU LOS, mechanical ventilation duration are also given. Being over 65 years of age significantly increases mortality compared to being under 65 years old. However, when the groups over 65 years of age are examined, being older then 65 does not increase mortality significantly.
Conclusions: Our results suggest that in patients over 65 the age increase is not the major determinant of mortality. As pointed with the saying "In the end it's not the years in your life that count; it is life in your years."

Table 1 (abstract 000478) Age and mortality

	Age: 18-65	Age: 65-74	Age: 75-84	Age>85	P values
APACHE II Median(min/max)	17(2/44)[a]	20(2/45)[b]	22(6/46)[c]	23(6/51)[c]	<0,0001
SOFA Median(min/max)	5(1/23)[a]	6(1/20)[b]	7(1/21)[b]	6(1/21)[b]	<0,0001
ICU length of stay/day Median(min/max)	6,3(2/247)[a]	5,5(2/164)[b]	6,1(2/110)[b]	5,8(2/91)[b]	0,014
Mechanical ventilation time/h Median(min/max)	87(1/4290)[a]	78(1/2504)[a]	80(1/2477)[a]	70(1/1139)[b]	0,037
Numbers of patient	2296	1021	900	537	4754
Mortality %	28[a]	32,6[b]	36,3[b]	34,3[b]	0,0001

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000479

Introduction: Intensive care (ICU) professionals from the Netherlands have initiated a widespread collaboration to collect all relevant routinely stored electronic health record data (EHR) related to ICU patients from participating hospitals to support the ongoing development of the application of data science and artificial intelligence for diagnosis, prognosis and decision support in intensive care medicine. Training models to perform these tasks benefits from large datasets to learn from naturally occurring practice variation, to avoid overfitting and to improve generalizability. Therefore, our aim is to combine all routinely stored data into the Dutch ICU Data Warehouse, with a strong focus on durability and scalability, to facilitate data driven research to ultimately benefit treatment and care of future critically ill patients.

Methods: For governance, the ICUdata foundation was established, which includes a general board, a participants' council, an advisory board, a scientific board, a technical committee and a privacy committee. The general board comprises representatives from the participating hospitals, the Dutch Society for Intensive Care and its research committee, the ICU patient and family federation, the ICU nursing federation, and the Dutch National Intensive Care Evaluation registry. With the support from united Dutch health insurers (ZN) the ICUdata foundation contracts a technical company, Pacmed, and medical PhD students from the Center for Critical Care Computational Intelligence at Amsterdam UMC to execute this project (Figure 1). To participate, hospitals sign a Joint Data Registry Agreement to comply with all relevant legislation, including the General Data Protection Regulation. All routinely collected data from ICU patients, except images and notes, are queried from three dominant EHRs in the Netherlands: HiX, EPIC and MetaVision. This initial query retrieves all retrospective data available, with planned addition of all new data on regular basis. This data is pseudonymized, encrypted and securely transferred to a protected cloud environment. There, the data is mapped from hospital variables to standardised concepts using machine learning software for suggestions, transformed to standardized concepts, and saved to the Observational Medical Outcomes Partnership (OMOP) common data model. All participating hospitals are granted access to the ICU data warehouse for research projects approved by the scientific board. The database cannot be used for commercial purposes (Figure 2). Initial example projects include prediction of safe extubation and prediction of mortality.
Results: In 2022, the ICUdata foundation was established, and contracting documents were signed with the technical company and PhD students. Nine hospitals, comprising five academic hospitals and four large non-academic hospitals, have signed the Joint Data Registry Agreement. Eleven more hospitals have expressed interest in joining. Three hospitals have already queried the data from their EHRs. The cloud environment has been designed, and first data transfers are underway. The mapping of this data and transfers of data from other hospitals will take place in subsequent months.
Conclusions: Based on collaborative governance between intensive care professionals as well as hospitals and their intensive care departments, the Dutch ICU Data Warehouse is a project that brings together large volumes of pseudonymised highly granular data on ICU patients in a data warehouse for research purposes. Governance, legal and technical aspects of the project have been finalized and data collection has commenced.

Introduction: Rapid molecular tests such as the BioFire® Blood Culture Identification 2 (BCID2) panel allow the simultaneous identification of a broad range of pathogens and resistance genes from positive blood cultures. Rapid identification of causative pathogens and resistance determinants supports the timely administration of targeted antimicrobial therapy and may improve clinical outcome in critically ill patients. In the United Arab Emirates (UAE) bloodstream infections (BSI) remain a challenge and the clinical impact of BCID2 has yet to be evaluated.

Objectives: This observational study aimed at evaluating the clinical impact of the BCID2 panel on the time to result informing targeted antimicrobial therapy, in adult patients admitted with a BSI in the intensive care unit (ICU) of three UAE hospitals.
Methods: Time to result informing targeted antimicrobial therapy was compared in patients recruited prospectively for a period of 6 months upon implementation of the BCID2 panel (performed in addition to conventional microbiological methods; thereafter referred to as "BCID2" patients) *vs.* retrospective data from patients evaluated using conventional methods only, during a 6-month period preceding the implementation of BCID2 (thereafter referred to as "pre-BCID2" patients). Clinical outcomes were also compared between pre-BCID2 and BCID2 study groups.
Results: Time to pathogen identification result was analysed in 99 pre-BCID2 and 86 BCID2 patients. The median time to result informing optimal therapy was 92 and 28 h in pre-BCID2 and BCID2 patients, respectively ($p < 0.0001$). After accounting for center-to-center variability, the time to results gained in BCID2 *vs.* pre-BCID2 patients was 73 h (95% CI: 59.8–88.6 h; $p < 0.0001$). At least one pathogen was detected in 99% BCID2 *vs.* 88% pre-BCID2 patients ($p = 0.003$). Two pathogens were detected in 15% BCID2 *vs.* 4% pre-BCID2 patients ($p = 0.011$). Antimicrobial resistance phenotypes were identified in 12% detected pathogens pre-BCID2, while resistance genes were identified by the BCID2 panel in 30% identified pathogens. Among BCID2 patients, 76% identified pathogens were concordant between the BCID2 panel and conventional cultures, and only three patients showed truly discordant pathogen identification. The 30-day mortality was statistically lower in BCID2 *vs.* pre-BCID2 patients (17% *vs.* 32%, respectively; $p = 0.019$). The duration of empirical antibiotics usage and the rate of antibiotics de-escalation were comparable in both groups.
Conclusions: The implementation of the BCID2 panel was associated with a shorter time to test result informing optimal targeted antibiotic treatment and with a reduced 30-day mortality among ICU patients with BSI in our UAE hospital setting. The use of the BCID2 panel has therefore the potential to improve clinical outcome in ICU patients with BSI.

Effects of therapeutic hypothermia on brain functions in a refractory cardiac arrest model using extracorporeal cardiopulmonary resuscitation

A. Moreau[1], F. Su[2], F. Manicone[2], B. Garcia[2], F. Annoni[1], F. S. Taccone[1]

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000484

Introduction: Cardiac arrest (CA) is a major cause of mortality and neurologic disability (1, 2). Extracorporeal cardiopulmonary resuscitation (ECPR) may be used in refractory CA in order to potentially reduce hypoxic ischemic brain injuries (3). Currently, targeted temperature management (TTM) with a target below 37.7 °C is recommended in patients who remain unconscious after CA (4). However, lower target temperatures might be needed during ECPR (5).
Objectives: To evaluate the effects of hypothermia on brain perfusion in an experimental model of ECPR.
Methods: Pigs were submitted to 5 min of untreated ventricular fibrillation (No flow) followed by 25 min of conventional CPR (Low flow). Thirty minutes after CA induction, V-A ECMO support was started and defibrillations were delivered until return of spontaneous circulation (ROSC). Pigs were then randomly assigned to receive either hypothermia (HT, body temperature of 33–34 °C) or controlled normothermia (NT, body temperature of 37–38 °C). A continuous infusion of norepinephrine was started to maintain mean arterial pressure

(MAP) between 65 and 70 mmHg. Respiratory rate and sweep gas flow were adjusted to maintain partial pressure of carbon dioxide ($PaCO_2$) between 35 and 45 mmHg. Brain oxygen pressure ($PbtO_2$), intracranial pressure (ICP), cerebral temperature (CT) and brain cortical activity were recorded during the whole experiment. Blood samples, allowing measurements of neuron-specific enolase (NSE), neurofilament (NfL), glial fibrillary acidic protein (GFAP), asparate aminotransferase (AST), alanine aminotransferase (ALT), Troponin I (TnI) and creatine-phosphokinase (CPK), were collected at several endpoints. Twelve hours after ROSC, the animals were killed by an intracardiac potassium injection. Brain tissues were harvested immediately and stored for histological and molecular analysis.

Results: Twelve pigs were enrolled in this study (6 in each group). The baseline characteristics (Table 1) were comparable between the 2 groups. ROSC was obtained in every pig included in this protocol. With the exception of one pig who died from refractory distributive shock in the HT group, all the pigs achieved the end of the experiment. The mean time (mean + SD) to reach targeted body temperature was 1.5 (1.2) hours in HT group and 2.1 (0.7) hours in NT group; $PaCO_2$ and MAP levels were similar between the 2 groups all along the protocol. In the 2 groups, $PbtO_2$ levels progressively decreased and ICP levels increased throughout the experiment. However, no difference was observed between the 2 groups, whether for $PbtO_2$ ($p = 0.8$) or ICP levels ($p = 0.8$) (Figures 1, 2). The levels of AST, ALT, TnI and CPK were similar in both groups. Biomarkers measurements, EEG interpretation and histological analysis are still in progress.

Table 1 (abstract 000484) Baseline characteristics

	Normothermia group	Hypothermia group	P value
Number of pigs (n)	6	6	–
Body weight (kg)	53.5 ± 3.4	51.3 ± 3.8	0.32
Body temperature (°C)	36.5 ± 0.8	35.7 ± 0.7	0.11
Cardiac output (L/min)	6.5 ± 0.9	6.3 ± 0.7	0.63
Mean arterial pressure (mmHg)	7 3 ± 4	70 ± 9	0.48
Blood lactate (mmol/L)	1.2 ± 0.2	1.3 ± 0.4	0.62
Blood glucose (mg/dL)	98 ± 28	124 ± 27	0.12
Cerebral temperature (°C)	36.8 ± 0.5	35.9 ± 0.9	0.06
$PbtO_2$ (mmHg)	51.3 ± 12.1	46.1 ± 11.3	0.46
ICP (mmHg)	8.7 ± 3.7	9.6 ± 3.1	0.67

Conclusions: In this study, HT was not associated with significant improvement in brain hemodynamics when compared to NT. Further analyses are still in progress to confirm our preliminary results.

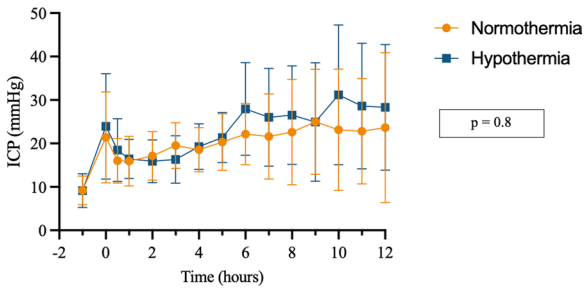

Figure 2 (abstract 000484) Evolution of ICP levels in hypothermia and normothermia groups throughout the experiment

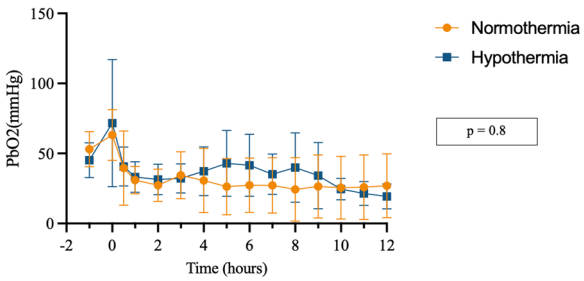

Figure 1 (abstract 000484) Evolution of $PbtO_2$ levels in hypothermia and normothermia groups throughout the experiment

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000485

Introduction: In those surviving severe corona virus disease 2019 (COVID-19) mental and physical recovery has been reported to occur at varying degree and following different trajectories. Incomplete recovery may have considerable impact on daily activities and health-related quality of life (HRQoL). HRQoL can be measured with the RAND-36 questionnaire, a multidimensional instrument that assesses health in physical and mental aspects in eight dimensions.
Objectives: To investigate HRQoL among intensive care patients treated for COVID-19 at three Nordic university hospitals.
Methods: A prospective cohort study at three Nordic hospitals. HRQoL was measured using RAND-36 at 3–9 months after discharge from intensive care unit (ICU). Also, one site performed a second follow-up after 12 months from discharge. The RAND-36 questionnaire was either sent to the participants in advance and collected at the follow

up visit, administered there or by mail. Demographic and clinical data were registered.
Results: We screened 542 patients for participation and included 252. Median age was 61 (52–69) years, hypertension was the most common comorbidity seen in 132 (52%), and 121 (48%) patients were mechanically ventilated for a median of 8 (Q14–Q314) days. In RAND-36, physical functioning, physical role, general health ($p < 0.001$ for all) and social functioning ($p < 0.05$) were below the lower limit of the 95% CI in a Swedish reference cohort (Ohlsson-Nevo et al., 2021), while bodily pain, role functioning and mental health were not. In a time to event analysis assessing predictors of reaching above the lower limit of the 95% CI of the Swedish reference cohort, (Figure 1) female sex was associated with decreased chance of reaching normal HRQoL in the bodily pain dimension; increasing BMI in the physical functioning dimension; hypertension in the physical functioning, bodily pain, vitality and social role functioning dimensions; diabetes mellitus in the vitality dimension; pulmonary illness in the physical functioning and physical role functioning dimensions; and psychiatric diagnosis in the social role functioning dimension. Mechanical ventilation during ICU stay was associated with decreased chance of reaching normal HRQoL in the physical functioning and bodily pain dimensions.
Conclusions: In a cohort of patients treated in the ICU with COVID-19, HRQoL was decreased three to nine months after ICU discharge compared to the general population. Female gender and comorbidities were associated with slower rate recovery.

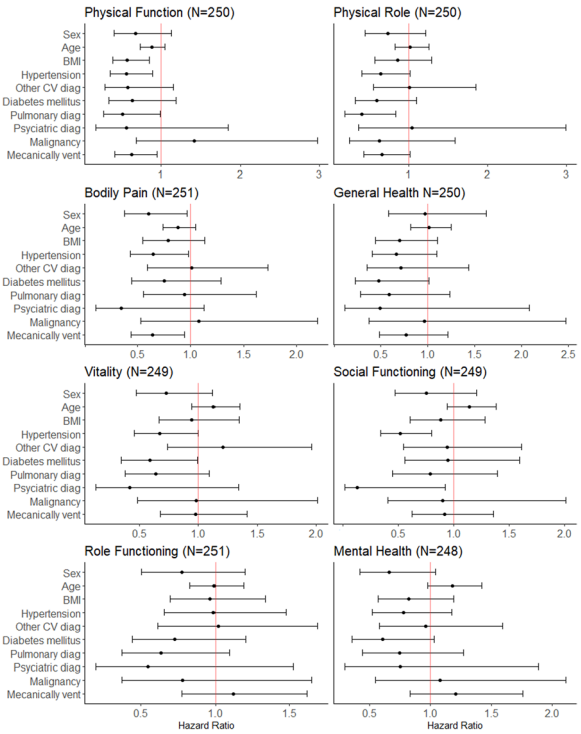

Figure 1 (abstract 000485) Hazard ratio over our RAND-36 data, based on our complete cohort. Lower values indicate slower recovery

The usefulness of VSI (Visensia® Safety Index) and other Early Warning Scores for detecting patients requiring Rapid Response Systems at an academic tertiary center

R. Tanii[1], K. Hayashi[2], T. Naito[3], T. Yoshida[3], S. Fujitani[3]
[1]Emergency and Critical Care Medicine, St. Marianna University School of Medicine, Yokohama City Seibu Hospital, Yokohama, Japan; [2]Data Science, Kyoto Women's University, Kyoto, Japan; [3]Emergency and Critical Care Medicine, St. Marianna University School of Medicine, Kawasaki, Japan
Correspondence: R. Tanii
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000487

Introduction: Rapid Response Systems (RRS) is a global standard for reducing in-hospital cardiac arrest (1). Various Early Warning Scores (EWS) have been implemented to identify deteriorating patients. Since incomplete vital signs lead to misclassification, EWS calculated with fewer parameters may be useful. Visensia® Safety Index (VSI) is an AI-based aggregated score calculated by fewer, at least three of five vital parameters.
Objectives: To compare the sensitivities toward RRS activation and the performance of adverse event detection of VSI and other EWSs.
Methods: A retrospective observational study at a single academic center in Japan was conducted. Patients activated RRS were collected from January 2019 to December 2022. Five different EWS: National EWS (NEWS)(2), VSI, Modified EWS (MEWS) (3), and Marianna-MEWS (MMEWS), were compared. These EWSs were calculated using vital data recorded when RRS activated. Positive thresholds were NEWS ≥ 7, VSI ≥ 3.0, MEWS ≥ 5, and MMEWS ≥ 7. First, we performed multiple comparisons based on McNemar's test to compare the sensitivities. Second, the accuracy of each score for detecting adverse events, defined as ICU transfer and one-month death after care unit transfer, was evaluated using AUCs of the receiver operating characteristic (ROC) curve. P-values < 0.05 were considered statistically significant, and all analyses were performed using R (version 4.1.1).
Results: During the study period, 666 patients were eligible. Among them, 234 patients had complete vital signs of seven parameters. Of the 234 cases, 131 were male (56%), and the median age was 72.5 (IQR 61.0–80.0). ICU transfer and one-month mortality rates were 30.8% and 24%. The sensitivity of each EWS was 0.66 for NEWS, 0.63 for VSI, 0.53 for MEWS, and 0.45 for MMEWS. Sensitivities between NEWS and VSI were not significantly different ($p = 0.41$); however, all others were significantly lower (Table). When we added the factor of consciousness level to VSI, the sensitivity increased to 0.79. On the other hand, if VSI was calculated with four parameters, except blood pressure (BP), respiratory rate (RR), or heart rate (HR), sensitivities dropped significantly. Regarding adverse event detection, AUC for one-month death after care unit transfer was 0.64 for NEWS, 0.61 for VSI ($p = 0.51$). The AUC for ICU transfer was 0.68 [95% CI, 0.61–0.75] for NEWS, 0.62 [0.54–0.69] for VSI ($p = 0.07$), and there were no statistical differences.

Table (abstract 000487) Sensitivities of RRS activation among different EWSs (n = 234)

EWS and alert criteria		Sensitivity	*p-value*	
NEWS	7/20	0.66	***ref***	
VSI	3.0/5.0	0.63	**0.41**	***ref***
MEWS	5/14	0.53	< 0.001	
MMEWS	7/15	0.45	< 0.001	
VSI + consciousness	3.0/5.0 VPU	0.79	**< 0.001**	**< 0.001**
VSI (exc BP)	3.0/5.0	0.41		< 0.001
VSI (exc HR)	"	0.59		0.02
VSI (exc RR)	"	0.53		< 0.001

EWS and alert criteria		Sensitivity	*p-value*
VSI (exc SpO_2)	"	0.61	0.13
VSI (exc Temp)	"	0.60	0.10

Note: Criteria are described as "alert threshold/total score"

ref: reference, exc: except

Conclusions: There were no significant differences in NEWS and VSI for sensitivities in detecting patients requiring RRS and for detecting adverse events. Our findings suggest that VSI might be useful for detecting patient deterioration with fewer parameters.

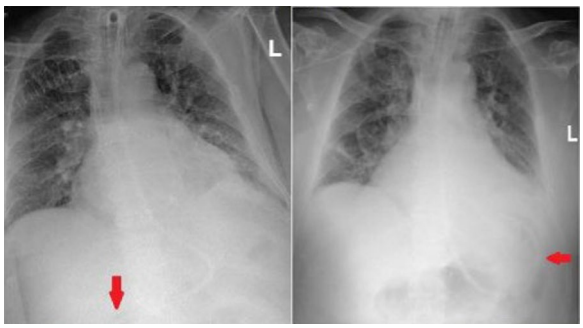
Comparison of gastric or post-pyloric blinded insertion of feeding tubes on target calories and enteral tolerance

V. Demirdogen[1], E. Aygün[2], E. Senturk[2], N. Cakar[1]
[1]Anesthesiology and Reanimation, American Hospital, İstanbul, Turkey; [2]Anesthesiology and reanimation, Koc University, Istanbul, Turkey
Correspondence: E. Senturk
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000488

Introduction: In critically ill patients post-pyloric (duodenal or jejunal) nutrition may have beneficial effects. However this was not proven.
Objectives: Our aim is to evaluate the anatomical placement (gastric or post pyloric) of feeding tubes inserted by blind method and to compare their time to reach the target calories.
Methods: All adult patients in between 2010 and 2021 were screened, the patients in which blind insertion of feeding tube (polyurethane, radiopaque, 14F, Bexen Medical, Hernani, Spain) was done were analyzed retrospectively in the general ICU of the American Hospital. For at least 5 days including 1st, 3rd, 5th days of feeding tube placement, chest X-rays were evaluated for anatomical location. (Figure A Post-pyloric tube, Figure B Gastric placement of feeding tube). If the patient's feeding tube is in the post-pyloric area in three chest X-rays these were accepted as post pyloric group (PG), the remaining are defined as gastric group (GG).
Enteral nutrition was started at a dose of 20 ml/h infusion, and if the amount of gastric residue (GRV) measured every 7 h is < 250 ml, infusion rate was increased 20 ml every 7 h. If GRV was > 250 ml, the infusion was interrupted for 2 h and then continued at half rate. In the presence of vomiting and/or abdominal distention, the infusion was also interrupted. The time to reach at least 75% of total daily calories (calculated by Harris Benedict and Schofield divided by two) of the patients were evaluated. The number of patients reaching target calories in 72 h were also recorded. The patients' gender, comorbidities (diabetes, neurological disease), medications (inotropic and/or sedative, prokinetic drugs usage), APACHE-II values were analyzed.
Results: 301 patients were retrospectively analyzed, 68% (206) were in PG and 32% (95) were in GG. In both groups there was no statistically significant difference between gender, diabetes, and neurological disease, use of sedative and inotropic agents. The mean time to reach the target calorie was 64 h in the PG, and 88 h in the GG ($p < 0.001$). The number of patients reaching target calories in 72 h or earlier in PG was 171 (83%), and it was 37 (39%) in GG. The rate of patients who developed enteral intolerance in the PG was 12 (6%), it was 22 (23%) in the GG ($p < 0.001$).
Conclusions: It was determined 68% of the blindly placed enteral feeding tubes were post-pyloric. PG has better feeding tolerance and reach targeted calories earlier. During insertion of feeding tubes this data has to be considered.



Enteral tube placement by bedside chest x-ray postpyloric and gastric tube.

Protecting mucosal immunity against SARS-CoV-2 variant of concern

J. Liang[1], S. Mubareka[2], A. Slutsky[3], H. Zhang[1]
[1]Anesthesiology and Pain Medicine, Critical Care Medicine, St. Michael's Hospital, University of Toronto, Toronto, Canada; [2]Microbiology and Infectious Diseases, University of Toronto, Toronto, Canada; [3]Critical Care Medicine, St. Michael's Hospital, University of Toronto, Toronto, Canada
Correspondence: H. Zhang
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000492

Introduction: The SARS-CoV-2 Omicron variant differs from the parental virus and other variants of concern in two significant ways: (1) it exhibits robust binding to the angiotensin-converting enzyme 2 (ACE2) receptor, while also being highly adept at evading the immune system; and (2) it relies more on the endocytic pathway for cell entry, resulting in a significant loss of endogenous mucosal ACE2, reducing lung protection, and increasing infectivity. The Omicron variant is more likely to cause upper airway infections and less likely to affect the lung distal tissue. Individuals with weakened immune systems or underlying health conditions are at high risk. Consequently, the urgent need to explore effective prophylactic and therapeutic interventions to boost mucosal immunity against Omicron in the upper airways has become apparent.
Objectives: The study aims to identify potential prophylactic and therapeutic strategies to protect mucosal immunity against breakthrough infections.
Methods: Based on the viral structure and its interactions with host cells, we are testing several potential strategies against SARS-CoV-2 infection and its variants of concern in human lung organoids and humanized mice. These strategies include, but are not limited to, using decoy viral particles, decoy host receptors and blocking host receptor complexes, to prevent VOCs from escaping with mutative spike proteins.
Results: We observed significant preservation of mucosal ACE2, decreased viral loads, lower clinical manifestation scores, and lung injury scores using recombinant human ACE2 in humanized mice

infected with SARS-CoV-2. We also demonstrated the potential prophylactic role of recombinant ACE2 and SARS-CoV-2 virus-like particles as decoys, attenuating the number of viral gene copies and cytopathic effects in human lung organoids infected with Delta and Omicron (BA.2) variants.

Conclusions: The use of decoy host receptors and viral particles has shown promising results in preserving mucosal host immunity, and this study highlights their potential for the development of effective prophylactic and treatment capabilities against breakthrough SARS-CoV-2 infections.

A novel method to reduce aerosol generation during non-invasive ventilation

Y. Angel[1], I. Moshkovitz[1], D. Stavi[1], N. Adi[1], A. Gal Oz[1]
[1]Division of Anaesthesia, Pain Management and Critical Care, Tel Aviv Sourasky Medical Center - Ichilov, Tel Aviv-Yafo, Israel
Correspondence: Y. Angel
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000493

Introduction: Non-invasive ventilation (NIV) is a fundamental tool in the care of critically ill patients suffering from respiratory failure and specifically in those with respiratory infections. NIV is commonly considered an "aerosol generating procedure" [1]: Environmental spread of exhaled air and/or respiratory droplets during NIV may spread contagious pathogens such as SARS-CoV-2 and infect nearby patients as well as healthcare personnel. Consequently, many societies and institutions now require staff caring for patients receiving NIV to use respiratory precautions [2]. There is a need for methods to reduce the risk of environmental contamination during NIV.

Methods: This is a single-center, prospective, open-label study evaluating the Lumena NIV mask (Inspir Labs, Kfar Saba, Israel), a novel mask composed of a standard nose-mouth interface surrounded by a second layer of interface, with the space between two negatively pressurized to minimize environment air leak (Figure 1). This study takes place in the Intensive Care, Cardiology, and Internal Medicine wards at the Tel Aviv Sourasky Medical Center. Patients requiring NIV who met inclusion criteria, did not meet any exclusion criteria, and provided written informed consent were enrolled. Patients underwent three 30-min NIV sessions during a 24-h period: with a standard NIV mask and with the study mask with and without negative pressure applied. Following an inhalation of 5 ml 0.9% NaCl, the concentration in the air of particles 0.3, 0.5, 1 and 2.5 microns (a range consistent with airborne transmission [3]) was measured 1 m from the patient's head using a particle measuring device (PCE Instruments PCE-PCO 01). Patients' vital signs, clinical status, and arterial or venous blood gas analysis were monitored as safety outcomes.

Results: The first 12 enrolled patients who completed the study are included in this interim analysis (median age 72 years; 9 [75%] male). A significant reduction in the concentration of particles 0.3, 0.5 and 1.0 micron was observed with the use of the study mask with negative pressure applied compared to the conventional (control) mask (One-sided t-test $P < 0.001$, $P = 0.006$, $P = 0.045$, respectfully), with the greatest reduction observed for 0.3 and 0.5 micron particles (Figure 2). No significant differences were observed in heart rate, respiratory rate, blood pressure, O_2 saturation, arterial O_2, CO_2, Lactate or pH between the three groups.

Conclusions: In this interim analysis of a single-center, open-label study, a reduction in the number of particles 0.3, 0.5 and 1.0 micron was observed with the application of negative pressure to the novel Lumena mask, compared to the use of a conventional NIV mask. Further studies are needed to validate these results and evaluate the effect of using the Lumena mask on cross contamination rates.

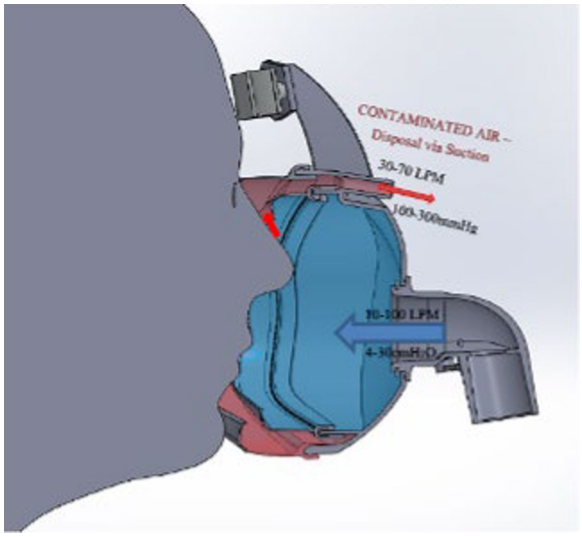

Figure 1 (abstract 000493) Illustration of the study mask. Positive-pressure ventilation is delivered through the conventional nose-mouth interface, while negative pressure is applied to the surrounding space, preventing dispersion of exhaled air to the surroundings

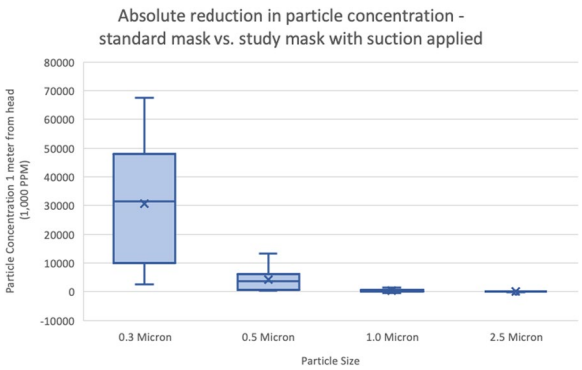

Figure 2 (abstract 000493) Boxplot comparison of the *absolute reduction* in particle concentration between standard mask and the study mask with suction applied. Boxes represent interquartile range, internal line represents median. Y axis is displayed in 1000 PPM

Introduction: In the Intensive Care Units (ICU), it is important to know the magnitude of a patient's illness and forecast disease prognosis. Different severity scores are being used to assess outcomes in ICU, but variable data have been reported so far regarding their performance. Are the standard scores such as Acute Physiology and Chronic Health Evaluation II (APACHE II) and the Simplified Acute Physiology Score II (SAPS II) accurate for predicting outcomes in COVID 19 patients?
Objectives: The main purpose of our work was to compare the performance of APACHE II and SAPS II regarding the outcomes of ICU COVID 19 patients, namely mortality and invasive mechanical ventilation (IMV) need.
Methods: We performed a prospective study with confirmed COVID 19 patients admitted to the ICU, from March 2020 to March 2021. APACHE II and SAPS II were performed in the first day. Age, gender, IMV need and total days intubated, cardiovascular risk factors and length of stay in ICU were recorded. Two groups were made: survived and nonsurvived patients, that were compared by chi-square test for categorical variables and independent sample t-test for continuous variables. ROC analysis was used to compare scores' accuracy.
Results: We enrolled 158 patients. In the survived group there were 105 patients (66,46%), 70 men (66,67%), mean age of 61,23 ± 14,56 years. In the nonsurvived group there were 53 patients (33,54%), 36 men (67,92%), mean age of 70,43 ± 9,86 years. Regarding mortality, APACHE II demonstrated a sensitivity of 73,6% and a specificity of 68,6% with an Area Under the Curve (AUC) of 72,3%. SAPS II showed a sensitivity of 66% and a specificity of 62,9% with an AUC of 68,9%. Regarding prediction of the requirement of mechanical ventilation, APACHE II showed a sensitivity of 58,0% and a specificity of 56,9% and SAPS II showed a sensitivity of 62% and a specificity of 53.4%. There was a positive correlation between APACHE II and the total number of days on IMV (r = 0,0198) and between APACHE II and the length of stay in ICU (r = 0,0239), although not statistically significant (p = 0,845 and p = 0,766, respectively). Similar results were seen in SAPS II (r = 0,044, p = 0,663 and r = 0,0476, p = 0,553, respectively). Older age and diabetes were associated with high mortality (p = 0,00003 and p = 0,03699 respectively). Obesity, hypertension and dyslipidemia were not associated with increased mortality (p = 0,37973 p = 0,10278 and p = 0,92796, respectively).
Conclusions: APACHE II and SAPS II are overall comparable and useful scores to predict outcomes in ICU patients. Both scores predicted mortality with similar sensitivity and specificity in COVID 19 patients, with APACHE II showing slightly more sensitivity than SAPS II. SAPS II showed more sensitivity regarding IMV need. Higher values of APACHE II and SAPS II scores are associated with higher mortality rates. There was a positive weak correlation between APACHE II and SAPS II scores and days on IMV and length of stay in ICU. Older age and diabetes are risk factors for mortality.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000501

Introduction: Viral replication and the majority of immune responses triggered by sars-cov-2 are believed to contribute to the clinical outcome of COVID-19, as recent studies show, however, it remains unclear whether there is a correlation between viral load and antibody production and clinical outcomes.
Objectives: The objective of this study was to determine the characteristics of critically ill, COVID-19 positive patients, with a prolonged PCR positivity and to investigate any association of this prolongation with mortality in a critical care setting.
Methods: Within the past year, from January 2022 to January 2023, 220 patients were admitted to the 3rd ICU of 'G. Papanikolaou' General Hospital. All COVID-19 patients who tested negative during their hospitalization participated in this study. The rest of them were either discharged to other departments or died with a positive PCR. Demographic characteristics, days of positivity (PD), Tocilizumab intake and mortality were also recorded.
Results: We studied a total of 83 patients, 25 of which were women (30.1%), with a mean age of 66.04 ± 13.1 years. A statistically significant moderate negative correlation was observed between age and positivity—Spearman's correlation was − 0.563 with confidence interval (− 0.691, − 0.39). Significance was found at $p < 0.0001$. No statistically significant difference was observed between the 2 sexes. For women PCR positivity days (PPD) were 18.9 ± 9.36 and for men 20.9 ± 9.9 respectively, with $p = 0.46$. Tocilizumab was prescribed and administered to 14 (15.7%) patients and featured a mean PCR positivity duration of 15.4 ± 9.9 days, compared to those who did not receive it, who were PCR positive for 21.2 ± 9.5 days, with a statistical significance of $p = 0.017$. Patient mortality under this study was estimated at 50.5%. Those who died had a mean PD of 20.9 ± 10.4 compared to those who lived who had a PD of 19.8 ± 9 with $p = 0.6$.
Conclusions: Duration of PCR positivity days in COVID-19, critically ill patients was statistically significantly related to age and previous Tocilizumab intake, while no correlation was observed with ICU mortality.

Introduction: Coronavirus disease 2019 (COVID-19) has resulted in a high mortality rate by evading the host's immune system through mechanisms that are not yet fully understood (1). Adrenal insufficiency may play an important role in this phenomenon and several potential mechanisms have been proposed. One of these is based on the fact that the SARS-CoV-2 amino acid sequence is highly close to human adrenocorticotropic hormone (ACTH) (1, 2). As a result, the hormone could also be neutralized by antibodies that target identical epitopes on the virus, preventing it from producing cortisol and resulting in a relative adrenal insufficiency. However, the information available on the presence of anti-ACTH antibodies and cortisol levels in COVID-19 patients is scarce (3).
Objectives: To investigate the prevalence of anti-ACTH antibodies in COVID-19 patients and their association with outcomes, complications, and endocrine alterations.
Methods: We conducted a prospective, observational, single-centre study in the intensive care unit (ICU) of a university hospital in Spain. Inclusion criteria: polymerase chain reaction (PCR)-confirmed infection by SARS-CoV-2 with COVID-19 symptoms, time from diagnosis to ICU admission < 14 days and mechanical ventilation (MV) > 48 h. Exclusion criteria: SARS-CoV-2 infection without COVID-19, use of MV for reasons other than COVID-19, or denial to participate in the study. Inclusion period: 01/11/21 to 28/02/22. We measured Ig-E class anti-ACTH antibodies on ICU day 10, by using ImmunoCAP® technology. We measured adrenocorticotropic hormone (ACTH) and cortisol levels on ICU days 5, 15 and 25. Patients were followed up until 90 days or hospital discharge (whichever occurred first). Results are expressed as median (interquartile range) or frequency (%). Chi-square, Student's T, and Mann–Whitney U tests were applied as appropriate.
Results: During the enrolment period, we identified 52 patients with a positive SARS-CoV-2 PCR, 35 of whom met inclusion criteria. Clinical characteristics of the patients included: 77% men, aged 60 ± 9 years-old, APACHE-II 13 (11–18). All the patients received MV, with a duration of 23 (12–41) days. Veno-venous extracorporeal membrane oxygenation (V-V ECMO) was required in 28.5% of the patients, with a duration of 19 (12–46) days. The observed 90-day mortality was 17%. We identified anti-ACTH antibodies in 46% of the patients.
Comparison between patients with *vs.* without anti-ACTH antibodies: age 61 ± 9 *vs.* 59 ± 9 years old, p = 0.62; male sex 75 *vs.* 79%, p = 0.78; APACHE-II 14 (12–20) *vs.* 13 (11–17) points, p = 0.44; length of MV 23 (13–58) *vs.* 24 (12–30) days, p = 0.61; length of ECMO 36 (12–53) *vs.* 12 (12–25) days, p = 0.39; 90-day mortality 19% *vs.* 16%, p = 0.81.
Association between anti-ACTH antibodies and complications (odds ratio, 95% confidence interval, p): colonization with multidrug-resistant bacteria 2.8 (0.6–14.7), p = 0.15; ventilator-associated pneumonia 1.37 (0.3–6.4), p = 0.64; bacteraemia 2.7 (0.5–15.4), p = 0.17; delirium 0.35 (0.1–1.7), p = 0.13; ICU-acquired weakness 0.9 (0.2–4.1), p = 0.87; thrombotic events 1.3 (0.3–6.6), p = 0.71; ischemic events 2.6 (0.2–159.9), p = 0.45; pulmonary fibrosis 2.8 (0.3–35.1), p = 0.26.
Hormone levels in patients with *vs*. without anti-ACTH antibodies on ICU days 5, 15 and 25. ACTH (pg/mL): 2 (0–7.2) *vs.* 2 (0–8.5), p = 1; 6.3 (2–9.4) *vs.* 15.3 (5.6–29.5), p = 0.10; 7.1 (2–11.7) *vs.* 9.1 (2–16.2), p = 0.65. Cortisol (μg/dL): 2.2 (1.6–7.6) *vs.* 2.4 (1.5–5), p = 0.76; 5.3 (2.1–13.5) *vs.* 8.4 (3.7–15.7), p = 0.37; 2.4 (1.5–5.4) *vs.* 2.7 (2.1–4.8), p = 0.69.
Conclusions: We found a high prevalence of anti-ACTH antibodies in patients with COVID-19. However, their role is yet to be determined. We could not find an association between the presence of these antibodies and the clinical outcomes, the incidence of complications, or the hormones from the pituitary-adrenal axis.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000504

Introduction: Bloodstream infection (BSI), a frequent cause of severe sepsis, is a life-threatening complication in critically ill patients and associated with a high mortality rate. Prompt pathogen identification is the crucial factor in the diagnosis and treatment of patients with suspected BSI in intensive care medicine. It allows for targeted antimicrobial therapy, thus improving patients' outcome, as emphasized in the surviving sepsis campaign. Currently, blood culture (BC) is still the gold standard method for diagnosis of BSI, despite of its low sensitivity, long culture time and high risk of contamination. Next-Generation-Sequencing (NGS) is a promising alternative which could potentially enhance patient outcomes and lower healthcare expenses by offering faster and more precise infection diagnosis and guiding appropriate treatment decisions [1–2]. NGS is based on the unbiased sequence analyses of circulating cell-free deoxyribonucleic acid (cfDNA) from plasma [3]. As cfDNA can originate from bacterial, fungal, parasitic and viral microorganisms, it allows NGS to detect multiple pathogens in a single sample which could be particularly beneficial in patients with suspected polymicrobial infections or unclear focus.
Objectives: This study aimed to evaluate the potential diagnostic benefit of additional NGS using the DISQVER® pathogen test for patients with suspected BSI in the Intensive Care setting and its impact on antimicrobial therapy.
Methods: In this retrospective single-centre study, adult patients admitted on intensive care unit (ICU) with suspected BSI were analysed with BCs and NGS simultaneously. Microbiological results of pathogen diagnostics of both tests were compared with clinical data of infection. The analysed timeframe included a maximum of five days before and after initiation of the first NGS diagnostic. Focus of the analysis was on relevant changes of antimicrobial therapy and infectious source control procedures in response to BC and NGS results within seven days after first initiation of NGS. A panel of at least two intensivists examined all medical files to assess the relevance of NGS and BC results. Data were analysed using the Chi-Square and Fisher's exact test and the independent student t-test. This study was approved by the Ethical Committee of University Hospital Cologne, Germany.
Results: 30 patients with parallel NGS and BC samplings were assessed. NGS had a positivity rate of 60% (18/30) and detected 35 relevant pathogens (bacteria: 22, viruses: 12, fungi: 1). In contrast, BC had a positivity rate of 23% (7/30) and detected nine relevant pathogens (bacteria: 7 fungi: 2). There were no significant differences between NGS positive and negative patients concerning demographical data, comorbidities, in hospital mortality and laboratory findings on sample

day. NGS led to initiation of antibiotic therapy in three cases and further diagnostics (real-time PCR) in two cases. Current empiric antibiotic treatment was confirmed by NGS results in seven cases (Fig. 1). In contrast, in 10 cases NGS diagnostics revealed negative results which were in concordance with clinical data. In two cases NGS failed to detect possible relevant pathogens.

Conclusions: Due to its higher sensitivity in detecting relevant pathogens in patients with suspected BSI, NGS may lead to a higher rate of targeted antibiotic treatment. Moreover, NGS may guide further virological diagnostics and consequently antiviral therapy. Vice versa, in our study NGS had a high negative predictive value which could be beneficial in avoiding overtreatment. Larger randomized multicentre studies are required to validate these findings.

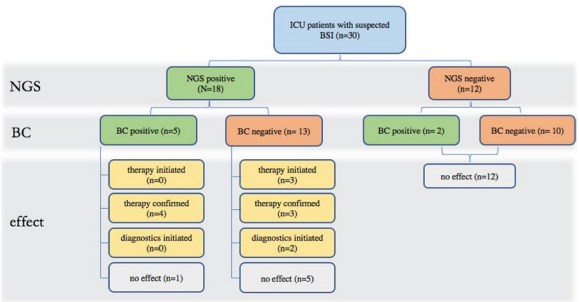

Figure 1 (abstract 000504) Flow-chart: effect of additional NGS considering BC results

Effect of different noninvasive respiratory support methods on gas exchange parameters in the postoperative cardiac surgery patients

D. Fomina[1], A. Eremenko[1], R. Komnov[1], L. Sorokina[1], A. Urbanov[1]
[1]Cardiac Intensive Care Unit, Petrovsky National Research Center of Surgery, Moscow, Russia
Correspondence: D. Fomina
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000509

Introduction: Methods of noninvasive respiratory support are used to improve gas exchange, reduce the work of respiration and straightening of the collapsed alveoli due to formation of hypoventilation and microatelectasis. The most commonly used methods: non-invasive mask positive pressure ventilation (NIMPPV), high-flow nasal oxygen therapy (HFNO) and non-invasive positive pressure ventilation with helmet (NIHPPV).

Objectives: Comparison of the effectiveness of respiratory support methods depending on their effect on gas exchange in patients with moderate respiratory failure in the early period after cardiac surgery.

Methods: In randomized prospective study (ClinicalTrials.gov—NCT 04787666) 42 cardiac surgery patients with 200 < P/F < 300 were divided into 3 groups depending on the methods of respiratory support used (NIMPPV; HFNO and NIPPVH). The main point of the study was to assess the dynamics of the gas exchange before, during and after their application. To carry out ventilation with a helmet, a higher level of pressure support then in mask ventilation was required due to the presence of an additional ventilated space inside it.

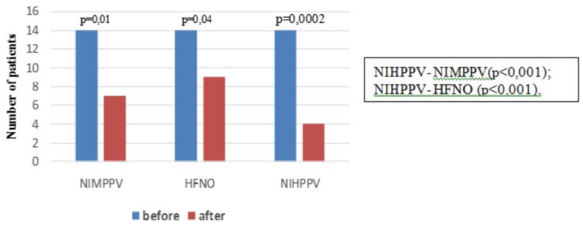
Results: All three methods demonstrated statistically significant improvement in gas exchange (SpO_2, PaO_2, HbO_2, Qsp/Qt), which persisted after the end of their application (Table 1). In this pilot study we did not receive significant differences between the methods investigated on their effect on blood gases and SpO_2.

Table 1 (abstract 000509) Dynamics of blood gases and SpO_2 during noninvasive respiratory support

Parameters	NIMPPV	p1–p2 p2–p3 p1–p3	HFNO	p1–p2 p2–p3 p1–p3	NIHPPV	p1–p2 p2–p3 p1–p3
SpO_2, % 1. Before 2. During 3. After	87 ± 3 97 ± 2 92 ± 3	< 0,001 < 0,001 < 0,001	90 [87; 98] 97 [93; 98] 92 ± 3	< 0,001 < 0,001 0,02	89 ± 2 98 ± 2 94 ± 3	< 0,001 < 0,001 < 0,001
paO_2, mmHg 1. Before 2. During 3. After	57 [50; 60] 107 ± 22 62 ± 7	< 0,001 < 0,001 < 0,001	57 [60; 62] 85 ± 20 60 ± 9	< 0,001 < 0,001 0,04	56 ± 10 100 ± 26 63 [59; 77]	< 0,001 < 0,001 0,01
HbO_2, %						
1. Before	88,1 ± 3,8	< 0,001	88,58 ± 3,36	< 0,001	89,27 ± 3,1	< 0,001
2. During	96,4 [94; 97,3]	< 0,001	95,72 ± 0,92	< 0,001	96,68 ± 1,02	< 0,001
3. After	90,4 ± 3,6	0,02	90,53 ± 3,36	0,02	91,98 ± 3,17	0,04
Qsp/Qt (est), %						
1. Before	29,28 ± 7,93	< 0,001	28,6 [7,9; 35,5]	< 0,001	23,63 ± 7,46	0,03
2. During	17,9 [7,9; 20]	0,37	19,8 ± 6,1	0,87	15,76 ± 5,54	0,87
3. After	18,49 ± 10,86	< 0,001	20,7 ± 7,83	0,03	16,46 ± 8,52	0,01

No significant changes in $PaCO_2$ was observed. NIHPPV significantly reduces the number of patients with P/F less than 300 in comparative with other group. In the course of this study, no data were revealed on changes in $PaCO_2$. A decrease in the proportion of patients with P/F < 300 after a single session in the NIMVL group by 2 times, in the HFNO group—by 1.6 times, in the NIVLH group—by 3.5 times

Conclusions: Noninvasive respiratory support significantly improves oxygenating lung function in the early postoperative period of cardiac surgery patients. NIHPPV and NIMPPV are more effective compared to HFNO. In case of helmet interface, a higher level of support was required and the most significant clinical effect was achieved.



Note: p—statistical significance between periods of respiratory support inside each group.
In the frame—statistically difference between effects of the helmet ventilation and mask and high flow support.

Topic: Acute respiratory failure and mechanical ventilation

Introduction: Exosomes are found to play an essential role in cell–cell crosstalk. Recent studies indicated that exosomes released by lung epithelial cell can activate pro-inflammatory macrophages by carrying microRNAs, which plays an important immunomodulatory role in ARDS1. However, the mechanisms that control the specific loading of microRNAs into exosomes remain unknown. Here we aimed to identify special pattern of microRNAs sorting into exosomes derived from lung epithelial cell, and the key molecule which determines the secretion of microRNAs during ARDS.
Objectives: To investigate the mechanisms that control the specific loading of microRNAs into lung epithelial cell-derived exosomes which are responsible for triggering inflammation of ARDS.
Methods: Exosomes were isolated from cell culture supernatants of murine lung epithelial (MLE-12) cells treated or untreated with LPS and intratracheally injected in C57BL/6 mice. RAW264.7 and alveolar macrophages MH-S were stimulated with LPS-treated exosomes (LPS-Exos). The microRNA sequencing for LPS-Exos and Ctrl-Exos were used to discover functional microRNAs and specific motif. We used biotinylated microRNA probe combining mass spectrometry to seek the key molecules that mediate the sorting of microRNAs into epithelial cell-derived exosomes. Western blotting and immunohistochemistry analysis were used to detect the expression of DDX21. Lentiviral infection was conducted to silence or overexpress DDX21 in epithelial cell line. Site-directed mutagenesis of the identified sequence was performed to exam the effect of the specific motif.
Results: LPS-Exos enhanced lung injury and polarization of M1 pro-inflammatory phenotype of macrophages (Fig. 1). Microarray analysis showed that the upregulated microRNAs were associated with pro-inflammatory factors and contained a "GGCGGGG" motif in LPS-Exos (Fig. 2a and b). Further detection the level of miRNAs containing the specific motif through RT-qPCR confirmed the microarray results (Fig. 2c). DDX21 could bind microRNAs containing specific motif (Fig. 3b). After silencing or overexpressing DDX21 by lentiviral infection (Fig. 3d), significant changes were observed in microRNA containing the specific motif in exosomes, such as microRNA-4332-3P, as well as IL-6 and TNF-α of macrophages treated with exosomes (Fig. 3e). DDX21 was increased in exosomes in bronchoalveolar lavage of ARDS patients (Fig. 3c), and in the lung tissues of mice intratracheal injected with LPS-Exo (Fig. 3a), as well as in LPS treated lung epithelial cells and LPS-Exos (Fig. 3c).
Conclusions: This study for the first time found that the microRNAs that promote ARDS inflammation contain specific motif. DDX21 could bind and sort series of pro-inflammatory microRNAs containing specific motif into lung epithelial cell-derived exosomes.

Introduction: Hemolysis during extracorporeal membrane oxygenation (ECMO) is a common complication often caused by increasing resistance to flow due to progressive thrombosis and excessive mechanical stress, especially high negative pressures (1). Carbon monoxide—formed through degradation of heme by heme-oxygenase—binds with high affinity to hemoglobin (2) producing Carboxyhemoglobin (COHb). High COHb levels caused by excessive hemolysis and reduced elimination due to impaired gas exchange through the oxygenator might therefore be a novel point-of-care marker of oxygenator dysfunction.
Objectives: The aim of this study was to evaluate COHb, sampled from a conventional arterial blood gas analysis, as a marker of oxygenator dysfunction and its predictive value for oxygenator exchange in patients on ECMO.
Methods: Retrospective single-center analysis of all patients requiring ECMO support having experienced at least one oxygenator exchange between 2018 and 2021 at our Institute of Intensive Care Medicine. Multivariable, generalized mixed-effects models and time-varying proportional hazards models, adjusting for a set of predefined, causally identified confounders of hemolysis and ECMO circuit lifespan, were employed.
Results: In total 484 ECMO patients were screened of whom 89 required one or more oxygenator exchanges and were included into the final cohort. Of these 33 (37%) patients received ECMO in v-v configuration and 56 (63%) in v-a configuration. Cumulatively, 116 oxygenator exchanges were detected over 1833 patient days, including 20,000 COHb measurements. COHb was independently associated with oxygenator performance assessed by means of the partial pressure of oxygen in a post-oxygenator blood gas analysis sampled after the performance of an oxygen challenge (log Effect Size −7.0 [95% CI −11.5 to −2.5], $p = 0.032$). Similarly, increasing COHb levels were independent predictors of an oxygenator exchange in the ensuing 6 h (log Odds Ratio 0.78 [95% CI 0.18 to 1.38], $p = 0.0111$) and rising levels were independently associated with an absolute increase in the hazard of oxygenator exchange (Hazard Ratio 1.55 [95% CI 1.11 to 2.17], $p = 0.0102$).
Conclusions: COHb is independently associated with reduced oxygenator performance and predicted imminent oxygenator exchange in a retrospective fashion. Its universal bedside availability, rapid turnover, and association with oxygenator performance makes COHb an interesting candidate for routine monitoring of ECMO patients.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000513

Introduction: It has been demonstrated that the implementation of an intensivist-led rapid response team (RRT) is associated with better clinical outcomes (1). Nevertheless, predictors of mortality among patients admitted to the intensive care unit (ICU) or to the stepdown unit (SDU) after a RRT activation are not fully understood.
Objectives: To describe clinical characteristics, resources, main outcomes, and to address predictors of hospital mortality among patients admitted to the ICU/SDU after RRT activation.
Methods: Retrospective, single center, cohort study, conducted in a medical-surgical ICU/SDU located in a private quaternary care hospital. Adult patients admitted to the ICU or SDU from 2012 to 2020 were compared according to hospital mortality. Multivariate logistic regression analysis was performed to identify the predictors of hospital mortality.
Results: Among the 3841 patients included in this analysis [3165 (82.4%) survivors and 676 (17.6%) non-survivors], 1972 (51.3%) were admitted to the ICU and 1869 (48.7%) were admitted to the SDU. Compared to survivors, non-survivors were older [76 (64–87) yrs. vs. 67 (50–81) yrs; $p < 0.001$], had higher SAPS III score [64 (56–72) vs. 49 (40–57); $p < 0.001$] and longer hospital stay before unit admission [8 (3–19) days vs. 2 (1–7) days; $p < 0.001$]. Non-survivors used more non-invasive ventilation (42.2% vs. 20.9%; $p < 0.001$), mechanical ventilation (36.7% vs. 9.3%; $p < 0.001$), vasopressors (39.2% vs. 12.3%; $p < 0.001$), renal replacement therapy (15.5% vs. 4.3%; $p < 0.001$), and blood transfusion (34.9% vs. 14.0%; $p < 0.001$). Results of the multivariate analysis are shown in Table 1.

Table 1 (abstract 000513) Multivariate logistic regression analysis addressing risk factors for hospital mortality in patients admitted to the ICU or to SDU after rapid response team activation

Predictors	OR (CI 95%)	p-value
SAPS III score		
≤ 42	1.00 (Reference)	
43–50	1.81 (1.07–3.07)	0.027

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000519

Introduction: In septic shock, hypotension/hypoperfusion may arise from multiple causes: vasodilation, absolute and relative hypovolemia, septic myocardial dysfunction, and microcirculatory dysfunction [1]. The severity of peripheral vasodilation is of particular interest because it impacts the need and timing of vasopressors introduction during treatment. Recently, Ospina-Tascón et al. [2] proposed the use of a new marker of vasodilation severity—the Diastolic Shock Index (DSI). The DSI is the ratio between heart rate (HR) and diastolic arterial pressure (DAP) and is suggested to represent the impact of DAP (mainly determined by vascular tone) on vasodilation, while reflecting the severity of circulatory dysfunction by accounting for HR. They postulated that higher DSI values were associated with higher mortality and that its identification during initial assessment could signal patients prone to benefit from early vasopressors initiation through shock resuscitation. A previous work from our group confirmed the prognostic value of DSI in septic shock patients (median DSI = 2.3 in non-survivors) [3].
Objectives: To test the impact on hospital mortality of using DSI as a trigger to early vasopressor initiation in septic shock patients.
Methods: We designed a target trial using the Medical Information Mart for Intensive Care IV (MIMIC IV) v0.4 database [4, 5]. Adult patients (≥ 18 years-old) with septic shock (according to the SEPSIS-3 definition [6]) at intensive care unit (ICU) admission were selected. DSI was calculated as HR/DAP obtained upon initiation of fluid resuscitation. Patients with DSI ≥ 2.3 (indicating a worse prognosis) were included for analysis and assigned to early (≤ 1 h after first fluid bolus) or late (> 1 h) vasopressor initiation groups. Propensity score matching (corrected variables: age, sex, lactate, SOFA and SAPS II scores) was used to evaluate the impact of early vs. late vasopressor initiation on hospital mortality in this septic shock population with high DSI.
Results: We studied 165 patients admitted for septic shock with DSI ≥ 2.3. Fifty-one percent were males, median age was 66 years (Interquartile Range [IQR]: 54–78) and the hospital mortality during the studied admission was 69%. At the first 24 h of ICU stay, the mean SAPS-II score was 56 ± 17 and the median SOFA score was 8 (IQR: 5–11). The mean DSI at enrolment was 2.6 (IQR: 2.4–2.9). After propensity score matching, early vasopressor group was associated with lower hospital mortality (odds ratio [OR] 0.85; 95% confidence interval [95% CI]: 0.77–0.95; $p = 0.004$).
Conclusions: Our findings reinforce the utility of DSI, not only as mortality predictor, but also as a trigger to early vasopressor initiation in septic shock patients. Its potential benefit on hospital mortality by highlighting vasopressor therapy urgency merits further research.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000520

Introduction: A higher incidence of blood stream infections (BSIs) has been reported among COVID-19 critically ill patients. Two frequently documented pathogens that often cause prolonged ICU stay or even death in these patients are Enterococcus and Candida.
Objectives: We aimed to compare characteristics of patients with candidemia and enterococcal BSI to those of patients who were not affected.
Methods: We included patients admitted to the ICU department from April 2021 to April 2023. Including patients with positive blood cultures (Enterococcus or Candida species), we extracted the following data: sex, age, APACHE score, ICU stay duration, outcome (death or ICU discharge), blood culture results, and vaccination status. We used SPSS Statistics for the analysis. Statistical significance was set at p = 0.05.
Results: We included 308 patients (mean age = 66.94 years, SD = 13.34) out of whom 201 (65%) were male and 177 were not vaccinated (57%). Thirty-three patients (11%) developed candidemia and 64 patients (21%) developed enterococcal BSI. In 13 patients both BSIs were reported, in different timepoints. In 7 of them, candidemia occurred prior to enterococcal BSI. For all patients, the mean ICU stay was 13.62 days (SD = 17.96), and mean APACHE score was 20.89 (SD = 9.68). Both BSIs were associated with longer ICU stay (Table 1).

Patients afflicted with candidemia during their stay presented an increased likelihood of developing enterococcal BSI (OR = 2.73, Confidence Interval—CI: 1.27, 5.84, p = 0.008). Neither BSI increased the likelihood of death (p = 0.18 for Candida and p = 0.14 for Enterococcus). *Enterococcus faecium* bacteremia increased the likelihood of death significantly (OR = 2.71, CI: 1.25, 5.89, p = 0.01). Unvaccinated patients showed an increased likelihood of developing enterococcal BSI (OR = 1.83, CI: 1.02, 3.26, p = 0.04).

Table 1 (abstract 000520) Age, ICU stay and APACHE score for different groups of COVID-19 patients (*is for parametrical data)

	Patients with candidemia (N = 33)				Patients without candidemia (N = 275)				p
	Median	IQR	Mean	SD	Median	IQR	Mean	SD	
Age (years)	67	59 73	65.82*	11.03	69	59 77	67.08	13.61	0.35
ICU stay (days)	17	9 35	28.48	32.91	8	2 16	11.77	14.14	**< 0.001**
APACHE score	22	17.5 28	22.45*	8.07	20	13 27.5	20.55	9.99	0.22

	Patients with enterococcal BSI (N = 64)					Patients without enterococcal BSI (N = 244)					
Age (years)	69	62 77	66.76*	13.57		68	59 77	67.61	12.54		0.79
ICU stay (days)	20	12 37	28.94	28.12		7	2 13	9.42	10.69		**< 0.001**
APACHE score	21	16.3 25	20.56*	6.54		20	13 28	20.97	10.33		0.78

	Patients who died in the ICU (N = 148)					Patients discharged from the ICU (N = 160)					
Age (years)	71	62 77	68.89*	11.31		66.5	56.5 77	65.01*	14.87		**0.02**
ICU stay (days)	9	5 20	14.11	15.76		7	2 16	13.15	19.92		**0.02**
APACHE score	24.5	20 32	25.71	8.47		15	10 21	16.12	8.38		**< 0.001**

Conclusions: Candidemia and enterococcal BSI both prolong ICU stay but do not increase the likelihood of death in the ICU for COVID-19 patients. Candidemia COVID-19 patients developed enterococcal BSI more often than COVID-19 patients without candidemia.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000521

Introduction: Cognitive and consciousness impairments have been associated with reduced electroencephalographic gamma power spectrum density (PSD) [1, 2]. Deep sedation associated with invasive mechanical ventilation (MV) has been associated with cognitive impairment and delirium in ICU survivors [3, 4].

Objectives: This study investigated whether diaphragm neurostimulation in synchrony with MV would result in changes in gamma PSD in critically ill patients receiving MV.

Methods: Five deeply sedated ICU patients undergoing MV for moderate ARDS were included in this study. A central-line catheter embedded with electrodes was inserted via the left subclavian vein to stimulate the phrenic nerves bilaterally, in synchrony with MV. The study protocol was comprised of two hours with no diaphragm neurostimulation (unpaced sessions), and two hours with diaphragm neurostimulation during inspiration on every breath (paced sessions). All ventilator settings and administered medications remained unchanged during the study. A 32-channel electroencephalogram was used to collect brainwave activity during the study. Data from the frontal, temporal and parietal lobes, only, were collected. Four occipital channels were not used. PSD for the gamma frequency band was calculated as mV2/Hz. Wilcoxon paired test was used for linear analysis between the sessions. Data are reported as median (interquartile range). P-values < 0.05 were considered statistically significant.

Results: A significantly greater gamma PSD was observed bilaterally in the medium prefrontal cortex, insula, posterior cingulate gyrus, and angular gyrus during paced sessions compared to unpaced sessions (eight out of 28 channels). Average gamma PSD during the paced and unpaced sessions were, respectively: medial prefrontal cortex (left) 0.10 mV2/Hz (0.04–0.70) vs. 0.03 mV2/Hz (0.00–0.06), p = 0.0312; medial prefrontal cortex (right) 0.10 mV2/Hz (0.05–0.70) vs. 0.02 mV2/Hz (0.01–0.05), p = 0.0312; posterior cingulate cortex 0.07 mV2/Hz (0.01–0.74) vs. 0.02 mV2/Hz (0.00–0.04), p = 0.0312; insula (left) 0.20 mV2/Hz (0.10–0.75) vs. 0.03 mV2/Hz (0.00–0.05), p = 0.0312, insula (right) 0.11 mV2/Hz (0.05–0.78) vs. 0.04 mV2/Hz (0.00–0.06), p = 0.0312; angular gyrus (left) 0.07 mV2/Hz (0.01–0.21) vs. 0.02 mV2/Hz (0.00–0.03), p = 0.0312; and angular gyrus (right) 0.07 mV2/Hz (0.01–0.70) vs. 0.03 mV2/Hz (0.00–0.03), p = 0.0312 (see Figure). No statistical difference in gamma PSD was observed between sessions, in the remaining 20 channels.

Conclusions: Diaphragm neurostimulation was associated with a greater gamma PSD bilaterally in the medial prefrontal cortex, the insula and the angular gyrus, and the posterior cingulate gyrus. The clinical effects of these changes warrant further studies.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000523

Introduction: Dynamic indicators derived from arterial pressure waveforms, such as stroke volume variation (SVV) and pulse pressure variation (PPV), have been used to assess fluid responsiveness (FR) in mechanically ventilated patients with septic shock. Aging is associated with an increase in the stiffness of the large arteries, resulting in the reduction of arterial compliance, which may increase pulse pressure and amplitude. Still, the stroke volume variation (SVV) does not change. Loss of arterial elasticity in elderly patients might affect PPV and SVV accuracy and its threshold value to predict FR. Several studies reported dynamic arterial elastance (Eadyn; PPV/SVV), which has been proposed to assess functional arterial load. Eadyn can predict arterial pressure response [mean arterial pressure (MAP) responder] after a fluid challenge in the fluid responder patient. The predictive accuracy of PPV, SVV, and Eadyn has never been evaluated in elderly patients with septic shock.
Objectives: To assess the ability of the SVV and PPV to predict FR in mechanically ventilated elderly patients with septic shock. The secondary outcome was to test the ability of the Eadyn to predict an increase in MAP following volume expansion in preload-responsive elderly patients.
Methods: A prospective observational study was conducted on elderly patients with septic shock at Ramathibodi Hospital. We enrolled mechanically ventilated patients with ages > 65 years diagnosed with septic shock. The patients with limitations of PPV and SVV interpretation were excluded. SVV, PPV, Eadyn, and other hemodynamic data were recorded before and after the FR test**.** Positive FR is defined as cardiac output (CO) increase of 10% or more, assessed using the Vigileo™ or EV1000 after a passive leg raise test (PLR), mini-fluid challenge test, or fluid challenge. In patients with positive FR, SVV, PPV, Eadyn, and other hemodynamics were recorded before and after the fluid bolus**.** MAP responsiveness was described as a raised MAP of at least 10% after fluid loading.
Results: Of 104 elderly patients, 46 (44.2%) were classified as positive fluid responsiveness (defined by a CO increase of 10% or more after PLR, mini-fluid challenge test, or fluid challenge). The mean age was 78 ± 7 years. PPV and SVV were significantly higher in patients with positive FR than those without FR (22.07 ± 11.02 vs. 9.34 ± 7.39; $P < 0.001$ and 20 ± 11 vs. 9 ± 6; $P < 0.001$, respectively). The area under the PPV and SVV ROC curves was 0.875 (95% CI 0.802–0.947) and 0.841 (95% CI 0.757–0.925), respectively (Fig 1). The optimal threshold values for discrimination between FR and non-FR were 13.5% for PPV (sensitivity 81.8%, specificity 87.0%) and 11.5% for SVV (sensitivity 81.8%, specificity 87.0%). Among 46 patients who were positive for FR, 28 patients were MAP responders. Baseline Eadyn was higher in the MAP-responder group than in the MAP non-responder group (1.40 ± 0.57 vs. 0.98 ± 0.93 $P = 0.013$). The area under the Eadyn ROC curve was 0.844 (95% CI 0.704–0.894). The threshold value of Eadyn to predicting MAP-responder was 1.00 (sensitivity 85.7% and specificity 75%).
Conclusions: Despite the increased arterial stiffness in the elderly, PPV and SVV can predict fluid responsiveness in elderly patients with septic shock who underwent mechanical ventilation. Eadyn can predict MAP responsiveness in elderly patients.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000524

Introduction: Respiratory tract infections (RTIs) represent a frequent cause for emergency department (ED) visits. The clinical trajectory of RTI can range from rapid recovery to severe respiratory and multiorgan impairment requiring ICU admission. Timely risk stratification is a critical component for the identification of patients at high risk for further deterioration requiring ICU care, since delayed ICU admission has been associated with worse outcomes.
Objectives: From 2020 to 2021, we conducted a biomarker study on patients presenting to the ED with respiratory symptoms. The present analysis aims to investigate the impact of deferred ICU admission on clinical outcomes and explore the potential utility of longitudinal Interleukin-6 (IL-6) measurements for early identification of patients requiring ICU care.
Methods: Patients presenting with symptoms of respiratory illness to the ED of the University Health Network (Toronto, CA) were enrolled. Individuals requiring inpatient management were categorized into three groups based on their ICU admission status: direct ICU admission from the ED, secondary transfer to the ICU after admission to the ward or discharge at home, and no ICU admission. The primary outcome was mortality at 28 days. As prognostic marker for ICU requirement, plasma IL-6 levels were measured on day 1, 2, 3, 5, and 7 after enrollment by immunoassay. In addition to descriptive statistics, we compared the discriminative ability of IL-6 for the prediction of ICU admission using ROC-curves.
Results: Of the 310 patients enrolled in the study, 168 required inpatient management, with 17 admitted to the ICU (11 directly and 6 secondary). Median age was 61 years; 12% had a community-acquired pneumonia, and 10% manifested signs of COVID-19 pneumonia, with no significant inter-group differences.
Patients with secondary ICU admission showed a higher mortality rate compared to directly admitted patients (4/6 vs. 1/11, $p = 0.03$, Figure 1A). Plasma IL-6 levels at enrollment could discriminate for the risk of mechanical ventilation ($p < 0.01$) and mortality ($p < 0.05$) but failed to stratify for the overall requirement of ICU admission ($p = 0.52$). Distinct longitudinal trajectories of plasma IL-6 levels were found for each of the 3 admission groups (Figure 1B). Higher IL-6 concentrations at day 1, 2, 3 and 7 were measured among patients with secondary admission compared to individuals not requiring ICU ($p < 0.05$). In patients not immediately admitted to ICU, IL-6 measurements at day 2 showed a higher discriminative ability for the prediction of secondary ICU admission (AUC 0.92; cut-off value 209.3 pg/ml, Sen 1, Spe 0.92) compared to day 1 (AUC 0.73; cut-off value 22.9 pg/ml, Sen 1, Spe 0.47).
Conclusions: These findings demonstrate an association of deferred ICU admission with poor outcomes in patients with respiratory symptoms. Sequential measurements of IL-6 might be useful for stratification and early identification of patients at risk of further deterioration requiring transfer to an ICU facility.

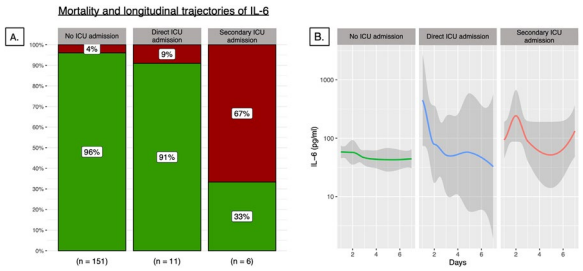

Figure 1 (abstract 000524) **A** Percentage of survivors (green) and non-survivors (red) at 28 days. Patients with secondary transfer to ICU had a higher 28-day mortality compared to directly admitted patients ($p = 0.03$). **B** Longitudinal trajectories of plasma IL-6 levels in patients who were not admitted to ICU (green line), directly admitted to ICU (blue line), and those who were secondary transferred to ICU after admission to the ward or discharge at home (orange line)

Change of pulse pressure variation during reverse tidal volume challenge predicts fluid responsiveness in high risk surgical patients

S. Tetcharoenpanit[1], S. Morakul[1], W. Mongkolpun
[1]Anesthesiology, Ramathibodi Hospital, Mahidol University, Bangkok, Thailand

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000525

Introduction: Volume expansion (VE) is applied during the perioperative period to restore blood pressure. However, excessive fluid balance is related to worse outcomes. A prediction of fluid responsiveness (FR) should therefore be performed before starting VE in order to optimize the fluid balance. A change in pulse pressure variation (PPV) during the recruitment maneuver (RM) is commonly used on surgical patients during the perioperative period, but the hemodynamic status might be deteriorated during RM.
Objectives: We aimed to evaluate whether a change of PPV from a transient reduction of tidal volume [reverse tidal volume challenge (rTVC)] can predict FR.
Methods: Patients who were scheduled for elective high risk abdominal surgery under general anesthesia using mechanical ventilation with an arterial catheter were included. After the induction of anesthesia, the tidal volume (VT) was set to 8 ml/kg for 5 min, and then rTVC was performed by decreasing VT from 8 to 6 ml/kg for 1 min. Hemodynamic variables, PPV were obtained before and immediately after rTVC was conducted. VE (250 ml, normal saline) was infused for 10 min. CI was measured by pulse contour analysis (HemoSphere®, Edwards). A positive FR (+veFR) was defined by the function of CI $\geq$ 10%. Changes to PPV during rTVC (ΔPPV) were calculated as absolute values. Receiver operating characteristic curves were constructed and reported as areas under the curve (AUC) to predict +veFR.
Results: Fifty measurements were performed on 29 patients. Of these, 17 of the 50 assessments (34%) were +veFR. The mean age was 60 ± 12 years old, while 17/29 patients (58.6%) underwent liver surgery and 15/29 (51.7%) were ASA III. There were no differences in procedures or baseline hemodynamic variables, except PPV, between patients with +veFR and those with negative FR (-veFR) (Table 1). Only PPV decreased during rTVC in patients with +veFR (Table 2) and ΔPPV was greater in patients with +veFR than in the group (4 ± 2 vs 2 ± 1,

p < 0.05, respoectively). ΔPPV (AUC 0.84 [0.73–0.95]) and baseline PPV (AUC 0.82 [0.71–0.93] had the highest AUC for predicting +veFR with cut off values of ≥ 3.5 (sensitivity (Sn) 59%, specificity (Sp) 91%) and ≥ 12 (Sn 82%, Sp73%), respectively (Figure 1).

Table 1 (abstract 000525) Baseline hemodynamic variables between patients with +veFR and −veFR

Hemodynamic variables	+veFR (n = 17)	−veFR (n = 33)	*p*-value
Pulse pressure variation (%)	15 ± 4	9 ± 5	< 0.01
Stroke volume variation (%)	14 ± 3	10 ± 4	< 0.01
Pleth variability index (%)	16 ± 4	10 ± 5	< 0.01
Stroke volume (mL)	70 ± 12	83 ± 26	0.1
Cardiac index (L/min/m^2)	3.0 ± 0.7	3.3 ± 1.1	0.2
Mean arterial pressure (mmHg)	76 ± 15	76 ± 11	0.9
Heart rate (bpm)	73 ± 15	67 ± 16	0.2

Table 2 (abstract 000525) Hemodynamic changes after reverse tidal volume challenge in +veFR and −veFR (*p < 0.05 Before vs After rTVC)

Hemodynamic variables	Before rTVC (Vt 8 ml/kg)	After rTVC (Vt 6 ml/kg)
Pulse pressure variation (%)		
+veFR	**15 ± 4**	10 ± 4*
−veFR	**9 ± 5**	7 ± 2
Mean arterial pressure (mmHg)		
+veFR	**75 ± 15**	76 ± 11
−veFR	**76 ± 10**	76 ± 10

Conclusions: ΔPPV during rTVC and baseline PPV can predict FR in high-risk surgical patients during perioperative period.

Frailty and outcomes among older critically ill patients with acute respiratory distress syndrome

S. Meng[1], Z. Jin[1], L. Wang[1], F. Guo[1]
[1]Jiangsu Provincial Key Laboratory of Critical Care Medicine, Department of Critical Care Medicine, Zhongda Hospital, School of Medicine, Southeast University, Nanjing, Jiangsu, China
Correspondence: S. S. Meng
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000529

Introduction: Acute respiratory distress syndrome (ARDS) is a common disease in intensive care unit. Frailty, as a new prognostic indicator to describe the pre-hospital status, has received more and more attention in older patients with critically illness. However, it has not been elucidated whether or not frailty is associated with outcome of older patients with ARDS.
Methods: This was a retrospective cohort study conducted in the intensive care unit of a tertiary hospital. Aged 65 or older critically ill patients with ARDS were included and we accessed the clinical frailty scale (CFS) score before admission of these patients retrospectively. CFS score ≥ 5 was considered frailty. The outcome of this study was 28-day mortality.
Results: A total of 281 patients were included in the final analysis and 59.8% (168) of them were frail according to CFS (≥ 5). Frail patients had higher risk of 28-day mortality compared to those not frail (Hazard Ratio [HR] 2.94, 95% Confidence Interval [CI] 1.53–5.66, $p = 0.001$). 28.1% (n = 79) of all patients died within 28 days and the incidence of frailty was higher in death group than that of survivor group (82.0% vs 53.6%, $p = 0.000$). In multivariable cox regression, frailty was an independent risk factor for 28-day mortality in older patients with ARDS (HR 2.1422, 95% CI 1.247–3.676), $P = 0.006$).
Conclusions: In older patients with ARDS, the presence of frailty increased hazard ratio of 28-day mortality. The findings of this study implicated the importance of risk stratification of older patients with ARDS by clinical frailty before critical illness.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000532

Introduction: The severe pressure ulcers (PUs) can worsen the patient's condition or require surgical treatment, which can increase the patient's medical expenses and increase the workload of medical staff in the intensive care unit (ICU) [1, 2].
Objectives: There are various evaluation tools for PU grade such as Braden score, Norton scale and Waterlow scale [3, 4]. These are widely used as important tools for assessing PU grade, but they have the disadvantage of being subjective and some factors are difficult to

understand [5]. Therefore, we developed an artificial intelligence (AI) model that can monitor the patient's condition in real-time to predict the occurrence of PUs and inform the medical staff.

Methods: In this study, patients with recoded for PUs occurrence in the nursing recodes and granted for PU grade were extracted from MIMIC-IV data [6]. Patients who had already occurred PUs before admission to the ICU were excluded from this study. Furthermore, we used almost variables that were used in previous studies related to pressure ulcers, as shown in Figure 1. We developed various machine learning (ML) models and deep learning (DL) models using multivariate time series data to develop predictive models, but we found that the performance of the model is degraded for missing values in the data. To overcome this problem, the multivariate time-series in real-data has missing values, and various models have been developed to solve this problem, including the GRU-D model. However, the GRU-D model also cannot handle such missing last observation value. So we developed the GRU-D++ model based on the GRU-D model to overcome this problem.

Results: As shown in Table 1, the logistic regression model and GRU-D++ model showed high performance among ML models and DL models. In the case of GRU-D++ model, AUROC was 0.941 at the PU occurrence time, and the AUROC was 0.910 at the 48 h before the occurrence of PU.

Table 1 (abstract 000532) Performance comparison of various AI models

	tzb*0 h		tzb12 h		tzb24 h		tzb48 h	
	AUROC	AUPRC	AUROC	AUPRC	AUROC	AUPRC	AUROC	AUPRC

Decision tree	0.572	0.138	0.576	0.147	0.573	0.151	0.57	0.163
Random forest	0.821	0.393	0.818	0.400	0.814	0.404	0.808	0.413
XGBoost	0.813	0.382	0.809	0.390	0.804	0.392	0.799	0.406
RNN	0.867	0.496	0.856	0.478	0.860	0.505	0.853	0.516
GRU	0.913	0.619	0.905	0.612	0.899	0.616	0.878	0.593
LSTM	0.910	0.589	0.902	0.595	0.895	0.583	0.876	0.577
GRU-D	0.938	0.694	0.933	**0.688**	0.926	0.677	0.906	0.654
GRU-D++	**0.941**	**0.694**	**0.936**	0.687	**0.930**	**0.683**	**0.910**	**0.659**

tzb*: time-zero base

Conclusions: The AI-based PU prediction model developed in this study can be utilized to monitor the patient's condition in real-time and provide the medical staff with estimated timing of occurrence. Through this model, we can predict PU status in advance to improve patient's conditions and alleviate the workload of the medical staff in the ICU.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000536

Introduction: The aim of this study was to establish clinical characteristics of patients after acute ischemic stroke (AIS).

Objectives: Our acute ischemic stroke database consist of cause, subtype, treatment, etc. We investigate clinical characteristics of these patients.

Methods: In total, 972 consecutive patients with AIS were included from 2017 to 2022. We analyzed database after acute ischemic stroke from the database and medical records including neurosonology lab.

Results: Among the risk factors, hypertension was observed in 684 patients (70.4%), diabetes mellitus in 326 patients (33.5%), hyperlipidemia in 284 patients (29.2%), previous stroke history in 170 patients (17.5%), coronary heart disease in 72 patients (7.4%), atrial fibrillation in 169 patients (17.4%) and a history of smoking in 378 patients (38.9%). Regarding the types of stroke, ischemic stroke was observed in 886 patients (91.1%), AIS with hemorrhagic transformation was seen in 18 patients (1.9%) and transient ischemic attack in 68 patients (7.0%). By TOAST classification with neurosonology lab., large artery atherosclerosis was observed in 339 patients (34.9%), small vessel occlusion in 235 patients (24.2%), cardioembolism in 181 patients (18.6%), other determined causes in 25 patients (2.6%) and undetermined causes in 192 patients (19.7%). Mildly severe strokes were observed in 694 patients (71.4%), moderately severe strokes, in 174 patients (17.9%), and severe strokes in 104 patients (10.7%). Recanalization treatment was performed in 135 patients (13.9%), IV thrombolysis in 67.5%, endovascular treatment in 16%, and combined IV thrombolysis and endovascular treatment in 16.5%.

Conclusions: Our findings suggest that stroke mechanisms were similar to those reported by previous studies; however, the mechanism of large artery atherosclerosis seems more prevalent than in other studies. Only 13.9% patients underwent recanalization treatment, so a better system for treating patients with acute stroke seems necessary.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000538

Introduction: Due to the improvement of intensive care unit (ICU) care, the number of patients with difficulty to wean and requiring home mechanical ventilation (HMV) after critical illness is increasing in Korea, but the predictors of patients requiring palliative care due to the high risk of death and clinical manifestations are not well known.
Objectives: The clinical characteristics and the predictors of the long-term survival of patients requiring HMV were analyzed.
Methods: From January 1, 2017 to September 31, 2022, a retrospective analysis was performed on patients who were admitted to the ICU and who were difficult to wean and consecutively applied HMV after tracheostomy in Konyang university hospital, Daejeon, Korea. At least 6 months after application of HMV were followed up, and predictors of 90-day survivors were analyzed by comparing clinical characteristics, laboratory findings, and HMV application status.
Results: During the study period, 89 of 95 HMV patients were analyzed, and 31 patients (34.8%) survived to 90 days and 22 patients (24.7%) survived to 180 days. 90-day survivors had low Charlson comorbidity index ($p = 0.024$), ICU admission due to respiratory and cardiovascular cause and sepsis ($p = 0.032$), low CRP level on HMV ($p = 0.001$) comparing 90-day non-survivors (Tables 1, 2). There were no significant differences between the two groups in APACHE II score, body mass index, vasopressor use, pro-BNP level at ICU admission, serum albumin, creatinine, hemoglobin, lymphopenia, cause and tidal volume/predicted body weight of kg and mode of HMV on applying HMV (Tables 1, 2). In univariate analysis, 90-day survival was associated with young age, low Charlson comorbidity index, respiratory and cardiovascular cause and sepsis at ICU admission, and low CRP level on HMV, and in multivariate analysis, it was associated with low CRP level (Table 3).
Conclusions: In conclusions, 34.8% of patients survived more than 90 days and was associated with young age, low Charlson comorbidity index, respiratory and cardiovascular cause and sepsis at ICU admission, and low CRP level on HMV.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000539

Introduction: Sepsis-associated encephalopathy (SAE), which is independently associated with increased mortality, may be worsen by systemic causes of secondary brain injury (SSBI), that are frequently observed in ICU patients.
Objectives: We aimed to investigate the association between the presence of at least one SSBI within the first 48 h of intensive care unit (ICU) admission with outcomes of SAE patients.
Methods: We performed a retrospective analysis using data from the French OUTCOMEREA multicenter prospective database. We included consecutive patients without primary brain injury with SAE [defined by a score on the Glasgow coma scale ≤ 13 and severe sepsis or septic shock (SEPSIS 2.0 definition) criteria] requiring invasive mechanical ventilation at ICU admission. For each patient, we analyzed SSBI events (abnormal glycemia (< 3 mmol/L or ≥ 11 mmol/L), hypotension (DBP£50 mmHg), temperature abnormalities (< 36 °C or ≥ 38.3 °C), anemia (hematocrit $< 21\%$), dysnatremia (< 135 mmol/L or ≥ 145 mmol/L), oxygenation abnormalities, dyscapnia (< 35 mmHg or ≥ 45 mmHg) present within the first 48 h of ICU admission and the impact of their control at day-3 on day-28 mortality and neurological recovery.
Results: Of the 4799 septic patients, 995 patients with SAE were included. Compared to decedents at day-28, alive patients had significantly less SSBI within the first 48 h of ICU admission, including less hypoglycemia (< 3 mmol/L), less hypotension (DAP < 50 mmHg), less hypothermia (< 36 °C) and anemia (hematocrit $< 21\%$) within the first 48 h of ICU admission. After adjusting for diagnostic, comorbidities and SOFA score, the control of the following SSBI at day-3 was significantly associated with lower day-28 mortality for blood pressure (diastolic pressure > 50 mmHg: aHR = 1.77 [1.34–2.34], oxygenation (PaO_2 between 60 and 200 mmHg: aHR = 1.78 [1.2–2.63], $p = 0.02$), glycemia (glycemia between 3 and 11 mmol/L: aHR = 1.41 [1.1–1.8], $p = 0.01$), temperature (36 °C–38.3 °C: aHR = 1.46 [1.12–1.91], $p = 0.007$). Control of the SSBI at day-3 was significantly associated with a better day-28 neurological recovery.
Conclusions: The control of several SSBI (particularly oxygenation, arterial pressure, glycemia, temperature) within the 3 first days of ICU admission is associated with lower mortality and better neurological recovery in SAE patients.

Table (abstract 000539) Multivariate analyzes of the controle of SSBI at day-3 on mortality and neurological recovery at day-28

Variable	Outcomes					
	Day-28 Mortality			Day-28 Neurological Recovery		
SSBI at D3	aHR	[95% CI]	p	aOR	[95% CI]	p
Blood pressure (DBP>50mmHg)			**<.001**			**<.001**

SSBI: Systemic causes of secondary brain injury, aHR: adjusted hazard ratio

Each line represents a separate adjusted analysis, evaluating the association of different SSBI with outcomes (Day-28 mortality, Day-28 Neurological recovery)

The outcomes at Day-3 concerned the patients with an initial anormal SSBI within the first 48h of ICU admission

*aHRs are calculated with univariate Cox models censored at Day-28 after adjustment to the SOFA score without neurological component at ICU admission, the type of admission (medical versus other) and the existence of hepatic comorbidities

*aORs are calculated with logistic regression model after adjustment to the SOFA score without neurological component at ICU admission, the type of admission (medical versus other) and the existence of hepatic comorbidities. Day-28 Neurological Recovery defined as Glagow score (GCS) > 13 at Day-28

If the patient was discharged survivors before Day-28, the value of the GCS on the day of discharge is used

If patient died on Day-28, non-recovery of the GCS on Day-28 is considered

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000540

Introduction: Inflammation is an important mechanism of stroke. Inflammatory cells and cytokines largely contribute the pathophysiology of inflammatory arthritis.
Objectives: We evaluated the risk of stroke and compared the medical expenses between the patients of inflammatory arthritis and matched population, using data from National Health Insurance Service.
Methods: We defined the patients of ankylosing spondylitis, seropositive rheumatoid arthritis, and psoriatic arthritis and enteropathic spondyloarthropathy, using the combination of main diagnosis and V code of rare incurable diseases. Control group was defined by 1:5 propensity matching in each disease. Newly developed stroke was defined as the patients with the main diagnosis of (I60–64) and (1) brain imaging, or (2) prescription of stroke medication or related intervention.
Results: Seropositive rheumatoid arthritis was associated with more frequent stroke occurrence in the population of patient and control group of seropositive rheumatoid arthritis (Hazard ratio 1.11, 95% CI 1.02–1.20, p value = 0.012). Medical expenses in outpatient clinic, which is not related to stroke, was larger in all inflammatory arthritis with stroke. In-patient medical expenses related to stroke in seropositive rheumatoid arthritis patients, was larger than the control group, though statistically insignificant.
Conclusions: Seropositive rheumatoid arthritis was a predictor of the more frequent stroke occurrence. To decrease the comorbid stroke and following burden of social cost, the careful concern is needed for the early diagnosis and active management of inflammatory arthritis, especially seropositive rheumatoid arthritis. The underlying correlation between the inflammatory arthritis and the stroke needs further studies.

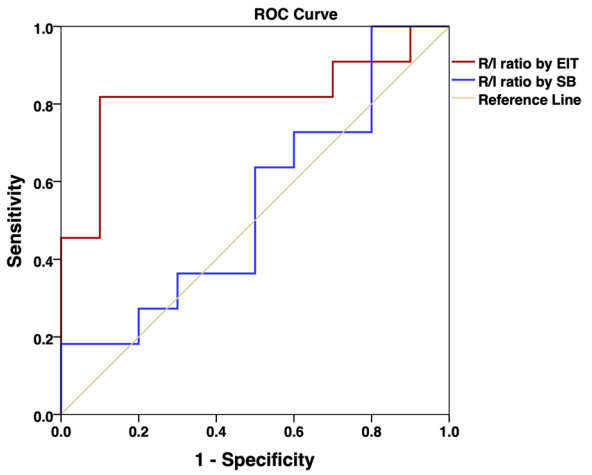
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000541

Introduction: Recently, the recruitment-to-inflation ratio (R/I ratio) from the single-breath (R/ISB) technique has been proposed for identifying lung recruitability in ARDS. This technique is modified from the end-expiratory lung volume (EELV) measurement principle of different positive end-expiratory pressure levels. Also, electrical impedance tomography (EIT) can estimate the delta EELV, providing the potential role of EIT in measuring the R/I ratio. However, a study comparing those techniques has not been conducted.
Objectives: We aimed to analyze the relationship between the R/ISB from exhaled tidal volume measurement and the R/I ratio from EIT-derived (R/IEIT) parameters. In addition, we analyzed the predictive performance of the R/I ratio regarding lung recruitability by the EIT technique.
Methods: The single-center prospective physiological study was conducted on moderate to severe ARDS. The R/ISB was initially performed. Simultaneously, the EIT data were recorded and followed by the recruitment maneuver (RM). Then, variables used to analyze the relationship were recruited volume (Vrec) by single-breath technique and EIT as well as R/I ratio by both methods. Regarding lung recruitability by EIT, we analyzed the average percentage change of gas distribution of dependent regions of interest (ROI) 3 and 4 during RM (difference of end of RM and before RM). We use the median value of the average percentage change in the ROI 3 and 4 for discriminating potential recruiters and non-recruiters.
Results: Twenty-one patients were enrolled. Eight patients (38%) were severe ARDS. The Vrec by EIT strongly correlated to the Vrec by single-breath technique (R = 0.680, P = 0.001). Similarly, a strong correlation was found between the R/ISB and the R/IEIT (R = 0.653, P = 0.001). Nevertheless, the Bland–Altman plot between Vrec by both techniques showed a mean difference of − 46.09 ml (with 1.96 SD of − 249.07 ml to 156.89 ml). The percentage of EIT-tidal impedance change at the dependent area during RM did not correlate with both

the R/ISB (R = 0.080, P = 0.732) and the R/IEIT (R = 0.191, P = 0.407). The median value in the average percentage change in the ROI 3 and 4 was 11.5% which was determined as the threshold value for discriminating potential recruiters and non-recruiters.
The area under the ROC curve was analyzed to determine the predictive performance of the R/I ratio from both methods. The R/IEIT showed the AUC of ROC of 0.818 (P = 0.014), while the R/ISB showed 0.545 (P = 0.725). The threshold value of R/IEIT to discriminate potential recruitability was 0.89, providing sensitivity and specificity of 81.8% and 90%, respectively.
Conclusions: The R/IEIT was strongly correlated with the R/ISB. The R/IEIT showed better predictive performance regarding lung recruitability than R/ISB.



The ROC analysis of the R/I ratio by EIT and the R/I ratio by single-breath method to predict lung recruitability.

Introduction: Apoptosis has recently been identified as an important mechanism of septic cell death. Efficient apoptosis requires the upregulation of key pro-apoptotic regulators, such as initiator or executioner caspases, Bax/Bak protein, and Smac (second mitochondria-derived activator of caspases). The pro-apoptotic regulators lead to outer membrane permeabilization and inhibit the antiapoptotic action of the survivin protein and the X-linked inhibitor of apoptosis protein (XIAP) on executioner caspases (1). The apoptotic and antiapoptotic interactions seem to orchestrate the septic processes and their fragile balance defines cell survival.
Objectives: The purpose of the study is to evaluate whether the induction of certain apoptotic (executioner caspase-3, initiator of the extrinsic pathway caspase-8, or of the intrinsic pathway caspase-9, Bax/Bak, and Smac) or antiapoptotic proteins (survivin, XIAP) might be related to mortality in sepsis.
Methods: The study sample of this prospective single-center study consists of adult and pediatric ICU patients with sepsis (S), compared to non-infectious inflammation (I) and healthy controls (H). Consecutive serum samples were collected on the 1st day of ICU admission. The expression of serum apoptotic and antiapoptotic biomolecules was determined through enzyme-linked immunosorbent assay (ELISA).
Results: Out of 82 patients enrolled in the study, 26 were adults (9 S, 9 I, and 8 H) and 56 children (31 S, 18 I, and 7 H). Caspase-8 was correlated with Bax/Bak ($r_s = 0.257$, $p = 0.03$), while XIAP was positively correlated with Smac ($r_s = 0.463$, $p = 0.001$) and ne caspase-9 ($r_s = -0.525$, $p = 0.021$). In adult sepsis, caspase-3 ($p = 0.005$) and survivin ($p < 0.001$) were increased and Bax/Bak decreased ($p = 0.02$) compared to controls; caspase-9 was increased in pediatric sepsis ($p = 0.017$). Among septic non-survivors, increasing trends were demonstrated for caspases 9 and 3, Smac, XIAP, and survivin and decreasing for caspase-8 and Bax/Bak (adults only, $p < 0.001$). In all ICU groups (S and I), Smac and XIAP were induced and Bax/Bak repressed among non-survivors, compared to survivors (Fig. 1).
Conclusions: Our results show that the orchestration of certain apoptotic and anti-apoptotic mediators might be linked to sepsis and to unfavorable outcome in ICU.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000545

Introduction: Mechanical ventilation (MV) is commonly needed in poor-grade subarachnoid hemorrhage (SAH) patients. Especially these patients commonly suffer from a lung injury, which may affect oxygen delivery to the brain.
Objectives: In this study, we aimed to investigate the association between lung injury and brain tissue hypoxia after SAH.
Methods: In this observational study, 72 consecutive SAH patients on MV with brain tissue oxygen tension ($PbtO_2$) monitoring (Fig 1) admitted between 2011 and 2021 to the Neurocritical Care Unit (NICU) at Innsbruck Medical University Hospital were included. Various determinants as $PbtO_2$, cerebral perfusion pressure (CPP), PaO_2, pCO_2, and FiO_2 were collected whenever available. Lung injury was defined based on the degree of hypoxemia using Horowitz Index (PaO_2/FiO_2 Ratio, mmHg): mild (> 200–300 mmHg), moderate (> 100–200 mmHg), and severe (≤ 100 mmHg) [1]. Generalized estimating equations were used to analyze the longitudinal data.
Results: Patients had a median Glasgow Coma Scale of 3 [IQR 3–9] and were 59 years old [IQR 47–67]. A total of 6966 data points were analyzed. The median PaO_2 was within the normal range 94 mmHg [IQR 84–104] and normocapnia was observed with a median pCO_2 of 40 mmHg [IQR 37–43]. The median Horowitz index during the hospital course was 231 mmHg [IQR 183–293] and brain tissue oxygen tension ($PbtO_2$) was 27 mmHg [IQR 20–33]. Mild lung injury was observed in 43.9%, moderate in 32.3%, and severe in 0.9% of measurements. The decrease in Horowitz index was observed between 3 and 10 days after bleeding, with the lowest HI 214 mmHg [IQR 88–588] on day 7 (Fig 2). There was no independent association between PaO_2/FiO_2 ratio and $PbtO_2$ ($p = 0.074$). Determinants for improved $PbtO_2$ were pO_2, pCO_2, inspired FiO_2, and cerebral perfusion pressure even adjusting for confounding factors of age and the Hunt & Hess scale.
Conclusions: Lung injury is common in patients with subarachnoid hemorrhage. Our results confirm the hypothesis that employing ventilator strategies and optimizing cerebral perfusion pressure is needed to prevent cerebral hypoxia independent of the degree of lung injury.

Introduction: *Streptococcus pneumoniae* (SPNE) and *Pseudomonas aeruginosa* (PA) are frequent causes of pneumonia. Patients with advanced lung disease commonly develop hypercapnia.
Objectives: This project aims to evaluate the bacterial survival and biological response of the co-culture of alveolar epithelial cells (HPAEpiC) and macrophages as a result of infection with different types of bacteria (PA and SPNE) under different CO_2 concentrations.
Methods: Co-cultures of HPAEpiC cells and THP-1 cells differentiated to macrophages were separately infected with PA or SPNE for 1 h at 37 °C under normocapnic (5% CO_2) or hypercapnic (15% CO_2) conditions. Extracellular and intracellular bacterial survival was then assessed after infection.
24 h after infection, at 5% or 15% CO_2, intracellular and extracellular proteins were analyzed by ELISA for inflammatory mediators (IL-1β, IL-8, CCL-2). Cell binding ZO-1 protein was measured 1 and 24 h after infection. Apoptosis was also assessed by cytometry and TUNEL assay.
Results: Infection with PA or SPNE in a culture of HPAEpiC and THP-1 cells under hypercapnia increases inflammation and decreases phagocyte chemotaxis (Figure 1A, B). Hypercapnia would potentiate ZO-1

production in the co-culture after infection but not 24 h later, showing SPNE infection the poorest regeneration levels (Figure 1C). In addition, PA-infected THP-1 cells show decreased apoptosis under hypercapnia compared to normocapnia conditions (Figure D, E).
The inflammatory response against PA eliminates most of the extracellular bacterial load, but hypercapnia allows PA to multiply intracellularly (Figure 1F, H). On the other hand, cell cultures achieve to eliminate 50–60% of the initial SPN inoculum, which could establish intracellular niches under 5% and 15% CO_2 (Figure 1G, I).
Conclusions: The hypercapnic condition on bacterial-infection response could play a detrimental role in PA and SPN infection.

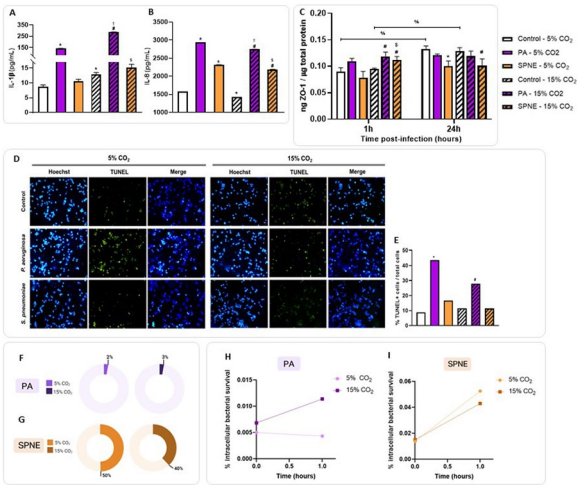

Figure 1 (abstract 000550) Biological response of HPAEpiC and THP-1 cells after infection at 5% and 15% of CO_2. (**A**, **B**) Protein concentration in cell culture supernatant of proinflammatory IL-1β (A) and chemoattractant IL-8 (B) mediators 24 hours post-infection with PA or SPNE of the HPAEpiC and THP-1 cells co-culture under 5% or 15% of CO_2. (**C**) ZO-1 protein concentration in total intracellular protein 1 and 24 hours post-infection with PA or SPNE of the HPAEpiC and THP-1 cells co-culture under 5% or 15% of CO_2. (**D**, **E**) Apoptosis was assessed in THP-1 cell cultures infected with PA or SPNE 24 hours post-infection. Analysis was done through fluorescence microscopy, TUNEL* cells were then quantified among total cells. (**F**, **G**) Extracellular bacterial survival of PA and SPNE immediately at the end of infection compared to the initial inoculum administrated. (**H**, **I**) Intracellular bacterial survival of PA and SPNE in HPAEpiC and THP-1 cell co-culture immediately at the end of infection and 1 hour after compared to the initial inoculum administered. n = 4 in bacterial survival assays, n = 9–12 in protein analysis and n = 2 in TUNEL assay. Data represented as mean ± SEM. *$p \leq 0.05$ vs control—5% CO_2. #$p \leq 0.05$ vs control—15% CO_2. †$p \leq 0.05$ vs PA—5% CO_2. $$$p \leq 0.05$ vs SPNE—5% CO_2. %$p \leq 0.05$ vs same experimental group at 1 h. Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000551

Introduction: Critical patients have high global morbidity and mortality rates. Some studies have used SEA-MAKE score to predict major adverse kidney events, but there is few data about it's validity as a predictor for mortality in UCI patients. This score can be used at point of care and may be a good predictive marker for mortality in critically ill patients.
Objectives: Main purpose of this study was to identify if SEA-MAKE score is a good predictor for mortality in patients admitted in intensive care unit (ICU).
Methods: This is a single-center, retrospective, observational study, that was conducted in ICU patients admitted at Gregorio Marañon hospital, between February–March 2023. Exclusion criteria were chronic kidney disease (CKD) and age < 18 years. SEA-MAKE score was calculated at admission in ICU, wich included following parameters: Glasgow coma scale (3 points), tachypnea (1 point), vasopressor use (1 point), invasive mechanical ventilation (IMV) (2 points), oliguria defined as output urinary < 0,5 ml/kg/h (2 points), serum creatinine rising > 3 times (5 points), Blood urea nitrogen (BUN) > 40 mg/dl (3 points), hematocrit < 30% (2 points) and trombocytopenia < 150 10E3/µL (1 point).
Additionally, the following data was collected: age, reason for admission, Charlson index, need for IMV, vasopressor requirements and outcome. Severity of illness at admission was established by Acute Physiology and Chronic Health disease Classification System II (APACHE II) score and Sepsis related Organ Failure Assessment (SOFA).
Categorical data was presented as percentages. Continuous data was expressed as mean and standard deviation (SD), or median with interquartile range (IQR) for continuous variables. Capacity of SEA-MAKE score to predict ICU mortality was stablished using the area under the receiver operating characteristic curve (AUROC). Estimation of calibration was established through Hosmer–Lemeshow goodness of fit test. To evaluate extent to which SEA-MAKE score was valid for prediction ICU mortality, sensitivity (S), specificity (E), overall validity of prediction, positive and negative predictive values (PPV, NPV) were determined.
Results: Seventy patients were included. Mean age was 58 ± 17 years and 50% were male. Most common reason for admission was sepsis (37.1%). Median Charlson index 1 (IQR 0–2). 42.9% patients required IMV, with a median 4 days (IQR 1–7), and 55.7% patients needed vasopressors. Median SEA MAKE 3 (IQR 1–6). Mean admission severity score by APACHE II 14 ± 7 and SOFA 5 ± 4. Median ICU stay was 5 days (IQR 3–9) and 8.7% mortality.
In univariate analysis we found that SEA-MAKE score determined at ICU admission was significantly higher in no survivors (10 ± 6) than in survivors patients (4 ± 3) ($p < 0.01$).
According AUROC curves, SEA-MAKE score had an adequate capacity for discriminating (AUC 0.83, 95% CI: 0.65–1) and a good calibration ability (Chi-squared test 5.5 $p = 0.590$) to predict mortality in ICU patients. A cut-off of 5 was the best value for predicting mortality: sensitivity 83% and specificity 76%, with positive predictive value (PPV) 25% and negative predictive value (NPV) 98%. (Figure 1).
Conclusions: In our experience SEA-MAKE score applied at admission in ICU patients, may be a good predictor for mortality.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000552

Introduction: Acute kidney injury (AKI) is a common complication in the Intensive Care Unit (ICU). According to studies, AKI affects 30–60% of critically ill patients. Renal Resistive Index (RRI) has shown promise in early detection of AKI in ICU patients.
Objectives: The aim of this study was to identify if RRI, measured within 24 h from admission, is a independent prognostic factor for AKI in critically ill patients.
Methods: This is an observational, prospective study performed in ICU patients admitted at Gregorio Marañon Hospital (Madrid, Spain), between February–March 2023. Exclusion criteria were chronic kidney disease (CKD), age < 18 years and bad echographic window. RRI was obtained within 24 h of admission in ICU, this was measured by one of four operators who had at least one year's clinical experience in RRI method. Both kidneys were examinated, measurements were made at two sites on each kidney in an interlobular or arcuate artery. From the pole RRI values, a mean RRI was computed.
The following data was collected for each patient at the time of RRI measurement and after 72h of admission: age, reason for admission, cardiovascular risk factors, need for invasive mechanical ventilation (IMV), vasopressor requirements, use of nephrotoxic drugs. Severity of illness was graded by means of APACHE II score. Urea, creatinine and BUN values, also glomerular filtration rate was calculated using EPI-CKD equation. For AKI diagnosis and classification, we used KDIGO criteria.
Descriptive statistics were expressed as mean ± SD, or median with interquartile range for continuous variables and percentages for categorical data. In univariate analysis, RRI means were compared by Student T test. Association between IRR and AKI was estimated by multiple logistic regression analysis, adjusted by confusional factors.
Results: seventy patients were included. Mean age was 58 ± 17 years and 50% were male. 44.3% had arterial hypertension and 25.7% mellitus diabetes. Mean admission severity score APACHE II 14 ± 7 points. 42.9% patients required IMV and 55.7% vasopressors. 41.4% patients were diagnosed AKI within 24 h ICU stay. After 72 h of admission 27.1% had AKI: 47.3% KDIGO-1, 5.2% KDIGO-2, 47.3% KDIGO-3 and 10% required continuous renal replacement therapy (CRRT).
In univariate analysis we found that RRI values measured within 24h of admission were significantly lower in patients without AKI (0,69 ± 0,06) than in those with AKI (0,78 ± 0,07) ($p < 0.01$). There was no difference in RRI between patients classified as KDIGO 1 (0,76 ± 0,06) ($p = 0.28$) compared to KDIGO 2, but RRI was higher in those with KDIGO 3 (0,82 ± 0,08) ($p < 0.01$) and patients with CRRT ($p < 0.01$). We confirmed that RRI values were associated with a significant increased risk of AKI: OR 7.7; 95% CI 2.5–23.9.
In Multivariable logistic regression analysis, which included main risk factors that could influence to development for AKI at ICU admission: age, arterial hypertension, Mellitus diabetes, APACHE II, IMV, vasopressors and nephrotoxic drugs, RRI was independently associated with AKI: OR 1.2; 95% IC 1.1–1.4. (Table 1).
Conclusions: In our experience RRI measured within 24 h of admission was an independent prognostic factor for AKI in critically ill patients.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000553

Introduction: Oxygen therapy with high-flow nasal cannulas (HFNC) is an increasingly used treatment (1). An important aspect of HFNC is the patient's comfort, which mostly depends on the set temperature and flow (2, 3), however the optimum initial humidification temperature setting has not been defined yet.
Objectives: To understand whether there is a difference in comfort among three approaches to target humidification temperature of 37 °C with HFNC in patients hospitalized in intensive care unit (ICU). The secondary aim is to assess the patient's dryness and perceived humidity of the nose.
Methods: This is a single-center pragmatic randomized trial (ClinicalTrials.gov Identifier: NCT05688189). Adult patients who need HFNC and able to express consent to study procedures were enrolled and randomly assigned to one of the following approaches: the 37 °C arm (A), in which patients started HFNC immediately at 37 °C; the 34–37 °C arm (B) with a starting temperature at 34 °C raised after 15 min at 37 °C; and the 31–34–37 °C arm (C) with temperature initially set at 31 °C, and then raised to 34 °C and 37 °C every 15 min. The HFNC treatment was delivered by AIRVO TM 2 (Fisher & Paykel Healthcare). After 30 min at 37 °C, patients were asked to indicate their comfort, dryness and humidity level, using a 1 to 5 visual numerical scale. Data are presented as median (I–III quartile).
Results: We enrolled 21 patients (15 males, 71.4%), aged 62.1 (53.4–76.5) years old; BMI was 25.7 (22.2–30.7); 19 (90.5%) presented with extra pulmonary respiratory failure after surgery, SOFA score was 2 (2–3). The FiO_2 varied from 30 to 65% and the flow from 35 to 60 l/min. The level of comfort was 3 (2–5), 4 (2–4) and 2 (1–5) in arms A, B and C, respectively (P = 0.6925). Nasal dryness (P = 0.0587) and humidity (P = 0.5878) did not show evidence of statistical difference among arms either.
Conclusions: After 30 min of HFNC therapy at target temperature of 37 °C, overall comfort was alike among study arms, regardless of the initial temperature setting.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000554

Introduction: Sepsis is a condition characterized by high morbidity and mortality which is commonly encountered in an emergency and critical care setting. Despite a substantial body of research, the ideal biomarker for the diagnosis and prognostic stratification of septic patients remains unknown.
Objectives: To asses the trend of sepsis biomarkers (CRP, PCT, Interleukin-6, Presepsin).
Methods: Since August 2022 up to March 2023 we collected in patients developing severe infection (i) comorbidities, SAPS II and SOFA at the admission (ii) mechanical ventilation (MV) and vasoactive drugs duration, ICU and hospital outcome; (iii) type of infection, antibiotic therapy; (iv) daily CRP, PCT, IL-6 and Presepsin trend. Differences for both quantitative and categorical variables assessed respectively by ANOVA test and X2 tests. Linear Regression (LR) and Bland Altman (BAp) plots were used for comparison among biomarkers. A $p < 0.05$ was considered for statistical significance.
Results: 50 patients (65% males) for 1150 biomarker determinations, were recruited with a median (IQR) (i) age 73 (64–82), 1st 24 h SAPS II of 55 (35–62) and SOFA score 8 (6–10), ICU LOS 7 (6–15), MV duration 6 (5–8) days. Recorded ICU mortality was 21.6%; 1150 biomarker values on onset sepsis day were for survived patients: CRP 142 (101–334) mg/ml, PCT 3.5 (2.5–8.1) (p = n.s.); IL-6 185 (100–470) (p = n.s.); Presepsin 2100 (950–3500) (p = n.s.), whereas in dead ones CRP 139 (101–334) mg/ml (p = n.s.), PCT 1.5 (1–4.1) ng/ml (p = n.s.); IL-6 115 (99–270) (p = n.s.) ng/ml; Presepsin 2800 (1250–5400) ng/ml (p = n.s.). On antibiotic stopping day biomarkers values were significantly decreased in survivors: CRP 42 (15–105) mg/ml (p = 0.03), PCT 0.2 (0.1–0.7) ng/ml (p = 0.025); IL-6 32 (16–78) ng/ml (p = 0.012); Presepsin 485 (250–740) ng/ml (p = 0.014); whereas in dead ones remained higher CRP 126 (111–364) mg/ml (p = n.s.), PCT 1.4 (1.2–4.1) ng/ml (p = n.s.); IL-6 105 (68–170) (p = n.s.) ng/ml; Presepsin 1830 (999–5485) ng/ml (p = n.s.). LR showed a proportional trend but with a low value of association: Presepsin/PCT (R2 = 0.55), Presepsin/IL-6 (R2 = 0.61). BAp showed the highest agreement between Presepsin and IL-6, but not between PCT/Presepsin both in survived and dead patients.
Conclusions: PCT, IL-6, and Presepsin showed a dichotomous trend in relation with patient outcome; we documented (i) by LR a low correlation among tested biomarkers (ii) the highest agreement between Presepsin/IL-6 by BAp in terms of sepsis measurement.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000555

Introduction: Acute kidney injury (AKI) is a common condition in patients admitted in Intensive care unit (ICU), it has great importance due to significant morbidity and mortality. Early diagnosis and adequate intervention could improve survival in these patients. Renal Resistive index (RRI) could be an especially helpful tool for early detection of AKI.
Objectives: The aim of this study was to identify if RRI measured within 24 h from admission in ICU, is an early predictor for AKI.
Methods: This is an observational, prospective study in ICU patients admitted at Gregorio Marañon Hospital (Madrid, Spain), between February–March 2023. Exclusion criteria were chronic kidney disease (CKD), age < 18 years and bad echographic window. RRI was obtained within 24 h of admission in ICU and was measured by one of four operators who had at least one year's clinical experience in RRI method. Both kidneys were examined, measurements were made at two sites on each kidney in an interlobular or arcuate artery. From the pole RRI values, a mean RRI was computed.
The following data was collected for each patient at time of RRI measurement and after 72h of admission: age, reason for admission, cardiovascular risk factors, need for invasive mechanical ventilation (IMV), vasopressor requirements, use of nephrotoxic drugs, urea, creatinine and BUN values, also glomerular filtration rate was calculated using EPI-CKD equation. Severity of illness was graded using the Acute Physiology and Chronic Health disease Classification System II (APACHE II) score. For AKI diagnosis and classification, we used KDIGO criteria.
Descriptive statistics were expressed as mean ± SD, or median with interquartile range (IQR) for continuous variables and percentages for categorical data. The ability of RRI to discriminate AKI was assessed using area under the receiver operating characteristic curve (AUROC). Estimation of their calibration was established through the Hosmer–Lemeshow goodness of fit test. To evaluate the extent to which the RRI was valid for prediction AKI, sensitivity (S), specificity (E), overall validity of prediction, positive and negative predictive values (PPV, NPV) were determined.
Results: Seventy patients were included. Mean age was 58 ± 17 years and 50% were male. 44.3% had arterial hypertension and 25.7% mellitus diabetes. Mean admission severity score APACHE II 14 ± 7. 42.9% patients required IMV and 55.7% vasopressors. 41.4% patients were diagnosed AKI within 24 h ICU stay while 27.1% after 72 h of admission. 10% required continuous renal replacement therapy (CRRT).
In univariate analysis we found that RRI values measured within 24h of admission were significantly lower in patients without AKI (0,69 ± 0,06) than in those with AKI (0,78 ± 0,07) ($p < 0.01$).
In AU-ROC curves analysis, RRI had a good capacity for discriminating (AUC 0.85, 95% CI: 0.74–0.95) and a good calibration ability (Chi-squared test 8.03 $p = 0.43$) to predict AKI after 72 h of ICU admission. Best RRI value was 0.73 to diagnostic accuracy in predicting AKI: sensitivity 74%, specificity 80%, positive predictive value (PPV) 64% and negative predictive value (NPV) 87%. (Figure 1).
Conclusions: In our experience RRI measured within 24 h of admission in ICU, could be an early predictor for AKI in critically ill patients.

Correspondence: K. Daenen
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000556

Introduction: Identification of illness severity in COVID-19 patients in the intensive care unit (ICU) is of critical importance. Analysis of host gene expression is a promising tool to prognosticate outcomes in these patients. The 29 host mRNA Inflammatix Severity-3b (IMX-SEV-3b) classifier has been reported to predict disease severity in emergency department and surgical ICU patients. The accuracy of IMX-SEV-3b to predict illness severity in COVID-19 patients admitted to the ICU is unknown.
Objectives: The goal of this study was to investigate the accuracy of IMX-SEV-3b to predict ICU-mortality compared to routinely measured biomarkers and APACHE-IV score.
Methods: A prospective observational cohort study enrolled COVID-19 patients admitted to the ICU of a tertiary hospital in Rotterdam, Netherlands. IMX-SEV-3b scores were generated by amplifying 29 host response genes from blood collected in PAXgene® Blood RNA tubes. A severity score was provided ranging from 0 to 1 and fall into one of five interpretation bands (very low, low, moderate, high and very high). The primary outcome was the accuracy of prediction of

ICU-mortality using IMX-SEV-3b. Results were compared to the predictive value of C-reactive protein (CRP), lactate dehydrogenase (LDH), and the APACHE-IV score.

Results: A total of 53 patients were included between March 1, 2020 and April 30, 2020, of which 18 (34%) died during ICU stay. Age, sex and BMI did not differ significantly between survivors and non-survivors. The performance of IMX-SEV-3b is shown in Table 1. IMX-SEV-3b scores were significantly associated with mortality with an unadjusted odds ratio of 204.63 (1.85–44,630.68); mean IMX-SEV-3b score was 0.57 in survivors versus 0.65 in non-survivors ($p = 0.05$, univariate regression analysis). The AUC of IMX-SEV-3b for prediction of ICU mortality was 0.65 (95% CI: 0.48–0.82) compared to an AUC of 0.86 (95% CI: 0.74–0.98) for APACHE-IV. The biomarkers CRP and LDH were not significantly associated with mortality (Table 2). In multivariate regression analysis, IMX-SEV-3b remained a predictor of mortality when adjusting for age, sex and BMI, whereas CRP and LDH did not.

Table 1 (abstract 000556) Performance of IMX-SEV-3b on ICU mortality

IMX-SEV-3b severity score		Survival status		IMX-SEV-3b performance per band			
		Survivor	Non-survivor	% Patients in band	Sensitivity	Specificity	Likelihood ratio
IMX-SEV-3b category	Very high bacterial	0	4	8%	22%	100%	Inf
	High bacterial	2	0	4%	0%	94%	0.00
	Moderate bacterial	9	6	28%	33%	74%	1.30
	Low bacterial	23	8	58%	56%	66%	0.68
	Very low bacterial	1	0	2%	100%	3%	0.00

Table 2 (abstract 000556) Univariate analysis of IMX-SEV-3b, CRP, LDH and Apache-IV

Test/biomarker/clinical score	Odds ratio (95% CI)	AUC (95% CI)
CRP	1.0 (0.99–1.0)	0.52 (0.34–0.70)
LDH	1.0 (1.0–1.01)	0.56 (0.37–0.74)
IMX-SEV-3b	204.63 (1.85–44,630.68)	0.65 (0.48–0.82)
APACHE-IV	130.77 (3.93–13,126.55)	0.86 (0.74–0.98)

Conclusions: IMX-SEV-3b was significantly associated with mortality in COVID-19 patients in the ICU. Further prospective studies are required to determine the accuracy of IMX-SEV-3b for prediction of mortality and its value for patient management.

Table 1 (abstract 000556) Performance of IMX-SEV-3b on ICU mortality

IMX-SEV-3b Severity Score		Survival status		IMX-SEV-3b performance Per Band			
		Survivor	Non-survivor	% Patients in Band	Sensitivity	Specificity	Likelihood Ratio
IMX-SEV-3b category	Very High Bacterial	0	4	8%	22%	100%	Inf.
	High Bacterial	2	0	4%	0%	94%	0.00
	Moderate Bacterial	9	6	28%	33%	74%	1.30

Renal Resistive Index as an independent prognostic factor for mortality in critically ill patients

G. Castañeda[1], N. Cango[1], C. Alvarez[1], A. Blanco[1], P. García Olivares[1], J. Cedeño Mora[1], J. C. Barrios[1]
[1]Intensive Care Unit, H.G.U Gregorio Marañón, Madrid, Spain
Correspondence: N. Cango
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000557

Introduction: There are many scoring systems to predict the likelihood of hospital mortality for patients admitted to intensive care unit (ICU). Over the last few years, the use of ultrasonography has become widely extended in ICU clinical practice, so it would be useful to know an echographic tool to predict mortality that can be used at the patient's bedside. Renal Resistive Index (RRI) could be used to predict mortality.

Objectives: The aim of this study was to identify if RRI, measured within 24 h from admission, is an independent prognostic factor for mortality in critically ill patients.

Methods: This is an observational, prospective study performed in ICU patients admitted at Gregorio Marañon Hospital (Madrid, Spain), between February–March 2023. Exclusion criteria were chronic kidney disease (CKD), age < 18 years and bad echographic window. RRI was obtained within 24 h of admission in ICU, this was measured by one of four operators who had at least one year's clinical experience with the RRI method. Both kidneys were examinated, measurements were made at two sites on each kidney in an interlobular or arcuate artery. From the pole RRI values, a mean RRI was computed.

The following data was collected for each patient: age, Charlson index, reason for admission, need for invasive mechanical ventilation (IMV), vasopressor requirements, development of acute kidney injury and outcome. Severity of illness was graded by APACHE II and SOFA scores. Descriptive statistics were expressed as mean ± SD, or median with interquartile range for continuous variables and percentages for categorical data. In univariate analysis mean IRR was compared using Student T test. Association between IRR and mortality was estimated by multiple logistic regression analysis, adjusted by confusional factors.

Results: Seventy patients were included. Mean age was 58 ± 17 years and 50% were male. Most common reason for admission was sepsis (37.1%). Median Charlson index 1 (IQR 0–2). Mean admission severity

score by APACHE II 14 ± 7 points and mean SOFA within 24 h 5 ± 4 points. 42.9% patients required IMV, median 4 days (IQR 1–7), and 55.7% needed vasopressors. Median ICU stay was 5 days (IQR 3–9) and 8.7% mortality.
In univariate analysis we found that RRI values were significantly higher in nonsurvivors (0,82 ± 0,07) than in survivors patients (0,70 ± 0,07) ($p < 0.01$). We confirmed that RRI measured in first 24h of ICU admission was a prognostic factor for ICU mortality (OR 1.21; 95% CI 1.07–1.37).
Multivariable logistic regression analysis included age, reason for admission, Charlson index, APACHE II, use IMV, vasopressors requirement and need for continuous renal replacement therapy, RRI was independently associated with mortality in critically ill patients: OR 1.69; 95% IC 1.04–2.74. (Table 1).
Conclusions: In our experience RRI measured within 24 h of admission in ICU, was an independent prognostic factor of death in critically ill patients.

Association between coagulation markers and acute kidney injury following cardiopulmonary bypass in younger children
S. Minami[1], T. Abe[1], H. Nagafuchi[2], I. Takeuchi[1]
[1]Emergency and Critical Care Medicine, Yokohama City University Medical Center, Yokohama, Japan; [2]Critical Care Medicine, Kanagawa Children's Medical Center, Yokohama, Japan

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000564

Introduction: Acute kidney injury (AKI) following cardiopulmonary bypass (CPB) is a common complication in both adults and children. Reportedly, endothelial damage of renal capillaries is involved in the development of AKI (1). Vascular endothelial damage activates the coagulation cascade (2), but no previous studies have examined the association between coagulopathy after CPB and the onset of AKI, especially among younger children.
Objectives: To investigate whether early postoperative coagulation-fibrinolysis markers are risk factors for the onset of AKI after surgeries using CPB in younger children.
Methods: This single-center retrospective cohort study included infants and toddlers who underwent cardiovascular surgery with CPB and were admitted to the pediatric intensive care unit (PICU) between August 1, 2020, and December 31, 2021. The outcome of the study was to assess the presence or absence of AKI onset. We collected data on coagulation-fibrinolysis markers, age in months, sex, weight, and AKI risk factors (single ventricular disease, pulmonary hypertension, risk adjustment in congenital heart surgery system (RACHS) -1 score ≥ 3, use of vasopressin, and cardiopulmonary bypass time) and compared those variables based on the AKI status. Subsequently, we performed multiple logistic regression analysis to evaluate coagulation-fibrinolysis markers as a factor controlling other variables.
Results: We enrolled 154 participants, of whom 55 (35%) developed AKI. Univariate analysis showed significant differences for thrombin-antithrombin complex (TAT) level ($p = 0.046$), fibrinogen level ($p = 0.007$), platelet level ($p = 0.008$), Plasminogen Activator Inhibitor-1 (PAI-1) level ($p = 0.023$), vasopressin use ($p = 0.006$), and CPB time ($p = 0.004$). However, in the multivariable analysis, only CPB time was significant. Although coagulation markers were significantly elevated in the AKI group, fibrinolytic markers were only mildly elevated in both the AKI and non-AKI groups, with no statistical significance.
Conclusions: The increase in coagulation markers in the early postoperative period following CPB was associated with the onset of AKI. Coagulation markers were elevated but fibrinolytic markers were not, suggesting that activation of the coagulation cascade due to vascular endothelial damage may be involved in the development of AKI. However, because this study was conducted at a single center with a limited number of patients, a further multicenter prospective study is needed to validate these findings.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000567

Introduction: Lung transplantation is a definitive treatment for end-stage lung disease, and the number of patients on the waitlist is increasing each year. Unfortunately, survival rates for lung transplantation are often lower than those for other solid organ transplants, with a 5-year survival rate of less than 60%. This is due to various recipient characteristics, such as age, frailty at the time of transplantation, and organ-specific complications. Prolonged postoperative mechanical ventilation (MV) leads to a longer stay in the intensive care unit (ICU) and ICU-acquired weakness. In this study, we assess the risk factors for prolonged MV in lung transplantation patients.

Methods: We collected electronic medical records of lung transplantation patients in Severance Hospital, a tertiary hospital in South Korea, from January 2016 to December 2020. We collected clinical information about pre- and post-lung transplantation. Prolonged mechanical ventilation was defined as the ventilator day over 7 days. We analyzed the risk factors for prolonged mechanical ventilation (MV) and intensive care unit (ICU) stay using logistic regression.
Results: A total of 224 cases of lung transplantation was conducted during the study period. After excluding re-transplantation (n = 5) and immediate postoperative death (n = 43), we analyzed 176 cases of lung transplantation. Patients with prolonged MV were younger, less male-dominant, and showed a higher ratio of connective tissue disease-associated interstitial lung disease. Preoperative mechanical ventilation (adjusted OR = 2.72, 95% CI [1.21–6.13]) and postoperative primary graft dysfunction within 72 h (adjusted OR = 14.6, 95% CI [4.00–53.57]) were associated with prolonged MV. Only waiting time was associated with 2-year mortality (adjusted OR = 1.002, 95% CI [1.00–1.004]).
Conclusions: In this study, preoperative mechanical ventilation was identified as important risk factors for prolonged postoperative mechanical ventilation. Additionally, postoperative primary graft dysfunction was also associated with prolonged postoperative mechanical ventilation. Prolonged waiting time was associated long term survival, but prolonged mechanical ventilation was not.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000568

Introduction: Cardiopulmonary bypass (CPB) during cardiac surgery has been associated with hemolysis that results in increased plasma hemoglobin and consequent nitric oxide depletion [1]. This may translate into worsened pulmonary hemodynamics after CPB. We hypothesized that CPB-related hemolysis is associated with lower pulmonary artery capacitance and worse right ventricular systolic function.
Methods: Patients undergoing cardiac surgery with CPB at Massachusetts General Hospital, Boston, USA, between June 2014 and March 2015 were prospectively included. Plasma nitric oxide consumption was assessed after CPB, at 15 min, 4 and 12 h. Pulmonary artery capacitance (stroke volume-to-pulmonary artery pulse pressure ratio), and right ventricular function index (right ventricular end systolic pressure-to-cardiac output ratio)—a surrogate of right ventricular systolic function [2]—were measured at 15 min, 4 and 12 h after CPB by a pulmonary artery catheter. Mixed-effects models for repeated measures and post-hoc multiple comparisons with Dunnett's correction were applied. We also evaluated the correlation among changes in nitric oxide consumption and hemodynamic parameters between 15 min and 4 h after CPB by the Pearson correlation coefficient.
Results: Forty patients (26% female, median [IQR] age 66 [57 to 75] years, median [IQR] body mass index 29.1 [26.6 to 33.0] kg/m^2) were included in this preliminary subanalysis. Pulmonary artery capacitance was the lowest immediately after the end of CPB and gradually increased over time (Fig 1A). Similarly, the right ventricular function index was the highest 15 min after the end of CPB (i.e., worst right ventricular systolic function) and decreased at the subsequent time points (Fig. 1B). The improvement of these hemodynamic parameters paralleled the decrease in nitric oxide consumption over the same time points (Fig. 1C). The nitric oxide consumption reduction between 15 min and 4 h after CPB significantly correlated with the improvement in pulmonary artery capacitance ($r = 0.46$, $p = 0.002$) and right ventricular function index ($r = -0.79$, $p < 0.001$).
Conclusions: In this study, patients undergoing CPB showed a gradual increase of pulmonary artery capacitance and a gradual decrease of right ventricular function index since 15 min until 12 h follow-up. The change in nitric oxide consumption—a robust biomarker of intravascular hemolysis—was significantly correlated with the change in pulmonary artery capacitance and right ventricular function index between 15 min and 4 h after CPB.

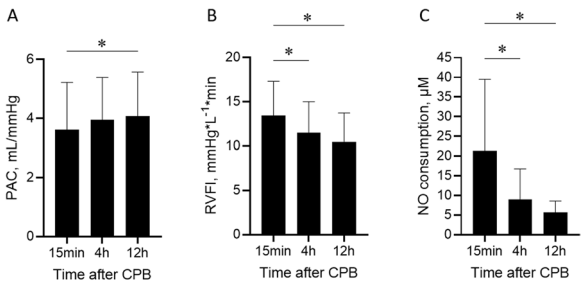

Figure 1 (abstract 000568) Hemodynamics and hemolysis parameters at 15 min, 4 h, and 12 h after cardiopulmonary bypass (CPB). A) Pulmonary artery capacitance (PAC) over time. B) Right ventricular function index (RVFI) over time. The higher the RVFI, the worse the right ventricular systolic function. C) Concentrations of plasma NO consumption over time. *$p < 0.05$. Data are presented as mean ± SD

The immune-mediated ferroptosis in acute lung injury/acute respiratory distress syndrome

A. Ma[1], L. Yang[1], W. Qin[1], Y. Jing[1], K. Yan[1]
[1]Department of Critical Care Medicine, West China Hospital of Sichuan University, Chengdu, Sichuan Province, China, Chengdu, China

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000569

Introduction: Acute lung injury/acute respiratory distress syndrome (ALI/ARDS) is one of the most life-threatening diseases in the intensive care unit, with high mortality and morbidity [1–3]. Ferroptosis is a newly discovered immune-related cell death that is associated with various lung diseases [4–6]. However, the role of immune-mediated ferroptosis in ALI/ARDS has not been elucidated.
Objectives: To investigate the interactions between lung immune cell infiltration and ferroptosis and to explore the underlying mechanisms by which characteristic ferroptosis-related genes are regulated by immune cells in ALI/ARDS.
Methods: We analyzed two Gene Expression Omnibus (GEO) datasets (GSE2411 and GSE109913) and extracted characteristic ferroptosis-related genes (FRGs) between the control and ALI groups through bioinformatic analysis. We prospectively collected BALF from patients with ARDS and verified the expression of characteristic FRGs. We constructed the ALI/ARDS model induced by LPS and isolated the primary neutrophils of mice. Erastin, an inducer of ferroptosis, was used at the cellular level to verify the effect of neutrophils on ferroptosis in lung epithelium cells. We used electron microscopy to observe mitochondrial ultrastructural changes associated with ferroptosis, the JC-1 assay to observe changes in mitochondrial membrane potential, quantitative real-time PCR, Elisa, immunofluorescence (IF), and western blot (WB) to detect gene and protein changes in tissues and cells.
Results: We identified three characteristic FRGs, Cp, Slc39a14 and Slc7a11, by analyzing two gene expression profiling datasets. Immune infiltration analysis showed that the three characteristic genes were significantly positively correlated with the infiltration levels of neutrophils. We collected BALF from 59 ARDS patients to verify the expression of Cp, Slc7a11 and Slc39a14 in humans (Figure 1). The results showed that Cp was elevated in patients with severe ARDS, Slc7a11 was significantly elevated in patients with moderate ARDS ($p = 0.0205$) relative to patients with mild ARDS. The levels of neutrophils in the peripheral blood of ARDS patients were positively correlated with the expression levels of Slc7a11 (Pearson's R2 = 0086, $p = 0.033$). Three characteristic FRGs were significantly activated after the onset of ferroptosis (6 h) early in LPS induced ALI model, and that ferroptosis was alleviated after the organism compensated within 12 to 48 h (Figure 2). The immunofluorescence staining suggested that the recruitment of activated neutrophils from the periphery to the lung after injury appears to be associated with an upregulation of Slc7a11. We extracted primary activated neutrophils from mice and co-cultured them with MLE-12 in transwell, Slc7a11, Cp and Slc39a14 in MLE-12 cells were significantly upregulated as the number of neutrophils increased (Figure 3). The results showed that neutrophil infiltration alleviated erastin-induced MDA accumulation, GSH depletion, and divalent iron accumulation, accompanied by upregulation of Slc7a11 and Gpx4, implying the existence of a compensatory effect of lipid oxidation in neutrophils after acute lung injury in the organism.
Conclusions: We identified three immune-mediated ferroptosis genes, namely, Cp, Slc7a11 and Slc39a14, which possibly regulated by neutrophils during the development of ALI, and their pathways may be involved in anti-oxidative stress and anti-lipid metabolism. Thus, the present study contributes to the understanding of ALI/ARDS and provide novel targets for future immunotherapeutic.

Sedentary behaviour and physical inactivity in individuals following critical illness: a prospective observational study

S. M. Parry[1], S. Abo[1], L. Denehy[1], A. Da Silva[2], P. Morris[3], C. Granger[1]
[1]Physiotherapy, The University of Melbourne, Carlton, Australia; [2]Physiotherapy, The Royal Melbourne Hospital, Parkville, Australia; [3]Critical Care, University of Alabama at Birmingham, Birmingham, United States of America

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000570

Introduction: Impairments in physical functioning and muscle strength are well recognised sequelae of critical illness. No studies have examined sedentary behaviour post discharge with limited evaluation of physical activity levels (largely < 3 months with small sample sizes).
Objectives: (1) Describe the physical activity and sedentary behaviour patterns over the first 12 months after hospital discharge in a cohort of ICU survivors; and (2) determine the relationship between physical activity and sedentary behaviour with a range of functional and patient report outcomes at 3 months.
Methods: Design/setting: Nested prospective observational study with serial data collection at hospital discharge, 3-, 6-, and 12-months post hospital discharge.
Participants: ICU survivors ventilated more than 48 h and in ICU at least four days and completed physical activity evaluation across at least two follow-up timepoints.
Outcome measures: Physical activity was assessed both objectively using Garmin VivoFit 2 device (triaxial accelerometer—steps per day over seven days) and subjectively using self-report questionnaire (International Physical Activity Questionnaire short form). Participants' levels of PA were compared with the recommended WHO Physical Activity Guidelines. Sedentary behaviour was assessed using the Sedentary Behaviour questionnaire from which average sedentary time (hours/day) was determined. Other measures included: quadriceps strength, physical function (Short Physical Performance Battery—SPPB), balance (Mini-BESTest), Clinical Frailty Scale, health related quality of life (EQ-5D-5L), fear of falls (measured by Falls Efficacy Scale International) and risk of falls (measured by Falls Risk for older people in the Community Screening Tool).
Results: 87 participants were included. 69% were male with mean age of 59.4 ± 16.1 years, mean APACHE II score of 21.2 ± 7.5, and ICU LOS of 8 days [5.0–15.0]. Physical activity levels were low across the 12 month follow up period with median daily steps per day of 4405 [2279–7036] at 3 months; 4316 [2777–7505] at 6 months and 5372 [3277–7447] at 12 months. Participants spent little to no time completing moderate to vigorous physical activity across the 12 month period (3 months: 0 [0–20]; 6 months: 0 [0–60] mins; and 12 months: 0 [0–60]. Participants had persistent high self-reported sedentary time across the 12 months (3 months: 7.5 ± 3.0 h/day; 6 months: 7.9 ± 3.3; 12 months: 8.2 ± 4.1) with increasing rates of sedentary behavior by 12 months (3 months: 48% classified as sedentary vs 12 months: 65%). The majority of participants (84–87% across the 12 months) did not meet the international PA guidelines of at least 150 min of moderate to vigorous activity per week. There was a fair correlation between higher steps per day at 3 months as measured by Garmin Vivofit2 with higher fatigue levels ($r = 0.493$, $p < 0.001$), quadriceps muscle strength ($r = 0.440$, $p < 0.001$) and quality of life ($r = 0.455$, $p < 0.001$). A moderate correlation existed between higher steps per day at 3 months with better physical functioning ($r = 0.598$, $p < 0.001$), and balance ($r = 0.562$, $p < 0.0001$). Higher steps per day at 3 months was associated with lower levels of depression ($r = -0.509$, $p < 0.001$) and lower concern for falls ($r = -0.509$, $p < 0.001$), lower falls risk ($r = -0.516$, $p < 0.001$) and lower frailty score at 3 months ($r = -0.587$, $p = 0.001$). Participants with higher PA levels at 3 months had lower severity of illness, lower ICU-acquired weakness incidence and less comorbidities ($p < 0.05$).
Conclusions: Survivors of critical illness demonstrate persistent low levels of activity and high sedentary behaviour 12 months after hospital discharge and the majority do not meet international recommendations regarding physical activity. Modifiable factors exist which need to be targeted in post hospital discharge rehabilitation trials.

Determinants of extracorporeal carbon dioxide removal rate in extracorporeal CO_2 removal integrated within a continuous renal replacement circuit

Z. Qian[1], S. Liu[1], L. Liu[1]
[1]Department of Critical Care Medicine, Zhongda Hospital Southeast University, Nanjing, China
Correspondence: Z. Qian
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000571

Introduction: Extracorporeal carbon dioxide removal (ECCO2R) can be integrated into standard continuous renal replacement therapy (CRRT) circuits (ECCO2R-CRRT), providing both CO_2 removal and hemofiltration/dialysis when there is concomitant acute kidney injury [1]. High CO_2 removal rate is critical for clinical practice. In the SUPERNOVA trial, compared with lower one, higher CO_2 extraction device are most likely to benefit from lung-protection of ECCO2R [2]. In a recent study, the CO_2 removal rate of the ECCO2R combined continuous veno-venous hemofiltration (CVVH) was about 5% lower than the elimination rate of the membrane lung alone [3]. However, the influence of CRRT to the CO_2 removal rate of entire extracorporeal circuits (VCO2EC) is unclear.
Objectives: For a higher CO_2 removal rate, how to choose the CRRT mode and substitution fluid in ECCO2R combined CRRT remain unanswered. In this large animal experiment, we plan to investigate the effect of different bicarbonate hemofiltration or dialysate on the CO_2 removal of entire extracorporeal circuit during CVVH and continuous veno-venous dialysate (CVVHD).
Methods: The study was approved by the Animal ethical Committee of Southeast University in China (ethical approval number: 20210901045). The experiments were performed in 12 domestic pigs (50–60 kg). The animals were generally anesthetized and connected to ECCO2R-CRRT devices, which was the combination of ECCO2R (OMNIset®, surface area 1.81 m^2, polymethylpentene membrane, filling volume 187 mL; BBraun, Germany), and the additional blood purification device, a hemoperfusion filter (OMNIfilter®, surface area 1.6 m^2, polymethylpentene membrane, filling volume 94 mL; BBraun, Germany), and its circuit. The membrane lung was inserted serially in the extracorporeal circuit upstream to the hemofilter [4]. VCO2EC was measured under different combinations of ECCO2R alone, ECCO2R + CVVH, and ECCO2R + CVVHD. Each setting was conducted at different combinations of $PaCO_2$ (50–69, and 70–89 mmHg), extracorporeal blood flow (200, and 350 mL/min), and bicarbonate substitution fluid and dialysate (25, and 16 mmol/L) with the same rate of 30 ml kg^{-1} h^{-1} and zero net fluid loss. (Fig 1). The sweep gas flow was constantly set to 10 L/min with a fraction of delivered oxygen at 1.0. VCO2EC was calculated as the difference of total CO_2 content before membrane lung and after hemofilter, and normalized to an inlet PCO_2 of 45 mmHg [5, 6].
Results: Baseline characteristics of the studied animals were comparable within each mild or severe hypercapnia. At extracorporeal blood flow of 200 mL/min and bicarbonate substitution fluid and dialysate of 25 mmol/L, VCO2EC was reduced in ECCO2R + CVVH (49.5 ± 7.1 vs 54.3 ± 7.5 mL/min, $p < 0.05$), and ECCO2R + CVVHD (50.9 ± 6.7 vs 54.3 ± 7.5 mL/min, $p < 0.05$) compared with ECCO2R alone. But with

bicarbonate substitution fluid and dialysate of 16 mmol/L, no significative effect on VCO2EC of CVVH and CVVHD was found (54.5 ± 7.1 vs 56.2 ± 9.7 vs 54.4 ± 8.4 mL/min; $p = 0.3$) (Fig 2). At extracorporeal blood flow of 350 mL/min and bicarbonate hemofiltration and dialysate fluid of 25 and 16 mmol/L, VCO2EC were unchanged in ECCO2R + CVVH and ECCO2R + CVVHD compared with ECCO2R alone (100.9 ± 24.0 vs 102.5 ± 27.9 vs 101.9 ± 22.9 mL/min; $p = 0.8$ and 98.1 ± 14.7 vs 96.2 ± 15.5 vs 96.6 ± 12.7 mL/min; $p = 0.7$) (Fig 3).

Conclusions: For ECCO2R-CRRT, low extracorporeal blood flow with conventional Bicarbonate hemofiltration and dialysis results in reduced VCO2EC. Lower Bicarbonate hemofiltration and Dialysate is an optional solution to diminish this effect when extracorporeal blood flow cannot be elevated.

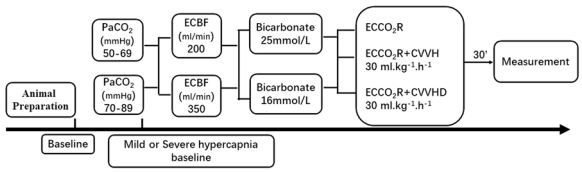

Figure 1 (abstract 000571) Experiment flowchart. Management of delirium in the intensive care unit

G. Bhardwaj[1], A. Hagana[2], S. Sivanesan[1], P. Duggleby[2], T. Ali[2]
[1]Anaesthetics and Critical Care, University of Buckingham, Eaglestone, United Kingdom; [2]Anaesthetics and Critical Care, Stoke Mandeville Hospital, Aylesbury, United Kingdom
Correspondence: A. Hagana
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000572

Introduction: Delirium is a common clinical phenomenon seen in critically ill patients and associated with significant adverse outcomes including increased morbidity, mortality, length of hospital stay and long-term cognitive impairment [1]. Although prevention and early recognition of delirium is the primary objective, the management approach has a significant effect on outcomes [1, 2]. This primarily involves identification and correction of the underlying source of delirium through a thorough clinical assessment, alongside non-pharmacological interventions including cognitive stimulation, reorientation, environment optimisation and family involvement [2]. Cautious pharmacological interventions may be utilised if required [2].

Methods: An audit was performed at Buckinghamshire Healthcare NHS Trust on patients admitted to the ICU between 22/09/22 and

5/10/22. 11 out of 38 patients were identified to have delirium during their admission. The management of delirium was investigated, focusing on the clinical assessment to identify the source, as well as non-pharmacological and pharmacological interventions based on NICE CKS guidelines [3].
Results: The results for this audit are summarised below.

Table 1 (abstract 000572) Summary of results

Clinical assessment	Factor reviewed (%)
Infection	Lines reviewed/ VIP 54.5% Blood/urine/ sputum culture 18.2%
Metabolic disturbance	Glucose 45.5% Electrolytes 72.7%
Cardiovascular	ECG 27.3% Troponin 18.2% Echo 45.5%
Respiratory	O_2 saturation 100% ABG 27.3% CXR 18.2%
Neurological	Imaging 27.3%
Gastrointestinal	Hydration 90.9% Constipation 72.7% Nutrition 100%
Pain	100%
Sleep	27.3%
Sensory impairment	27.3%
Mobility	45.5%
Non-pharmacological management	–
Re-orientation	36.3%
Family involvement	18.2%
Environment optimisation	18.2%
Cognitive stimulation	9.1%
Pharmacological management	–
Medication review	45.5%
Medication prescribed	72.7%

Conclusions: The results indicate that delirium management can be improved through a more thorough investigation of the underlying source of delirium. It shows particularly low non-pharmacological management, and a high reliance on pharmacological intervention, with 72.7% of delirious patients receiving haloperidol. We propose the introduction of a delirium management bundle, ensuring a comprehensive clinical review is performed and simple implementations made to every patient identified to be delirious. The ABCDEF bundle (Assess, prevent and manage pain; Both spontaneous awakening/spontaneous breathing trials; Choice of sedation and analgesia; Delirium: assess, prevent, manage; Early mobility and exercise; Family engagement and empowerment) has been shown to significantly improve outcomes in critical illness [2, 4].

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000573

Introduction: Mechanical power (MP) reflects the energy delivered from the ventilator to the respiratory system (1, 2). Several studies have investigated the association between mechanical power and mortality in ARDS patients; however only few studies have focused on the variations of mechanical power on healthy patients during general anesthesia (3). Aim of this study was to evaluate the effect of two different positive end-expiratory pressure (PEEP) levels on MP in healthy mechanically ventilated patients of different ages.
Methods: 172 healthy (ASA classes 1–2 with no history of respiratory disease) patients undergoing elective surgery were prospectively enrolled. After induction, patients were ventilated in volume-controlled mode: tidal volume 8 mL/kg of predicted body weight (PBW), respiratory rate to obtain an end-tidal CO_2 of 35–40 mmHg, I:E 1:2, PEEP 5 cmH_2O and FiO_2 0.40. Inhalational anesthesia was maintained by sevoflurane or desflurane. Before the start of the surgery, PEEP was set to 0 cmH_2O and, after 10 min, respiratory mechanics was measured and mechanical power was calculated. Consequently, the same was performed after setting and maintaining PEEP at 7 cmH_2O. Thus, the PEEP level was set according to the attending physician and the surgeon was allowed to operate. We performed a linear regression between age and the variation of mechanical power, driving pressure and peak pressure between the two PEEP levels (0 and 7 cmH_2O of PEEP). We divided patients into 5 equal quintiles according to their age; to assess the differences in terms of variation of MP (D0-7MP) among age-related quintiles a Kruskal–Wallis test with *post-hoc* comparisons was used.
Results: The median age was 60 [44–70] years old. Linear regression showed a negative association between MP variation from 7 and 0 cmH_2O of PEEP (…MP 0–7) and age, with elderly patients exhibiting a lower MP increase ($p < 0.001$, Figure 1). The variation in driving pressure significantly increased in older patients, while the variation in peak pressure was similar within different ages. When comparing age-related quintiles, the first and the last quintiles exhibited the highest and the lowest MP variation ($p < 0.05$, Figure 2).
Conclusions: In healthy subjects, age plays a significant role in response to PEEP adjustment in terms of MP mainly due to DP (elastic component) without an in increase in peak pressure (resistive component).

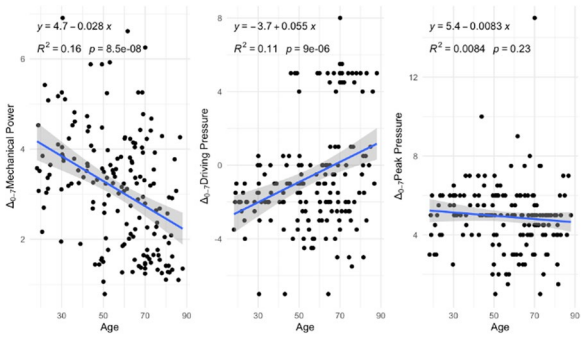

Figure 1 (abstract 000573) Linear regression that investigate the relation between age and (a) Variation in terms of mechanical power,

(B) Variation in terms of Driving pressure (dynamic component of the mechanical power) and (C) Variation in terms of Peak Pressure (resistive component of the mechanical power)

Tracheostomy weaning and functional outcomes in adult ICU stroke patients: clinical observation from a large London Teaching Hospital

B. H. Azhar[1], R. Davies[2]
[1]Physiotherapy, Kings College Hospital, London, United Kingdom; [2]Therapies, King's College Hospital NHS Foundation Trust, London, United Kingdom
Correspondence: B. H. Azhar
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000574

Introduction: Use of a tracheostomy is common practice in intensive care units (ICU) to facilitate weaning from mechanical ventilation. Neurological deficits associated with ischaemic and haemorrhagic strokes often require prolonged mechanical ventilation and subsequent tracheostomy insertion [1, 2]. However, the evidence within the literature on functional and weaning outcomes of this cohort of patients is sparse.
Objectives: To determine the functional and weaning outcomes in stroke patients who received a tracheostomy in a large South London teaching hospital.
Methods: A retrospective observational cohort study was conducted of adult ICU patients admitted with a primary diagnosis of a stroke requiring a tracheostomy. Data collected included: type and location of stroke; the number of days from intubation to tracheostomy insertion; number of days from tracheostomy insertion to ventilator liberation and decannulation; number of extubation trials prior to tracheostomy insertion; hospital length of stay (LoS); Glasgow Coma Scale (GCS) at tracheostomy insertion and hospital discharge; Rehab Complexity Scale (RCS) on ICU/hospital discharge; method of transfer from bed to chair at ICU/hospital discharge and discharge destination. Data was collected from the IntelliSpace Critical Care and Anaesthesia information system (Philips healthcare, Murraysville, USA) between 1 November 2021 and 31 November 2022.
Results: Data was collected from 13 patients. Of these, 10 (77%) experienced an ischaemic stroke and 3 (23%) haemorrhagic. Right sided MCA territory strokes were most common (n = 5; 38%). 4 (31%) died in hospital.
Median time from intubation to tracheostomy insertion was 13 days (range 7–35). Median time from tracheostomy insertion to ventilator liberation was 25 days (range 8–110). 2 (16%) were decannulated prior to discharge from our hospital. The mean hospital LoS was 74 days (range 15–162). 11 (84%) were tracheotomised without an extubation trial; 2 (16%) failed extubation more than once. Median GCS prior to tracheostomy insertion was 6 (range 3–11), and 10 (range 9–14) on hospital discharge. Median RCS on ICU discharge was 15 (range 13–18), and 14 (range 12–17) on hospital discharge. All patients were dependent on hoist transfers on hospital discharge. 4 patients (31%) were discharged straight to a rehabilitation unit from our hospital. 5 (38%) were repatriated to their local hospital. None were discharged directly home.
Conclusions: Our observed population experienced limited functional improvements and a low occurrence of in hospital tracheostomy decannulation. Due to the repatriation of patients from our hospital, data collection on discharge was limited. Further data collection is required to understand longer term weaning trajectory and functional outcomes of this patient group. Further exploration of the impact of time to tracheostomy formation, stroke severity/location and longer term quality of life could also be of benefit.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000575

Introduction: Obtaining a thorough social history and frailty assessment is a crucial component of a patient's admission to the intensive care unit (ICU), with frailty associated with prolonged ICU admission, adverse outcomes post-admission as well as poor quality of life on discharge [1–4]. A quality improvement project on improving social

history taking and frailty assessments was undertaken in 2020 for ICU admissions at Buckinghamshire Healthcare NHS Trust, which led to the introduction of a social history proforma that was implemented into the clerking pack. As a result, significant improvements in documentation for social history and frailty assessments were observed. The trust has since transitioned to an online system for documenting medical records and notes within the ICU. This was re-audited to assess whether set standards were being maintained and translated to the online system.

Objectives: To improve the quality of social history and frailty assessment through re-audit and review.

Methods: Data was collected retrospectively on social history and frailty documentation for ICU admissions in September 2022. Forty-one admissions were identified, and their clerking subsequently analysed to assess adherence to the use of the proforma. This was compared to the results of the previous audit cycle to review whether improvement was still observed.

Results: The results prior to proforma introduction and cycle one and two are summarised below:

Table 1 (abstract 000575) Summary of results

	Pre-audit (% documented)	Audit cycle 1 (% documented)	Audit cycle 2 (% documented)
Smoking	15	100	27
Alcohol	10	88	15
Illicit drugs	5	94	10
Occupation	20	100	29
Accommodation	5	94	39
Living alone	80	100	71
Care packages	15	100	44
DNA CPR	20	94	83
Walking ability	55	100	44
Walking aids	47	100	41
Walking distance	11	100	12
Exercise tolerance limitations	0	56	15
Stairs ability	15	100	12
Stair aids	0	71	12
Number of stairs managed	6	78	5
Exercise frequency	5	65	10
Activities of daily living	25	94	34
Clinical Frailty Score	5	94	22

Conclusions: Analysis of the results found that the quality of documentation reduced between cycle one and cycle two across all domains. However, when compared to pre-audit data, documentation improved in 72% of the areas assessed. This suggests that whilst the proforma remains a valuable tool in the documentation of social history and frailty assessments, adherence has declined. This may be due to challenges completing it initially whilst the patient is being admitted, with relevant information not being readily available from the patient themselves or there being no previous documentation. By encouraging doctors to gain a full social history from either the patient or next of kin early in the admission, as well as encouraging other healthcare professionals such as nurses, physiotherapists and occupational therapists to contribute to completing the proforma, this will allow for a more comprehensive social history and frailty assessment.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000578

Introduction: Pulmonary fibrosis can be a complication of COVID-19 ARDS leading to severely diminished quality and expectancy of life. However, the mechanisms of fibrosis development in COVID-19 ARDS remain unclear. SARS-CoV-2 infections can cause pulmonary inflammation and damage inducing ARDS. This significantly involves inflammasome caspase-1 signaling with interleukin (IL)-1β and IL-18 production. Inflammasome-capase-1 activation can promote lung fibrosis in various inflammatory conditions. Thus, we hypothesized that inflammasome-caspase-1 signaling contributes to the fibrotic response in COVID-19 ARDS.

Methods: Bronchoalveolar lavage fluid (BALF) was obtained from non-pulmonary (n = 11) and COVID-19 ARDS (n = 39) patients. BALF cells were incubated ex vivo with the caspase-1 inhibitors tetracycline or VX-765 and examined after 16 h. K18-hACE2 mice were intratracheally infected with SARS-CoV-2. Lungs and BALF were analyzed after 8d. Lung damage, fibrosis-associated mediators, inflammatory cytokines, and caspase-1 were analyzed in human and murine BALF and cell culture supernatants by multiplex immunoassay, ELISA, qRT-PCR and immunoblotting. Lung damage and fibrosis in murine samples were analyzed histologically.

Results: In contrast to non-pulmonary ARDS patients, COVID-19 patients showed significantly increased levels of profibrotic matrix metalloproteinases (MMP) -1, -2, and -7 ($p \leq 0.01$) in the BALF. In addition, fibrosis-associated mediators CC-chemokine ligand-18 ($p < 0.0074$) and plasminogen activator inhibitor type 1 ($p < 0.0189$) as well as N-terminal procollagen I ($p < 0.0001$) concentrations were increased in the lungs of COVID-19 patients. In terms of caspase-1 orchestrated inflammation, we detected higher IL-1β and IL-18 ($p < 0.0008$; $p < 0.0045$) concentrations in COVID-19 compared to non-pulmonary ARDS patients. Consistent with that, caspase-1 activation was increased ($p < 0.0019$). The correlation between IL-18 and both MMP-2 ($r = 0.8074$; $p < 0.0001$) and SOFA score ($r = 0.6497$; $p < 0.0001$)

suggests a strong association between caspase-1 mediated inflammation, fibrotic response and organ failure in COVID-19.
BALF cells from COVID-19 patients continued producing IL-1β and IL-18 ex vivo. Tetracycline and VX-765 inhibited IL-1β and IL-18 production as well as caspase-1 activation ($p \leq 0.0256$). Furthermore, tetracycline limited caspase-1 activation and subsequent IL-1β and IL-18 production, thereby reducing lung injury ($p < 0.0161$) in SARS-CoV-2 infected mice. Of note, tetracycline reduced collagen I and III mRNA-levels ($p < 0.0296$), the production of profibrotic MMP-9 ($p < 0.0061$) and S100A8/9 proteins ($p \leq 0.0039$). Consistent with these findings, tetracycline treated mice showed reduced pulmonary fibrosis.
Conclusions: Our study demonstrates the close link between caspase-1 activation, disease severity and pulmonary fibrotic response in COVID-19 ARDS patients. In SARS-CoV-2 infected mice, both lung injury and pulmonary fibrotic response were reduced by caspase-1 inhibition. Caspase-1 inhibition should therefore be evaluated as a therapeutic option of COVID-19 ARDS and associated lung fibrosis.

Conservative fluid management does not reduce biomarkers of vascular injury in critically ill patients: data from the RADAR-2 randomised control trial

C. McGrath[1], R. Mcmullan[2], N. Cody[2], S. Scannell[2], J. Conlon[3], C. O'kane[4], D. McAuley[5], J. A. Silversides[6]
[1]Critical Care, Royal Victoria Hospital, Belfast, United Kingdom; [2]Critical Care, Wellcome-Wolfson Institute for Experimental Medicine at Queen's University, Belfast, United Kingdom; [3]Centre for Experimental Medicine, Queen's University Belfast, Belfast, United Kingdom; [4]Centre for Infection and, Queen's University Belfast, Belfast, United Kingdom; [5]University, Queen's University Belfast, Belfast, United Kingdom; [6]Wellcome Wolfson Institute for Experimental Medicine, Queen's University Belfast, Belfast, United Kingdom

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000579

Introduction: Sepsis is associated with high morbidity and mortality. Administration of intravenous (IV) fluids is advocated by the Surviving Sepsis guidelines [1]. However, IV fluids can induce or exacerbate vascular injury [2, 3], and both greater volumes of administered IV fluid and accumulation of a positive fluid balance are associated with higher mortality in sepsis and other critical illness states [4]. In the Role of Active Deresuscitation After Resuscitation-2 (RADAR-2) trial, 180 critically ill patients were randomised to conservative fluid therapy and deresuscitation or to usual care [5]. This was an exploratory analysis of the RADAR trial.
Objectives: To test the hypothesis that a strategy comprising conservative fluid administration and deresuscitation would lead to a reduction in biomarkers of vascular injury compared to usual care.
Methods: Participants in the RADAR-2 trial were randomised to either a fluid strategy comprising conservative fluid administration and, if fluid overload was present, active deresuscitation; or to usual care. Blood samples were taken at baseline, day 3 and day 5. Plasma levels of angiopoietin-2 (usual care—84 patients; intervention 81 patients), hyaluronan (usual care—82 patients; intervention 82 patients) and syndecan-1 (usual care—82 patients; intervention 82 patients) were measured in duplicate using a sandwich enzyme-linked immunosorbent assay (DuoSet, R&D systems). GraphPad Prism version 9.5.1 was used for statistical analysis.
Results: Samples were available for 165 patients, 67 of whom had sepsis. No significant differences were detected between intervention and usual care groups at any of the time points for any biomarker, either in the overall cohort or in the sepsis subgroup (Figure 1).
Conclusions: There was no evidence that a conservative fluid strategy improves vascular injury. Five days of conservative fluid management may be insufficient to mitigate early vascular injury associated with IV fluid administration.

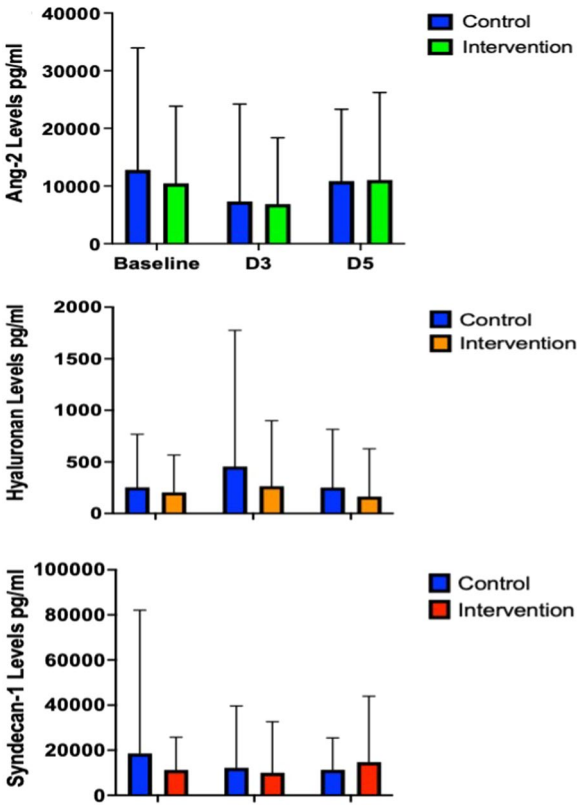

Figure 1 (abstract 000579) Levels of Ang-2, Hyaluronan and Syndecan-1 by group allocation

Relationship between SOFA scores and alarm metrics in intensive care units: implications for alarm fatigue

A. Chaoui[1], A. R. Flint[1], K. Rubarth[1], F. Balzer[1], A. S. Poncette[1]
[1]Institute of Medical Informatics, Charité – Universitätsmedizin Berlin, Berlin, Germany
Correspondence: A. Chaoui
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000580

Introduction: Alarm fatigue is a growing concern in intensive care units (ICUs): high number of alarms generated by monitoring systems [1, 2] can lead to desensitization, missed alarms, and delayed responses, compromising patient safety [3, 4]. However, the relationship between clinical conditions and alarms is not yet fully understood. Previous studies linked worse patient conditions to higher alarm loads [5, 6], but they did not use large quantities of alarms for analysis in their study, nor put the number of alarms in relation to the patient's monitoring time. This study aims to provide an extensive evaluation—based on millions of alarms—of the relationship between SOFA scores as a proxy for clinical condition and alarm metrics in ICU patients.

Objectives: Primary objective: assess whether patients with higher SOFA scores generate more alarms than patients with lower scores. Secondary objective: determine if there is a relationship between SOFA scores and alarm response metrics, including the time taken to address an alarm and the frequency of interventions following an alarm.

Methods: After IRB approval (Ethics vote no. EA1/127/18), we extracted alarm metrics, such as number of alarms and alarm duration, from ICU bedside monitoring devices; SOFA scores recorded by clinical staff; and interventions after an alarm based on a set of annotation guidelines [7] for each patient in 15 ICUs in a tertiary care center over a 23-month period. We performed a retrospective analysis and included all SOFA score measurements with at least 1000 vital sign alarms of each type (heart rate (HR), blood pressure (BP), and peripheral oxygen saturation (SpO_2)) for the analysis. We used point plots to visualize the relationships between SOFA scores and mean alarm metrics and calculated Spearman's rank correlation coefficient and tested its statistical significance with a two-tailed test.

Results: We collected 6,143,128 vital sign alarms from 9969 ICU admissions and 77,414 SOFA score entries. We observed a positive relationship between SOFA score and HR alarm rate ($corr = 0.856$, $p < 0.001$), but no statistically significant relationship to SpO_2 alarm rate ($corr = -0.385$, $p = 0.115$) and a negative relationship to BP alarm rate ($corr = -0.542$, $p = 0.020$) (Fig. 1a). For the rate of actionable alarms, we observed a positive relationship to the SOFA score for all 3 alarm types: HR ($corr = 0.897$, $p < 0.001$); BP ($corr = 0.996$, $p < 0.001$) and SpO_2 ($corr = 0.839$, $p = 0.000$). The rate of interventions increased by almost threefold for BP and SpO_2 alarms, while only increasing by less than twofold for HR alarms (Fig. 1b). For alarm duration, we observed a negative relation to the SOFA score with: HR ($corr = -0.942$, $p < 0.001$); BP ($corr = -0.942$, $p < 0.001$) and SpO_2 ($cor = -0.944$, $p < 0.001$). For all three alarm types, the mean alarm duration reached almost half the time for patients with high SOFA scores in comparison to patients with lower SOFA scores (Fig. 1c).

Conclusions: Our study highlights the limited research on the relationship between patient characteristics and alarms in the ICU. We show that there is a complex relationship between the SOFA score and alarm metrics in the ICU. Contrary to our hypothesis, our results suggest that there is no clear increase in the number of alarms with a more severe SOFA score. While we observed a strong positive relationship for HR alarms, there was no statistically significant positive relationship for SpO_2 alarms and, surprisingly, a negative relationship for BP alarms. However, we observed a reduction in alarm response time and an increase in the rate of interventions following alarms, suggesting that healthcare providers become more responsive to alarms from patients with worse clinical conditions, possibly because of the greater risk of clinical deterioration. The almost constant rate of alarms produced across the whole range of SOFA scores may be caused by alarm settings and thresholds being adjusted more adequately for these patients, resulting in fewer alarms being generated. The observed increase in heart rate alarm rates, possibly representing worse alarm management, could also be the reason why the rate of interventions doesn't increase as much in comparison to the other investigated alarm types. These findings have implications for optimizing alarm systems in the ICU, as they suggest that a more nuanced approach is needed to ensure that alarms are effective in identifying life-threatening situations while minimizing alarm fatigue.

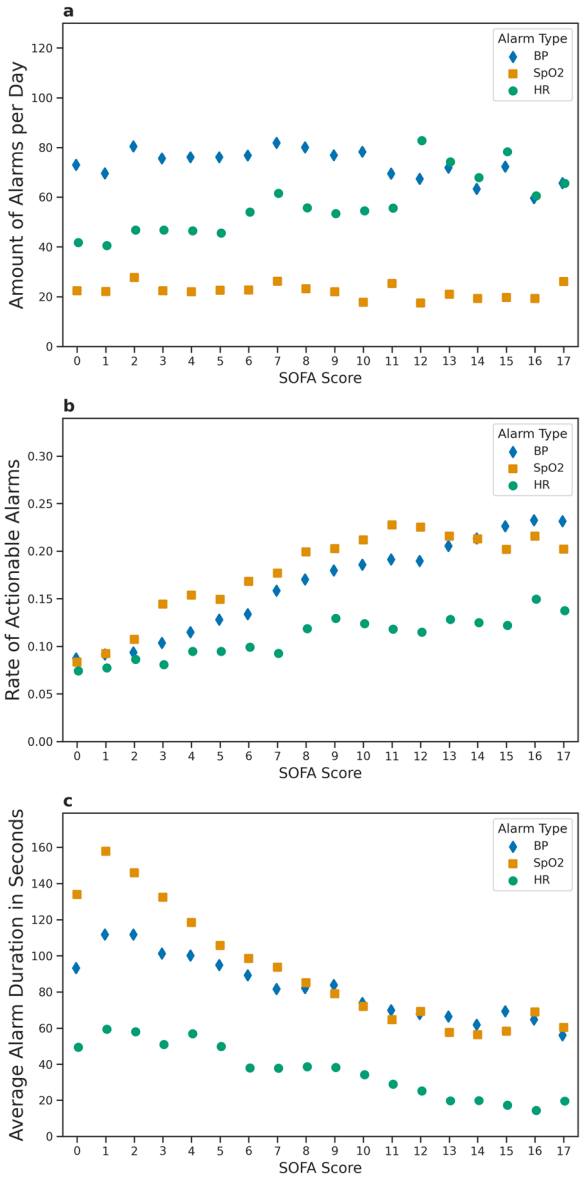

Figure 1 (abstract 000580) Point plot showing the relationship between the SOFA score and multiple alarm metrics presented for blood pressure (BP), heart rate (HR), and peripheral oxygen saturation (SpO_2) alarms: a) Amount of alarms produced per day; b) Rate of clinical interventions after an alarm; c) Average alarm duration

Octane in exhaled breath to diagnose acute respiratory distress syndrome in invasively ventilated intensive care unit patients

L. Hagens[1], N. Heijnen[2], M. Smit[1], A. Verschueren[3], T. Nijsen[3], I. Geven[3], C. Presură[3], R. Rietman[3], D. Fenn[4], P. Brinkman[4], M. Schultz[1], D. Bergmans[2], R. Schnabel[2], L. Bos[1]

Correspondence: L. Hagens
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000581

Introduction: The concentration of exhaled octane has been postulated as a reliable biomarker of acute respiratory distress syndrome (ARDS) using metabolomics analysis with gas chromatography mass spectrometry (GC–MS) [Bos, ERJ 2014]. A point-of-care (POC) breath test was developed in recent years to accurately measure octane at the bedside [Hagens, Analyst 2021].
Objectives: To validate the diagnostic accuracy of exhaled octane for ARDS using a POC test in invasively ventilated intensive care unit (ICU) patients.
Methods: This was an observational cohort study of consecutive patients receiving invasive ventilation for at least 24 h, recruited in two university ICUs. GC–MS and POC tests were used to quantify the exhaled octane concentration. ARDS was assessed by three experts following the Berlin definition and used as reference standard. The area under the receiver operating characteristics curve (AUROCC) was used to assess diagnostic accuracy. As a secondary endpoint the added value of the breath test on top of the Lung Injury Prediction Score (LIPS) was assessed.
Results: 519 patients were included and 190 (37%) fulfilled the criteria for ARDS. The concentration of octane using the POC breath test was not significantly different between patients with ARDS (0.14 ppb; IQR: 0.05–0.37) and without ARDS (0.11 ppb; IQR: 0.06–0.26; P = 0.64). The AUROCC for ARDS based on the octane concentration in exhaled breath using the POC breath test was 0.52 (95% confidence interval (CI): 0.46–0.57, Figure 1 panel A). Analysis of exhaled octane with GC–MS showed similar results, (AUROCC 0.53; CI: 0.48–0.59; Figure 1, panel B). Combining LIPS with the octane concentration increased the AUROCC to 0.66 (CI: 0.62–0.71) and 0.67 (CI: 0.62–0.72) for the POC test and GC–MS respectively.
Conclusions: Octane in exhaled breath has insufficient diagnostic accuracy for ARDS. This disqualifies the use of octane as a biomarker in the diagnosis of ARDS and challenges most of the research performed up to now in the field of exhaled breath metabolomics.

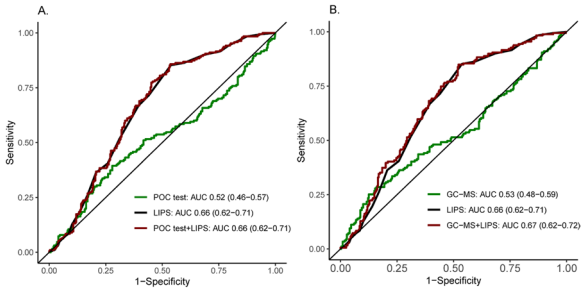

Figure 1 (abstract 000581) Panel A, AUROCC curves describing the diagnostic accuracy for the octane concentration measured with the POC breath test and LIPS for ARDS. Panel B, AUROCC curves describing the diagnostic accuracy for the octane concentration measured with the GC–MS and LIPS for ARDS

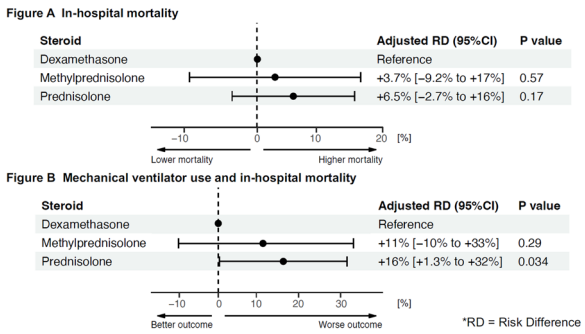
Introduction: International guidelines recommend the use of dexamethasone for patients with severe or critical COVID-19 [1, 2]. If dexamethasone is not available, other corticosteroids at doses equivalent to 6 mg dexamethasone daily may be helpful [1, 2]. A recent study suggested that dexamethasone, rather than methylprednisolone, is beneficial in acute respiratory distress syndrome (ARDS) due to its potent anti-inflammatory and weak mineralocorticoid effects [3, 4]. However, little is known about the efficacy of other corticosteroids compared with 6 mg dexamethasone in COVID-19 [5, 6].
Objectives: To compare the efficacy of dexamethasone, methylprednisolone, and prednisolone in patients with severe COVID-19.
Methods: This retrospective cohort study used a nationwide registry of hospitalized patients with COVID-19 from 66 hospitals in Japan

from January 2020 to September 2020 [7]. We identified patients with severe COVID-19 (defined as $SpO_2 \leq 94\%$ on ambient air and imaging findings of pneumonia) who were treated with one of the following corticosteroids: dexamethasone, methylprednisolone, and prednisolone. Corticosteroid treatments equivalent to pulsed corticosteroid therapy were excluded. The primary and secondary outcomes were all-cause in-hospital mortality and the composite of mechanical ventilation use and in-hospital mortality, respectively. We evaluated the associations between the use of each corticosteroid and each outcome using inverse probability–weighted (IPW) analyses based on multiple propensity scores to adjust for potential confounders (e.g., age, sex, Charlson Comorbidity Index [CCI] score, sequential organ failure assessment [SOFA] score, and PaO_2/FiO_2 ratio [PFR]) at admission [8–10].

Results: Of 347 patients eligible for analysis, 258 (74.3%) were male and the median age was 65. 259 (74.6%), 27 (7.8%), and 61 (17.6%) patients were treated with dexamethasone, methylprednisolone, and prednisolone, respectively. Adjusted for multiple propensity scores, there were no significant differences in in-hospital mortality among the three groups (e.g., risk difference of methylprednisolone vs. dexamethasone: +3.7%; 95% confidence interval [CI] −9.2 to +16.7%) (Figure A). However, the risk of the composite outcome of mechanical ventilation use and in-hospital mortality was significantly higher in the prednisolone group (risk difference of prednisolone vs. dexamethasone: +16.4%; 95% CI +1.3 to +31.6%) than in the dexamethasone group (Figure B). We observed higher risk of the composite outcome in the methylprednisolone group (risk difference of methylprednisolone vs. dexamethasone: +11.6%; 95% CI −9.9 to +33.1%) than in the dexamethasone group, although the effect estimate was statistically imprecise with a wide CI.

Conclusions: In patients with severe COVID-19, methylprednisolone and prednisolone could serve as alternative agents to dexamethasone. However, prednisolone was associated with increased use of mechanical ventilator, possibly attributable to its mineralocorticoid effect.



Risk difference in A. All-cause in-hospital mortality B. the composite of Mechanical ventilator use and in-hospital mortality. Adjusted risk differences in outcomes were estimated using inverse probability-weighted (IPW) analysis based on multiple propensity scores. (Dexamethasone as a reference). Abbreviations: RD, risk difference; CI, confidence interval.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000584

Introduction: Monitoring the consumption of antibiotics is necessary in services with a high demand, such as the Intensive Care Unit (ICU). The use of these antibiotics has changed over the years, being the global pandemic by COVID 19 one of the events that has a greater influence on the increase of patients in our ICUs, as well as the widespread use of empirical antibiotic therapy in COVID patients. Other epidemics and the change in antibiotic resistance also influence this change.

Objectives: To evaluate the consumption of antibiotics between 2018 and 2022 in a multipurpose ICU, differentiating 3 periods: pre-pandemic, pandemic and post-pandemic. It's also analyzed the stay in the ICU, the variation that they have suffered over the years and the consumption with stays.

Methods: Retrospective descriptive observational study of the consumption of antibiotics in a 12-bed ICU, expanded to 24 beds with the pandemic, during the years 2018 to 2022. The consumption of antibiotics and stays in the ICU Service are collected. The following are analyzed: the defined daily dose (DDD: consumption (gr) × 100/DDD–WHO × stays) per stay (S) in the ICU) of the most used antibiotics, stays in the ICU per year, the DDD/100S in ICU by family of antibiotics and by most used antibiotics.

Results: The stay in our ICU was: 2018: 1818, 2019: 1915, 2020: 3801, 2021: 4173, 2022: 2638, which represents a variation in stays compared to the previous year of: 2019: 5.34%; 2020: 98.49%; 2021: 9.79%; 2022: − 36.78% respectively.

In terms of the antibiotics with the highest consumption per year (DDD): 2018: Levofloxacin (LVF), Meropenem (MPN) and Linezolid (LZD); 2019: MPN, LVF and LZD; 2020: MPN, Ceftriaxone (CFX) (COVID 19 treatment) and LZD; 2021: MPN, LZD, Tigecycline (TGC) (*Acinetobacter baumanii* outbreak); 2022: MPN, LZD and LVF.

Regarding to antibiotic consumption (by groups) and ICU stay (Table 1):

AB 2018	DDD/100S 2018	AB 2019	DDD/100S 2019	AB 2020	DDD/100S 2020	AB 2021	DDD/100S 2021	AB 2022	DDD/100S 2022
Global consumption	**188,88**	**Global consumption**	**212,21**	**Global consumption**	**237,24**	**Global consumption**	**199,13**	**Global consumption**	**192,49**
Quinolones	47,58	Carbapenems	44,89	Carbapenems	45,96	Carbapenems	41,76	Other (linezolid)	41,38
Penicillins	40,14	Quinolones	41,06	Macrolides	45,00	Cephalosporins	33,82	Carbapenems	40,60
Carbapenems	40,11	Penicillins	34,99	Cephalosporins	39,52	Other (linezolid)	30,81	Cephalosporins	27,22

with a variation in such consumption compared to the previous year (DDD/100S total): 2019: 12.35%; 2020: 11.79%; 2021: − 16.06% and 2022: − 3.33%.

Conclusions: The COVID 19 pandemic increased the stay in the ICU by 98.49% in 2020, decreasing 36,78% in 2022.
During those two years (pandemic), the most used antibiotics in our ICU changed. By connecting antibiotic consumption to hospital stay, the greatest increase occurs in 2020 where macrolides and cephalosporins appear among the most frequent antibiotics. In 2022 it decreases to similar values to pre-pandemic.

Association between COVID-19 vaccination and mortality of COVID-19 pneumonia hospitalized in Intensive Care Unit during the COVID-19 pandemic

S. Ruangchan[1], S. Krudphu[1], P. Saengsanga[2], N. Kiamkan[1]
[1]Internal Medicine, Songkhla Hospital, Songkhla Province, Thailand; [2]Critical Care Unit, Songkhla Hospital, Songkhla Province, Thailand
Correspondence: S. Ruangchan
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000586

Introduction: COVID-19 is a very high-transmission disease with a variable prognosis in the general population. Higher risks of severe disease were found in older individuals and with underlying health conditions (1). COVID-19 vaccination has substantially altered the course of the pandemic and its severity, lower mortality in critically ill COVID-19 pneumonia (2, 3).
Objectives: To evaluate the association between COVID-19 vaccination and mortality among COVID-19 pneumonia who were admitted to Intensive Care Unit (ICU) and needed mechanical ventilator support.
Methods: A retrospective, cross-sectional study was conducted in Songkhla Provincial Hospital, a 508-bed hospital, in Southern Thailand. All patients (≥ 15 years old) with a presumptive or confirmed diagnosis of COVID-19 pneumonia (4) who were admitted to the ICU and needed invasive or non-invasive mechanical ventilators from January 2021 to December 2022 were enrolled**.** Baseline patients' characteristics, COVID-19 Vaccine status, clinical manifestations, treatment, and outcome were collected from the medical records.
Results: A total of 224 patients were included in the study. Mean age, 65.95 ± 16.57 years, 124 (55.4%) were men, 158 (70.5%) were older than 60 years old, 209 (93.3%) has at least one co-morbid medical conditions including diabetes 37.9%, heart disease 23.7%, chronic kidney disease 20.1%, history of cerebrovascular disease 13.4%, chronic lung disease 12.1%, obesity (BMI ≥ 30) 10.3% and immunocompromised patient 9.3%. Only 54 (24.1%) completed 2 doses of the primary COVID-19 vaccination series more than 14 days before admission. The overall hospital mortality was 131 (58.5%), factors influencing mortality were older age (61.57 ± 18.16 years in the survival group VS 69.06 ± 14.62 years in the non-survival group; *p-value* < 0.001), at least one medical condition 87.1% in survival group VS 97.7% in the non-survival group; *p-value* < 0.027 and initial palliative care condition in survival group 1.1% VS 19.1% in non-survival group *p-value* < 0.001. Multivariate analysis showed at least 2 doses of the COVID-19 vaccine were significantly associated with lower mortality compared with controls (110 of 170 patients [64.7%] died in the control group VS 21 of 54 [38.9%] in the full vaccination group; adjusted OR, 0.26 [95% CI, 0.11–0.6]; *p-value* = 0.002) and decrease day of non-invasive ventilator support 3 (3, 5) in control group VS 2 (2, 3) in full vaccination group *p-value* = 0.03, but not decrease in length of hospital stay and day of invasive ventilator support. Patients with ≥ 3 risk factors were significantly increasing mortality, adjusted OR 7.36 [95% CI, 1.28–42.28]; *p-value* = 0.025.
Conclusions: At least 2 doses of COVID-19 vaccination is a significant protective factor in preventing deaths due to COVID-19 pneumonia hospitalized in an Intensive care Unit.

Infective endocarditis at ICU admission

J. M. Bonell-Goytisolo[1], C. March Cladera[1], T. J. Leal Rullan[1], O. Bonnin Gubianes[2], M. Picornell Noguera[1], N. Suárez Rovira[1]

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000587

Introduction: Infective endocarditis (IE) remains a very serious clinical identity in intensive care unit (ICU) although its frequency is lower than other acute infections. Complications of IE are often severe and can put the patient in a critical situation which requires ICU assistance.
Objectives: To analyze all cases with IE whose complications were the main reason for ICU admission.
Methods: Retrospective study of 20 patients recorded between 2011 and 2021, in all them IE was the main reason for admission in ICU and its diagnosis was established during their ICU stay following basically modified Duke criteria. Transesophagic echocardiography, as well as transthoracic, was routinely performed. Our ICU has 16 boxes and treat patients with many different pathologies, including cardiac surgery.
Results: Mean age was 60 years, IE diagnosis was established at day 4 of average after admission. Nine patients came from the emergency, 8 from hospital ward, 2 from other hospitals and 1 from surgery area. Heart failure (55%) was the most common admission reason, followed by ischemic stroke (20%), septic shock (15%), spondilitis and embolic myocardial infarction. Sixty percent of patients had fever on the first 48 h hours, and during their evolution 65% suffered from heart failure and 60% from shock. Eight patients (40%) had embolic events (cerebral, coronary, spinal, splenic). In 6 cases origin was nosocomial or related to health system (patients with previous sepsis, renal insufficiency, cancer). Most common microbial etiology were grampositive (65%, specially Staphylococcus aureus), in 30% cultures were negative. No multiresistant microorganisms were isolated. Aortic valve was the single affected in 45%, mitral in 40% and both in 15%. No cases of right endocarditis, pacemaker or valvular prothesis infections were recorded. Surgery was performed in 55%, 6 days of average after diagnosis. Hospital mortality was 40% (8 cases), in almost all (7) surgery could not be made. 6 months later after diagnosis, among 12 patients who survived 5 were asymptomatic, 4 with minor neurological deficits in recovery process and in 3 cases no information was registered (foreign tourists repatriated to their home land).
Conclusions: Possibility of IE should always be suspected in the presence of some clinical situations as heart failure or acute ischemic stroke in order to begin proper therapy as soon as possible. Mortality is high and complications are frequent.

Introduction: Although vascular leakage is a major feature of systemic inflammatory response syndrome associated with shocks, its molecular mechanisms remain poorly characterized in humans. RNAseq analysis of circulating monocytes, performed in 11 patients after resuscitated cardiac arrest, revealed 860 genes that were differentially expressed between patients with and without massive vascular leakage. Ingenuity® pathway analysis identified clusters of genes related to (i) inflammation, (ii) Hypoxia-Inducible Factor-induced angiogenesis, and (iii) cell cycle regulation. Thirty-eight genes were retained after correction for false discovery rate. Among them, a gene coding for a protein P (protein with an ongoing patent protection), ligand of a receptor involved in vascular biology, had a 56 times higher expression in patients with massive leakage. In accordance, plasma levels of P-PROTEIN were found strongly associated with the level of vascular leak in an independent validation cohort of 52 post-cardiac arrest patients. The objective of the study was to test the hypothesis that P-PROTEIN may play a role during cardiac arrest induced vascular leakage.
Methods: We first set up a model of resuscitated cardiac arrest in mice, with a no-flow and a low-flow time of 8 min each. Survival and vascular leakage were then compared after cardiac arrest between *P-protein* knock-out (KO), wild-type (WT) mice, and WT mice injected with recombinant mouse P-PROTEIN (rmP-PROTEIN) at the time of resuscitation (after the no-flow). Vascular leakage was compared between conditions using i.v. injected fluorescent dextrans.
Results: We confirmed an important vascular leak in all organs after the return of spontaneous circulation (ROSC) in WT mice, and an induction of circulating P-PROTEIN levels at one-hour post-ROSC. Intra-venous injection of rmP-PROTEIN significantly reduced the vascular leakage quantified by extravasation of fluorescent dextrans. Survival was also significantly affected by modulating P-PROTEIN activity. We demonstrated a beneficial effect of rmP-PROTEIN injection, with 88% of ROSC in WT mice injected with rmP-PROTEIN vs. 67% in controls and an improved survival in rmP-PROTEIN injected mice vs controls (Figure 1). The proportion of mice achieving a ROSC was on the contrary strongly reduced in *P-protein* KO mice compared to their WT littermates (10%, $p < 0.0001$ *vs*. WT).
Conclusions: These results demonstrate that the P-PROTEIN, isolated from observations in human, is a key regulator of post-cardiac arrest vascular leakage, with beneficial effects on vascular leakage and survival of P-PROTEIN gain of function in mice. Further experiments are ongoing to characterize its mechanisms on vascular leakage, as well as its optimal dosing regimen in a pre-clinical setting.

Predictors of circuit coagulation in continuous blood purification therapy for septic AKI

M. Akatsuka[1], H. Tatsumi[1], Y. Nakamura[2], S. Chihara[3], Y. Masuda[1]
[1]Department of Intensive Care Medicine, Sapporo Medical University School of Medicine, Sapporo, Japan; [2]Division of Clinical Engineering, Sapporo Medical University Hospital, Sapporo, Japan; [3]Department of Clinical Engineering, Japan Health Care University Faculty of Health Sciences, Sapporo, Japan
Correspondence: M. Akatsuka
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000589

Introduction: Continuous blood purification (CBP) is an essential therapeutic modality in an intensive care setting that is used to remove accumulated fluid and waste products in patients with acute kidney injury (AKI) and to remove chemical mediators in sepsis. However, it is often necessary to change the CBP circuit in a short time. Circuit coagulation in CBP reduces the filtration function of the hemofilter, and frequent coagulation necessitates circuit replacement, resulting in problems such as downtime and insufficient blood purification volume due to the interruption of CBP. Although there have been several reports on predictors of CBP lifetime, these have not yet been clarified.
Objectives: The aim of this study was to clarify variables as predictors of circuit coagulation in CBP for septic AKI patients.
Methods: We carried out a retrospective observational study. The study subjects were patients with septic AKI who were admitted to the ICU and received renal replacement therapy during the period from January 2012 to December 2020. The definition of sepsis was according to Sepsis-31) and AKI was defined by the KDIGO guidelines2). We obtained information on the characteristics of patients including age and sex, SOFA score, APACHE II score, focus of infection, length of ICU stay, shock, number of ventilation days, circuit coagulation, KDIGO classification, and disseminated intravascular coagulopathy (DIC) as well as laboratory data. We performed multivariate logistic regression analyses to clarify the predictive factors for circuit coagulation and calculated the cut-off value from the ROC curve.
Results: A total of 126 patients were included and 64 patients were excluded due to the exclusion criteria. Sixty-two patients were eligible for the study. Circuit coagulation occurred in 41.9% of the patients. Platelet count was significantly lower in the circuit coagulation group than in the non-coagulation group ($p=0.002$). The circuit coagulation group also had a higher incidence of DIC than that in the non-coagulation group ($p=0.013$). Platelet count was found to be a predictive factor for circuit coagulation by multivariate logistic regression analysis ($p=0.011$). The cut-off value of platelet count was determined from the ROC curve to be 52,500/μL.
Conclusions: Platelet count might be associated with circuit coagulation during CBP in sepsis patients with AKI. Circuit coagulation might be more likely to occur in patients with platelet counts below 52,500/μL. On the other hand, this study did not show whether other coagulation/fibrinolysis markers were associated with circuit coagulation. Further study is needed to extend our study on circuit coagulation during CPB for sepsis patients with AKI.

Low global ejection fraction (GEF) in patients with impaired global indexed end-diastolic volume (GEDVI)

C. González[1], A. Traverso[1], A. Giordana[1], E. Papini[1], J. Rodriguez Louzan[1], D. Latasa[1], C. Lovesio[1]
[1]Intensive Care, Sanatorio Parque, Rosario, Argentina

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000592

Introduction: Transpulmonary thermodilution is a technique that has gained great interest in recent years. Global ejection fraction (GEF) is one of the parameters that it provides. It reflects cardiac pump function. The calculation of the GEF is done using the formula (SV/ GEDV) *4. This algorithm depends on SV and GEDVI, so in hypovolemic patients with decreased preload, GEDVI could be decreased and leads to altered GEF values. In the same way, low stroke volume (SV) could generate low GEF by mathematical coupling without a disorder in cardiac contractility.
Objectives: To evaluate whether impairment in GEDVI and SV may constitute a limitation for the interpretation of GEF and to describe characteristics of patients with impaired GEF. Secondarily, to determine factors independently associated with the development of impaired GEF.
Methods: A retrospective study was conducted in a 24-bed medical-surgical intensive care unit in Argentina. Baseline characteristics and hemodynamic variables of the opening measurement were recorded. Patients were classified according to GEF, GEDVI, and VS values.
Statistical analysis was performed by means of the Mann Whitney test for continuous variables and for categorical variables, Pearson's Chi2 test was used. To determine factors independently associated with the presence of impaired GEF, binary logistic regression was performed.
Results: We included 95 patients in shock. 48 were female. Median age were 62 [49–72] years. Apache II and SOFA score were 23 [17–27] and 8 [6–10] respectively. Etiology of shock were septic in 61%, hipovolemia 14%, cardiogenic 6% and perioperative 9.5%. (Table 1).
The haemodynamic characteristics of the opening measurement with transpulmonary thermodilution are shown in Table 2. Overall mortality was 49%. 47 (49%) patients had low GEDVI 534 ± 82 ml/m^2, 26 (27%) patients had high GEDVI 901 ± 73 ml/m^2 and 22 patients had normal GEDVI (23%). Of the 47 patients with low GEDVI, low GEDVI in 27 (57%) low GEF coexisted. Of all patients with decreased GEF, 36 (65%) had low SV. On the other hand, 47 patients presented low SV, in 37 of them (79%) the GEDVI was low.
Factors independently associated with impairment in GEF were decreased GEDVI, SV and cardiac output (Table 3).

Conclusions: In a high percentage of patients with altered GEF, low SV or GEDVI coexisted. The presence of low GEDVI and cardiac output was independently associated with altered GEF. Due to the formula by which GEF is calculated, there could be mathematical coupling between both parameters, so in hypovolemic patients with deterioration in the GEDVI, the GEF could also be altered without this implying disorders in pump function.

In vitro validation of intra-abdominal pressure measurement with the Accuryn system

M. Smit[1], M. W. Nijsten[1]
[1]Department of Critical Care, University Medical Center Groningen, Groningen, Netherlands
Correspondence: M. Smit
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000593

Introduction: Intra-abdominal pressure (IAP) measurement is an important tool in critical care medicine as it helps in diagnosing intra-abdominal hypertension and abdominal compartment syndrome.

New technology has become available to automatically perform frequent IAP measurements. IAP and diuresis are measured using a SmartFoley® bladder catheter that is connected with the Accuryn® monitoring system (both from Potrero Medical, Hayward, CA, USA). Active drain line clearance of the catheter prevents urinary backflow and enables continuous urine output measurement. At the tip of the urinary catheter, a semi-flaccid balloon connected to a pressure sensor measures IAP.

Objectives: In the current study we examined the accuracy of the Accuryn system in measuring IAP under in vitro conditions.

Methods: In an experimental set-up using a water reservoir with levels of water varying between 0 and 52.5 cm, IAP in millimeters of mercury (mmHg) was measured using the Accuryn system. The tip of the Accuryn catheter was placed on the bottom of the reservoir for each measurement. The water level was measured in cm of water (cmH_2O) using a regular measuring tape and then converted to mmHg (1 $cmH_2O = 0.7356$ mmHg).

Results: The water pressure was varied from 0 to 52.5 cm (0 to 38.6 mmHg). IAP was measured by the Accuryn Monitoring System for a total of 15 times with increasing water levels (see graph).

At the various water pressures, the reported IAP differed less than 1 mmHg from the applied pressure. This may be due to small inaccuracies in measuring the water level and in placement of the tip of the catheter on the bottom of the reservoir.

Conclusions: In this in vitro experiment, IAP values reported by the IAP-monitoring system Accuryn system were sufficiently accurate for values between 0 and 40 mmHg.

Change in our clinical practice in the nutrition of critical patients by the use of indirect calorimetry

M. Prieto Mora[1], L. Garcia Ezpeleta[1], B. Ongil García[1], M. Vazquez Hernandez[1], M. V. Perez Sanchez[1], M. A. Hurtado[1]
[1]Department of intensive care, Hospital Universitario Virgen de Valme, Seville, Spain
Correspondence: M. Prieto Mora
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000594

Introduction: Indirect calorimetry (IC) is a tool that helps the clinician to create a more personalized nutritional therapy, which is very important in the management of critical patients.

Objectives: - Assess the modification or maintenance of the diet based on the results of IC.
- Compare the calories calculated by IC and by the Harris-Benedict equation (HBE).
Methods: Retrospective descriptive and analytical observational study of patients admitted to a 23-bed polyvalent ICU who underwent IC (Cosmed Q-NRG calorimeter) from December 2020 to November 2022. We collected clinical variables (comorbidities, SOFA, phase of the critical illness), epidemiological and nutritional variables (calories calculated by IC and HBE, laboratory parameters, type of nutritional therapy, modification of nutritional therapy). The qualitative variables are expressed as percentages, and the quantitative ones as mean and standard deviation (SD). The comparative analysis of quantitative variables was done with the Student's t test, and in the case of qualitative variables we used the Chi-square test. Sample size calculation: 23 IC performances to find a difference of 5 kcal/Kg (alpha 5%, power 80%, expected loss 5%). Data analysis was run in SPSS v28.0.
Results: We included 35 IC test, performed on 31 patients.

Qualitative variables		Number of patients	%
Sex	Male	20	57,1
	Female	15	42,9
Cardiovascular risk factors	Yes	23	65,7
Surgical patients		27	77,1
Medical patients		8	22,9
Critical illness phase	Acute	4	11,4
	Chronic	31	88,6
Nutritional therapy modification	No	7	20
	Yes	28	80
Type of nutritional therapy	EN	28	80
	TPN	2	5,7
	EN + SPN	4	11,4
	oral + EN or SPN	1	2,9

EN: enteral nutrition. TPN: total parenteral nutrition. SPN: supplemental parenteral nutrition

Variable	Statistics	t (CI 95%)	p
Age (years) (mean ± SD)	62,54 ± 10,5		
Previous kcal/kg administration	17,77 ± 8,15		
BMI (median, minimum, maximum)	28,4 (18,2–57,1)		
SOFA at admission	4 (2–16)		
SOFA at IC performance	7 (2–14)		
Kcal/kg calculation (mean ± SD):		3,35	0,002
IC	21,96 ± 5,71		
HBE	19,22 ± 2,1		

Conclusions: - The performance of IC is useful to guide the nutritional therapy of critically ill patients.
- After comparing the calorie requirement calculated by HBE and by IC, an statistically difference was revealed, being higher the result obtained by IC.
- Most of the patients who underwent IC were in the chronic stage of their critical illness.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000596

Introduction: Ceftolozane/tazobactam (C/T) is indicated for the treatment of complicated intra-abdominal infections (cIAI) [1], complicated urinary tract infections (cUTI), including pyelonephritis [2], and hospital acquired bacterial and ventilator-associated bacterial pneumonia [3]. Information on real-world use and outcomes of patients treated with C/T in critical care settings is important to help inform disease management and clinical practice.
Objectives: This study presents findings on patient/treatment characteristics and outcomes associated with C/T use in patients managed in the critical care setting.
Methods: Data were collected from the SPECTRA study, a multinational, multicenter, retrospective, inpatient, observational study of patients treated with C/T across hospitals in 7 countries (Spain, The United Kingdom, Germany, Italy, Austria, Australia, and Mexico) from 2016 to 2020. All adult patients admitted to the intensive care unit during the index hospitalization and treated with C/T for $\geq$ 48 h were included. Demographics, clinical characteristics, treatment management patterns, and outcomes were assessed.
Results: The study sample included 298 critical care patients receiving C/T (mean age 57.0 years; 68.8% male), 41.9% of which had an infection-related ICU admission. Sites of infection were respiratory (50.0%), skin/wound/tissue (21.1%), blood (13.7%), urine (10.3%), pleural fluid/cerebrospinal fluid/other fluid (9.3%), line/device (2.9%), abdominal (1.0%), bone/joint (0.5%), and stool (0.5%). The most common pathogens were *Pseudomonas aeruginosa* (89.7%) and *E. coli* (6.4%). Most patients (81.5%) had at least one comorbidity, with the most common being immunocompromised state (44.6%), sepsis (41.6%), heart disease (29.2%), and chronic pulmonary disease (27.2%). Renal replacement therapy was initiated in 21.5% of patients during index hospitalization, with 14.4% on continuous renal replacement therapy. The most common C/T regimen was 1.5 g every 8 h (36.9% of patients). About 51.6% of patients received C/T as third line or salvage (24.8% and 23.5% received C/T as 1st or 2nd line, respectively). Median C/T treatment duration was 11.0 days (Q1, Q3: 7.0, 16.5 days). Clinical success was 53.4%. All-cause in-hospital mortality was 35.6% overall, and 13.8% infection related. 30-day all-cause readmission was 3.4% overall, and 1.7% infection related.
Conclusions: This multinational real-world study included a high number of critical care patients and reported outcomes associated with C/T use. In this very high-risk cohort presenting with severe gram-negative infections, most C/T patients had beneficial outcomes despite their clinical complexity and late intervention with C/T.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000597

Introduction: The severe acute respiratory distress syndrome (ARDS), refractory to usual supportive care, due to COVID-19, expanded the use of extracorporeal support therapies worldwide (1). Under the surge of the pandemic, ECMO therapy was urgently organized and implemented according to Extracorporeal Life Support Organization (ELSO) recommendations (2) in our academic 17-beds ICU. As long-term survival benefit of receiving ECMO in COVID-19 remains uncertain (3), any additional data from patients connected on ECMO will be useful to determinate factors which can affect outcome.
Objectives: The 6-month outcome and factors correlated with survival of patients connected on ECMO during COVID-19 pandemic in Greece.
Methods: All patients treated with ECMO, in our department, during Covid-19 period were followed for six months after hospital discharge. Data are presented as median (IQR) and were analyzed with non-parametric Mann–Whitney U test and Spearman rank correlation.
Results: From February 2021 until June 2022, 20 patients (3 women and 17 men), median age 44.7(IQR 35.5–54.0) years old, have been supported with ECMO due to life threatening acute respiratory failure due to COVID-19. Prior to ECMO initiation, all patients had received protective ventilation with recruitment maneuvers, prone positioning sessions and neuromuscular blockade. P/F ratio was 64 (IQR 51.3–73.5) for more than 6 h, pCO_2 59 (IQR 55.3–72.0) mmHg, PH 7.32 (IQR 7.28–7.37) and respiratory system compliance was 24 (IQR 16–34.5) ml/cmH_2O. Median ECMO duration was 26 (IQR 15–63) days. Eleven patients (55%) were weaned from ECMO and 9 of them (45%) were discharged from the hospital (5 of them needed rehabilitation center). Six months later, all 9 were alive at home in a good health without requirement of oxygen therapy (5 of them returned to work).
The most frequent complication related to intervention was major bleeding, that appeared to 50%. Major causes of death were sepsis and multiorgan failure. Non-survivors as compared to survivors had longer duration of mechanical ventilation before ECMO initiation (11 vs 6 days, $p=0.036$), longer ECMO running time (63 vs 16 days, $p=0.04$), were more frequently complicated with acute renal failure (72.7% vs 11.1%, $p=0.07$) and multi-organ failure (81.8% vs 11.1%, $p=0.02$). The age was not correlated with outcome.
Conclusions: Under urgent circumstances ECMO implementation was feasible and obtained reasonable chances of six-month survival. In our cohort, factors found to be associated with in-hospital mortality were prolonged time from intubation to ECMO initiation, longer ECMO running time and acute renal failure. We didn't find any correlation between age and outcome as we only provided ECMO support in younger than 65 years old patients, in accordance with ELSO guidelines (2). Our results are consistent with data of Euro ECMO-Covid survey (4) and could add in the estimation of long-term outcome of COVID-19 patients connected on ECMO.

Endotracheal intubation of children and infants before transfer to paediatric intensive care—are we choosing the correct size tube?

D. Anderson[1], A. Hargedon-Lowe[1]
[1]Paediatric Intensive Care, Southampton General Hospital, Southampton, United Kingdom

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000599

Introduction: The use of cuffed endotracheal tubes (ETTs) is routine in infants and children requiring admission to a paediatric intensive care unit (PICU). Commonly, paediatric patients are intubated by non-paediatric anaesthetists or intensivists, before being transferred to a hospital with a PICU. Non-paediatric practitioners may be less familiar with optimal ETT selection in children, and traditional formulae can result in overestimation of ETT size—an issue discussed in European Resuscitation Council guidelines. Incorrectly sized ETTs can lead to complications including airway injury and extubation difficulties. The incidence of incorrect ETT size selection in the paediatric population has not been described previously.
Objectives: To describe the incidence of incorrectly sized ETTs used in patients aged 0–5 years admitted to a PICU from district general hospitals.
Methods: Data were collected from all intubated patients up to 5 years old who were transferred to our tertiary PICU over a 6-month period. Sizes of ETTs were compared to manufacturers guidance and to the traditional calculation used to decide ETT diameter. Further data were collected including how often incorrectly sized ETTs were changed in the first 24 h of PICU stay.
Results: 123 intubated patients were transferred to the PICU over the 6-month period. Of these, 117 had adequate clinical records for inclusion. The majority of intubated patients (97%) had cuffed ETTs inserted. Of patients with cuffed ETTs, 42% were incorrectly sized as per manufacturer's guidance. Of the patients with an incorrectly sized ETT, the majority (94%) had a larger size than recommended. The traditional formula adapted from calculating uncuffed ETTs was applied to the results, showing that 27% of ETTs incorrect as per manufacturer's advice were correct as per the calculation, 13% were incorrect by both the calculation and manufacturer's guidance, and 60% of cases were under 1 year of age and therefore too young to apply the formula. 24 h into PICU admission 56% of incorrectly sized ETTs were

left unchanged, 31% changed to the correct size, and 13% changed to another incorrect size.
Conclusions: Many patients intubated prior to PICU admission had an ETT size different to manufacturers guidance for age. In the majority of cases a larger than recommended tube was inserted. 24 h into their PICU stay, many patients either had the same incorrect ETT in situ or had their ETT changed to another incorrect size. These data raise concerns regarding risk of complications relating to oversized ETT placement in PICU patients, including subglottic or tracheal stenosis and failed extubation. Traditional calculations used to determine ETT diameter can overestimate the optimal size of ETT, however this only potentially explained incorrect tube size in 27% of our cases. Risks of complications may be reduced by promoting awareness amongst intubators regarding optimal ETT sizes, alongside greater vigilance of admission ETT size within PICU itself.

The contribution of the combination of transthoracic and transcranial ultrasonography to the titration of positive end-expiratory pressure in patients with acute respiratory distress syndrome and acute brain injury

T. Schizodimos[1], P. Ioannidis[1], G. Pitsiou[2], C. Iasonidou[1], E. Kerezidou[1], N. Kapravelos[1]

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000600

Introduction: Up to 30% of neurocritical care patients with acute brain injury (ABI) develop acute respiratory distress syndrome (ARDS), a complication that has been associated with poor outcome. The need to apply positive end-expiratory pressure (PEEP) in these patients can lead to an increase in intracranial pressure (ICP) measured invasively via intracranial probes. Non-invasive methods, such as lung (LUS) and brain (BUS) ultrasound, could help guide the appropriate mechanical ventilation (MV) strategy to improve lung function while protecting the brain from secondary injury.
Objectives: To investigate the alteration in the optimal PEEP level according to the use of LUS and BUS in mechanically ventilated patients with ARDS and ABI.
Methods: A preliminary, interventional, prospective clinical study was performed in a Greek ICU from June 2021 to March 2023, including 9 patients with ABI (3 TBI, 1 SAH, 5 ICH) and ARDS. GCS on admission, APACHE II and LISS score were recorded. The intervention included a gradual increase in PEEP level from 5 to 8, 12 and 16 cmH_2O. Simultaneously, LUS and BUS were performed after each PEEP level change, ICP and brain tissue pO_2 ($PbtO_2$) values and MV parameters were recorded, and arterial blood gas samples were obtained after 20 min. We performed LUS in 6 regions in each lung and calculated the LUS score. We also performed BUS and recorded the pulsatility index (PI) and diastolic flow velocity (FVd) values. During these maneuvers we ensured normal ICP (< 22 mmHg) and adequate cerebral perfusion pressure in all patients.
Results: Included 9 patients had a mean age of 55.1 (0SD ± 20.1) years, mean ICU admission GCS 6.4 (SD ± 1.66), mean APACHE II score 19.3 (SD ± 3.08) and mean LISS score 2.1 (SD ± 0.48). There was a marginally significant difference in LUS score regarding the PEEP 8–PEEP 16 pair ($p = 0.05$) (Table 1).

Table 1 (abstract 000600) LUS score comparison between PEEP levels

PEEP (cmH_2O) level pairs	p value
PEEP 5/PEEP 8	0.121
PEEP 8/PEEP 12	0.062
PEEP 12/PEEP 16	0.076
PEEP 5/PEEP 12	0.052
PEEP 5/PEEP 16	0.051
PEEP 8/PEEP 16	0.05

A non-significant trend towards a progressive decrease in LUS score as PEEP level increased was also observed (Figure 1). We were not able to detect a uniform pattern of reduction or rise in PI value as PEEP level was increased (Figure 2). Alterations in PI value was also not significant between different pairs of PEEP levels. A gradual rise in ICP was observed as PEEP level was increased but this was not statistically significant (Figure 3). All ICP comparisons between different PEEP levels were not significant. The lowest PEEP level with the greatest LUS score was compared with the maximum PEEP level that was safe according to BUS. There was no significant difference in PEEP according to LUS, BUS or ICP, although the BUS or ICP selected PEEP was lower than PEEP selected with LUS (Tables 2, 3).

Table 2 (abstract 000600) Comparison of selected PEEP according to LUS and BUS

Variable	PEEP (cmH_2O) (LUS)	PEEP (cmH_2O) (BUS)	p value
Median (IQR)	16 (0)	16 (0)	0.586
Mean (SD)	15.56 (SD 1.33)	14.67 (SD 2.83)	0.447

Table 3 (abstract 000600) Comparison of selected PEEP according to LUS and ICP

Variable	PEEP (cmH_2O) (LUS)	PEEP (cmH_2O) (ICP)	p value
Median (IQR)	16 (0)	16 (0)	0.773
Mean (SD)	15.56 (SD 1.33)	15.11 (SD 1.67)	0.447

Conclusions: LUS could contribute to the titration of PEEP in patients with ABI and ARDS. In contrast, BUS adjunct to invasive ICP monitoring did not appear to be helpful in our small sample. Since our study is ongoing, we expect a larger sample size to provide more accurate and reliable results in patients with ABI and ARDS.

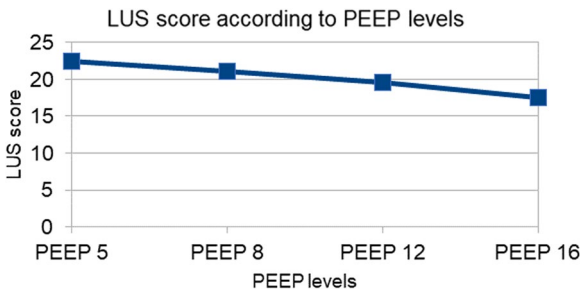

Figure 1 (abstract 000600) LUS score according to PEEP levels

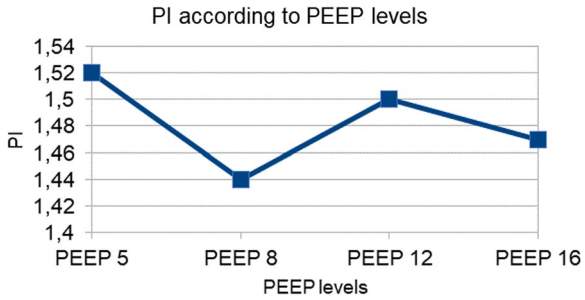

Figure 2 (abstract 000600) PI according to PEEP levels

Factors associated with delayed intubation in trauma patients with rib fractures

J. Catlin[1], S. Marks[2], A. Cano[3], M. Aboutanos[1]
[1]Surgery, Virginia Commonwealth University, Richmond, United States of America; [2]Medical Scientist Training Program, VCU School of Medicine, Richmond, United States of America; [3]Computer Science, Virginia Commonwealth University, Richmond, United States of America

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000601

Introduction: Blunt thoracic trauma is common and contributes significantly to trauma admissions. Even among patients with rib fractures who initially appear stable, many are at risk of developing respiratory failure. Targeted management of the higher risk subset of patients may prevent decompensation requiring intubation. And allow for the proactive identification of patients who will require intubation, enabling planned intubation before decompensation. We sought to identify risk factors for delayed intubation (intubation more than one hour after arrival) that would be identifiable on admission to facilitate more aggressive management and triage for patients at the highest risk of developing clinically significant respiratory failure.
Objectives: To identify factors associated with delayed intubation in patients with rib fractures.
Methods: This an analysis of data from the American College of Surgeons' Trauma Quality Improvement Project from 2020 to 21. We included patients 15 years or older with multiple rib fractures or flail chest and an AIS chest score of ≥ 2 or greater. We excluded patients going to the operating room from the emergency department (ED) or who had advanced directives limiting care. Descriptive statistics were used to compare characteristics of patients with delayed intubations to those patients not progressing to require intubation; multivariate logistic regression was used to identify factors associated with delayed intubation. Variables examined include patient demographics, injury type and severity, pre-existing conditions and initial vital signs upon arrival in the ED.
Results: A total of 146,908 patients were included in the analysis data set; 4.9% had a delayed intubation (median of 30 h (IQR: 6–74)). Characteristics of patients are described in Table 1. Partial multivariate model results are shown in Figures 1 and 2.

Table 1 (abstract 000601) Characteristics of patients by timing of intubation

	Delayed intubation	No intubation	Difference (95% CI))
Age (mean (SD))	59.0 (17.1)	57.8 (18.2)	1.2 (0.8–1.6)*
Male (%)	74.1	67.2	6.9 (5.8–7.9)*
ISS (mean (SD))	21.6 (10.1)	13.6 (6.5)	8.0 (7.2–8.2)*
Flail chest (%)	14.4	4.6	9.7 (8.9–10.5)*
Pulse (mean (SD))	95.3 (21.8)	86.7 (17.8)	8.6 (8.2–9.2)*
SBP (mean (SD))	130.8 (29.1)	139.8 (25.4)	8.8 (8.3–9.7)*
GCS (mean (SD))	14.2 (1.9)	14.8 (0.6)	−0.60 (0.56–0.65)*
Supplemental O_2 in the ED (%)	38.9	16.7	22.2 (21.1–23.4)*

*$p < 0.001$.

Conclusions: Patients who progressed to requiring intubation were more likely to have flail chest injuries (vs only multiple rib fractures) and have pre-existing medical conditions. Need for supplemental oxygen upon arrival, higher ISS and other physiological parameters in the ED were also associated with delayed intubation. These results may aid in the development of prediction tools to identify patients who would benefit from more aggressive management within the first hour of presentation and guide patient triage to the appropriate level of care.

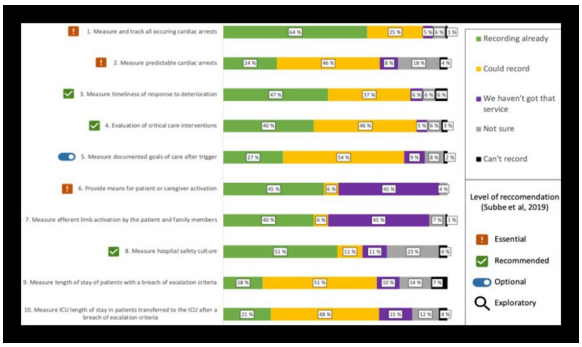
The metric of rapid response systems: can you measure the quality of your rapid response system?

R. K. So[1], E. Edwards[2], F. Haegdorens[3], C. Subbe[4]
[1]Intensive Care Unit Adults, Albert Schweitzer Hospital, Dordrecht, Netherlands; [2]Betsi Cadwaladr University Health Board, Tremadog, United Kingdom; [3]Department of Nursing and Midwifery Sciences, University of Antwerp, Antwerpen, Belgium; [4]Bangor University, Bangor, United Kingdom
Correspondence: R. K. So
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000602

Introduction: In 2018 the international society for Rapid Response Systems (iSRRS) convened a consensus conference to agree on ten metrics for quality improvement1 related to structure, process and outcome of rapid response system (RRS) with outcomes following the domains of the quadruple aim.
It is not known whether hospitals are currently collecting data on these indicators or are capable to collect these data. This is an essential piece of information needed to initiate regional collaboratives that strive to improve the quality and safety of patients at risk of catastrophic deterioration in hospital.
Objectives: This study set out.

1. To assess readiness of international hospitals to implement recommended quality metrics for RRS
2. To evaluate feasibility of improvement collaboratives based on currently collected data categories

Methods: The study is a prospective international digital survey. The survey captures the current standard of data collection against the recommended metrics of the iSRRS and a small number of contextual items.
Inclusion criteria: hospitals who have a Rapid Response System (RRS) or are in the process of setting up a RRS and caring for acutely unwell patients. Exclusion criteria: hospitals caring only for palliative patients or specialising in post-acute care were excluded.
Recruitment
Participating units were recruited through national societies of critical care or Critical Care Outreach, national or international conferences and through social media postings by the iSRRS.
Data were collected, from July 1st to November 30th 2022, through an online survey.
(https://www.surveymonkey.co.uk/r/iSRRS_METHOD3_Survey_2022).
Data collection
The survey collected data on the size of the hospital (approximate bed number), location of the hospital (region), nature of the current RRS, and details on the ability to collect data for each of the 10 recommended quality metrics1. Response to each for the metrics contained categorical responses: recording already, could record, can't record, haven't got that service, not sure.
Statistics and analysis
Statistical analysis was limited to a descriptive evaluation collating capability of participating units. The predefined analysis plan included reporting of results by country and by size of hospital.
Results: In total 109 hospitals participated in the survey, of which 92 hospitals located in 11 countries could provide full data: UK (n = 45), Australia & New Zealand (n = 25), USA & Canada (n = 13), Europe (n = 8), Singapore (n = 1). Half of all hospitals (54%) can be considered as large centers (i.e. > 500 beds). Percentages of hospitals indicating the application of the ten core metrics on the assessment of Rapid Response Systems (n = 109) are presented in the figure.
Conclusions: What we have found: most of the metrics are feasible for organizations to measure and track, but metrics 6–8 are culturally linked and require more effort.
Clinical implications: Breakthrough collaboratives could help clinicians to share data and learning for improvement based on the wide availability of the metrics.
Research implications: Context is needed for the non-measurables to understand barriers and enablers for wider spread of high quality care.



Percentages of hospitals indicating the application of the ten core metrics on the assessment of Rapid Response Systems

Prevalence of spinal injury in trauma patients with hemodynamic or neurological instability: 3-year analysis of data from Lombardia (Italy) trauma registry (LTR)

V. Punzi[1], M. Leone[2], R. Giudici[3], M. Brioni[2], G. Bassi[3], C. Martinet[2], B. Franchi[4], E. Chironi[4], F. Marrazzo[3], S. Peron[5], F. Villa[6], V. Terzi[3], E. Borotto[4]

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000603

Introduction: The shared prehospital management of critically injured trauma patients assumes the presence of spinal injury until proven otherwise (1). However, there is growing evidence documenting harm and a delayed time to intervention associated with the use of rigid collar and spinal stabilization (2, 7), especially in trauma victims with hemodynamic or neurological instability (3, 4). In these patients, any prehospital procedure (spinal immobilization included) should never preclude or delay lifesaving interventions as it is proved that longer on-scene time is associated with increased mortality (5). Besides, there is no randomized trial showing superiority of usual spinal immobilization (cervical collars, long boards) over manual in line stabilization and recent literature is even highlighting several complications related to their use (increased intracranial pressure, reduced functional residual capacity, delay in airway management, pressure lesions) (6–8).
Objectives: To evaluate the prevalence of spinal injury in trauma patients with hemodynamic or neurological instability and to describe their median on-scene time and total prehospital time.
Methods: Inclusion criteria were trauma patients admitted to the trauma centers of Lombardia, who underwent a total body CT scan and whose data were reported in Lombardia Trauma Registry (LTR). In this LTR registry-based retrospective cohort study, demographic data, level of prehospital care (advanced life support—ALS, basic life support—BLS), prehospital time, abbreviated injury score (AIS, 2015 version), injury severity score (ISS) of all trauma patients were retrospectively reviewed. Moreover, the prevalence of spinal injuries ($AIS \geq 3$), their localization (cervical or thoracic) and the severity of spinal lesions (spinal cord injuries or unstable vertebral fractures or ligamentous injuries) were recorded. Conventionally, an $ISS \geq 16$ was defined as major trauma (2).
Prehospital hemodynamic and/or neurological instability was also detected. Hemodynamic instability (Hem-I) was defined as prehospital shock index (SI) > 1 or cardiac arrest, while neurological instability (Neu-I) was defined as Glasgow Coma Scale (GCS) < 9 and pupilar signs of intracranial hypertension. Moreover, prehospital time (PHT), defined as time elapsed between BLS or ALS arrival on scene and the arrival at the hospital, and on-scene time (OST) was recorded. Data are presented as median and interquartile range (IQR).
Results: The cohort is based on 7334 patients, victims of major trauma, from January 2020 to December 2022 and included in LTR. Among the 361 patients (77.8% male, 53 ± 15 years old, overall mortality 1.4%) that suffered from post-traumatic spinal injury (SPI), 72 (19.9%) reported spinal cord injury (SCI) and 299 (82.8%) vertebral unstable injuries (VUI). Details of these lesions according to their location (cervical or thoracic), their prevalence in hemodynamic or neurological unstable patients, the median OST in each group, and the severity of trauma (defined by ISS) are summarized in Table 1. Median PHT for Hem-I and Neu-I patients was respectively 54 (42–70) and 54 (42–68) minutes while PHT in stable patients was 49 (38–68).
Conclusions: The prevalence of SPI in Hem-I and Neu-I patients was respectively 12.1% and 8.3%; in these patients the median OST and total PHT was longer than recommended, especially in Neu-I patients with cervical injury (major head trauma). This result suggests that the goal of optimizing prehospital time in case of instability, especially in patients with early signs of intracranial hypertension, for most patients may be reached also by customizing immobilization protocols without an increased risk of spine lesion.

	Total		Hem-I		Neu-I		ISS
	N° (%)		N° (%)	OST (min)(IQR)	N° (%)	OST (min)(IQR)	Median (IQR)

Impact of an early and comprehensive communication strategy on the long-term prevention of depressive symptoms in patients with severe Covid-19

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000604

Introduction: A important number of patients hospitalized in Chile with COVID-19 have required Intensive Care Unit (ICU) (1). The isolation measures implemented in the ICU to reduce the spread of infection (social distancing, suspension of visits, etc.), and the increase in the number of severe patients, make it difficult to maintain fluid and constant communication between patients, family members and health care team (2). Under these conditions, communication has been a permanent challenge that has not been easy to address. The usual strategies for communication have been proved ineffective and difficult to implement given the increasing demand for care to which these teams are subjected. We know from recent reports about the negative impact not being able to maintain communication has on the mental health of patients, family members and health teams (3–5) and it is urgent to develop and implement simple and effective strategies that facilitate such communication, and that in turn does not become an additional workload for health teams.
Objectives: To determine the effect of an early and comprehensive communication strategy (ECCS) versus standard care on the rate of depressive symptoms at 3 and 6 months post ICU discharge in patients with severe Covid-19.
Methods: A longitudinal, quasi-experimental before-after, multicenter study was conducted in patients hospitalized in the ICU for severe COVID-19 (NCT05035563). The intervention consisted of a comprehensive and intensive strategy to facilitate communication between family, patients and healthcare team through written material, via web (tablet and webmaster) and telephone. Participants were evaluated 3 times: at ICU discharge and at 3 and 6 months post ICU discharge. Subjects completed a survey screening for anxiety and depression symptoms (Hospital Anxiety and Depression Scale—HADS), and post-traumatic stress disorder (Event Impact Scale-Revised—EIS-R). In addition, sociodemographic and clinical variables in addition to clinical outcomes of interest were collected. The results are reported using mean ± standard deviation (SD) and percentages and compared using chi-square or t-test as deemed appropriate. The associations between risk factors and outcomes were presented as odds ratios (ORs) and 95% CIs, after adjustment for selected potential confounders. The study was approved by the ethics committee.
Results: A total of 444 patients were recruited between March 2021 and February 2022, of whom 351 patients corresponded to the control group or usual communication strategy and 93 patients to the intervention group or early and comprehensive communication strategy. Seventy-nine percent of the participants survived and only 2 patients died after hospital discharge. Follow-up was completed at 3 months post ICU discharge for 117 participants and at 6 months post ICU discharge for 65 patients. The demographic and clinical characteristics of the cohort are shown in Table 1. Participants were 63% male, the main comorbidities were obesity (56%), hypertension (30%) and diabetes II (21%). Participants had prolonged ICU and hospital stay, 65% of the cohort presented delirium in ICU and 29% (n = 119) required tracheostomy. 260 participants were in prone position during their ICU stay, with an average of 6.5 days in prone position, while 83% (n = 338) of the cohort required neuromuscular blockade in their treatment. Only 6% (n = 25) were readmitted to the ICU. In relation to psychological symptoms post ICU discharge, of the total subjects evaluated at 3 months post ICU discharge (n = 114), 21% presented anxiety, 20% depression and 36% PTSD; while at 6 months post ICU discharge follow-up (n = 65), 31% presented anxiety, 17% depression and 25% PTSD. Mixed-effects logistic regression analysis showed that the intervention under study decreased depressive symptoms (OR, 0.54; CI 0.25–1.15) and anxiety (OR, 0.83; CI 0.43–1.58), in the long term, but these results did not present statistical significance.
Conclusions: In this study concerning the effects of an early and comprehensive communication strategy on long-term psychological symptoms in patients hospitalized in ICU for severe COVID-19 in Chile, participants reported high rates of depression, anxiety, and long-term post-traumatic stress, however, there was no significant decrease in the interventional group.

Table 1 (abstract 000604) Patients demographics and clinical characteristics

Variable	Total n = 444	Usual communication strategy n= 351	ECCS n = 93	p-value
Age, media (SD)	53 (±14)	52 (±14)	59	**<0.001**

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000605

Introduction: In the last decade, artificial intelligence, large databases and neural network models have been used to develop various predictive models. Many of these models aim to predict the mortality of

patients in the ICU using different variables. Despite achieving adequate AUC-ROC, none of them have been implemented in daily clinical practice.
Objectives: Validating a predictive model of ICU discharge mortality using data extracted automatically from the clinical information system (CIS).
Define the data infrastructure to allow predictive model to be automatically implemented during the patient care process.
Methods: Prospective study in a 30-bed polyvalent ICU (Tarragona, Spain). All patients admitted to the ICU since the implementation of de CIS (2018–2022) were included. Variables for creating the predictive model were selected according to professional criteria (gender, admission type, admission reason, admission source, APACHE, SOFA, SpO_2/FiO_2, pH, creatinine, lactate, weight, height and RASS). Demographic variables, severity scores, ventilation parameters and laboratory data from the first 24 h after ICU admission was collected through the extraction, transformation and loading (ETL) process. The data was extracted using SQL and processed using Python. Null values were replaced through imputation. The 80% of the data was used to train a neural network model (multilayer perceptron) and the remaining 20% was used to validate the results.
To implement the real-time neural network model, it was isolated and inserted in compressed format into a Django project that runs in a Docker container from a server. Then, using Django and Python, the ETL process was replicated to feed the neural network model with real-time data. Finally, the model performs a patient mortality prediction that is saved and displayed on an ICU web map using HTML and Javasript (Figure 1).
Results: 3979 patient stays were included. Mortality was 15%. The model showed an accuracy of 81% and an AUC ROC of 80%. The model was integrated into de UCI maps, which show the current status of patients in real-time (Figure 2). Every time the map is accessed, the entire data pipeline is executed to obtain a mortality prediction for each patient. Clinicians are able to view the mortality prediction as a probability of death between 0 and 1. The model is not applied in patients with less than 24 h in the ICU due to lack of data.
Conclusions: Implementing the mortality prediction value obtained through a neural network based on real-time data with a complementary information tool, visible and actionable by the clinician, is the only way to assess its real impact on clinical practice.

Health-related quality of life trajectories in critical illness: protocol for a Monte Carlo simulation study

B. S. Kaas-Hansen[1], M. Hylander Møller[1], M. B. N. Kjær[1], H. C. Thorsen-Meyer[1], M. E. Larsen[1], A. Perner[1], A. Granholm[1]

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000606

Introduction: Health-related quality of life (HRQoL) is a patient-important outcome enjoying increasing use in intensive care unit (ICU) trials [1]. Although it does capture salient aspects of clinical improvement in ICU patients that elude harder outcomes such as mortality, the most common approach of sampling HRQoL once after 6 or 12 months is suboptimal. Several aspects of HRQoL have recently been or are currently being reviewed [1–3], and an operationalisation is needed that both reconciles the seemingly paradoxical effect of interventions lowering mortality while hurting HRQoL [2] (caused by truncation due to death [4]) and is sensitive to early/accelerated improvement in patients who more quickly reach their eventual HRQoL level [5]. To this end, we propose the area under the HRQoL trajectory curve (AUTC) as a candidate solution.
Objectives: We will undertake an extensive Monte Carlo simulation study to gauge the performance of AUTC and compare it with that of the conventional single-sampling approach.
Methods: We will simulate 100,000 two-arm randomised clinical trials, as recommended by FDA when designing clinical trials [6], with equal, fixed randomisation for each of 15,360 clinical scenarios. These scenarios arise by combining unique values of 7 simulation parameters such as sample size, 6-month mortality, proportion of *mortality benefitters* in the active arm and dampening effect of mortality on HRQoL at ICU discharge.
The clinical scenarios are based on published HRQoL values, and to the extent possible on EQ-5D, from real patients, to ensure the relevance of the results and insights for our population of interest: critically-ill patients potentially eligible for a randomised, embedded, multi-factorial, adaptive platform (REMAP) ICU trial [7] such as the Intensive Care Platform Trial (INCEPT, www.incept.dk).

We will simulate fortnightly HRQoL sampling to balance the desire for high temporal resolution with practical considerations. Intra-arm and intra-patient noise will be added; the former to reflect the spread of HRQoL within arms and the latter calibrated to yield an intra-class correlation of 0.80 (lower range of excellent agreement [8]). Finally, the resultant HRQoL levels will be connected with straight lines to yield one stepwise-linear HRQoL trajectory per fictive patient.
For each clinical scenario we will compute the following statistics:

1. HRQoL (mean, standard error, median, inter-quartile range) in survivors and all patients at end of follow-up; for the all-patient calculation, patients who die before end of follow-up will be assigned HRQoL = 0
2. Absolute and relative cumulative attained HRQoL
3. Type-1 error rate and power for scenarios without and with effect in the active arm, respectively.

Results: We expect to have run all simulations by and present the results at LIVES 2023.
Conclusions: The results of this study will inform subsequent work on devising and testing a low-friction data-collection system to collate HRQoL trajectories from real ICU patients and quantify the effect sizes by way of Bayesian regression analyses, in future ICU trials and observational research.

Clonidine dose finding for sedation and delirium

E. Klaas[1], H. van den Oever[2], M. Arbouw[3], M. Zeeman[4], EVDH M[5]
[1]Intensive Care, Deventer Hospital, Deventer, Netherlands; [2]Intensive Care Unit, Deventer Hospital, Deventer, Netherlands; [3]Department of Clinical Pharmacy, Deventer Hospital, Deventer, Netherlands; [4]Department of Clinical Geriatrics, Deventer Hospital, Deventer, Netherlands; [5]Office of Science, Deventer Hospital, Deventer, Netherlands
Correspondence: E. Klaas
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000607

Introduction: Clonidine is commonly used off-label in the intensive care (ICU) to manage sedation and agitation in critically ill patients. However, the optimal dose of clonidine as an add-on sedative in the ICU is unknown. The use of clonidine is associated with side effects such as hypotension and bradycardia. No formal dose-finding studies for clonidine as an add-on to standard sedation have been performed [1].
Objectives: The objective of the study was to provide a dosage recommendation for clonidine use in the ICU. Three aspects of clonidine were studied to determine the optimal dose within ventilated and sedated ICU patients: (1) hemodynamic adverse events (2) sedative effects and (3) *days alive without sedation and delirium.*
Methods: This was an exploratory study performed as a post-hoc analysis of a pharmacokinetic open-label study of clonidine in ventilated ICU patients [2]. The study included 24 mechanically ventilated and sedated adults admitted to a mixed medical and surgical ICU of the Deventer Hospital. Patients received clonidine after standard sedation with morphine, combined with midazolam or propofol. Patients received clonidine 600 (n = 8), 1200 (n = 8) or 1800 µg/day (n = 8). Four patients in each group received a loading dose of 50% of the daily dose in 4 h. Richmond sedation scores, delirium scores, hemodynamic parameters and clonidine plasma levels were measured at several time points during follow up for a maximum of 9 days.
Results: No association was found between hemodynamic adverse events and clonidine dose ($p = 0.114$). Patients who received a loading dose had a 1.7 fold higher incidence of hemodynamic adverse events ($p = 0.004$). There was an association between the number of blood pressure events and the clonidine plasma concentration at each given time point ($p = 0.027$). No association was found between the level of sedation and clonidine dose ($\beta = -0.160$, CI −0.338–0.017, $p = 0.077$). The number of days alive without sedation and delirium was significantly higher in the 1800 µg/day group compared to the other two dose groups ($p < 0.001$), Figure 1.
Conclusions: This pharmacodynamic study supports the use of clonidine at a fixed daily dose of 1800 µg/day as an add-on sedative and in the prevention of delirium in ventilated and sedated ICU patients. This recommended dosage should be used with caution and should be further investigated in a randomized clinical trial to confirm its safety and effectiveness in a larger patient population.

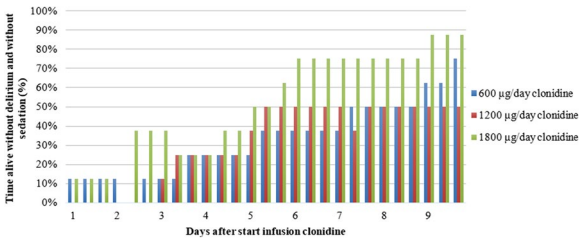

Figure 1 (abstract 000607) Patients alive without sedation and delirium comparing the clonidine dose groups. Data presented as the percentages of time patients were alive without sedation or delirium. Delirium and RASS scores were measures three times a day, every eight hours

Improvement of SSC guidelines compliance is associated with improvement of outcome of septic patients admitted to ICU: a quality improvement study

K. Belkhouja[1], A. Aljubairy[1], B. Aljedaani[1], W. Algarni[1], M. Jarad[1], M. Alshanqeeti[1], H. Al-Sharif[1]
[1]Intensive Care Department, King Fahad Armed Forces Hospital, Jeddah, Saudi Arabia
Correspondence: K. Belkhouja
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000609

Introduction: Sepsis and septic shock are major healthcare problems. The last Surviving Sepsis Campaign (SSC) guidelines were updated and published in 2021. The SSC guidelines compliance in our department is unknown and the impact on the outcome of the SSC guidelines compliance is not clear.
Objectives: To determine the rate of compliance with the SSC guidelines 2021 and the impact on the outcomes.
Methods: Retrospective and prospective, observational, quality improvement study of compliance to the SSC guidelines 2021, was conducted in King Fahad armed forces hospital, Kingdom of Saudi Arabia. The study had three periods (before and after study). The first period, Retrospective study (pre-intervention group) from November 1, 2021, to April 15, 2022, followed by an interventional period from April 15, 2022, to April 24, 2022. The third period is the prospective observational study (post-intervention group) from April 25, 2022, to March 25, 2023. All patients met the criteria for diagnoses of sepsis or septic shock and needs ICU admission were included. The exclusion criteria were patient who the decision of do not resuscitation (DNR) was activated within the first 3 days of ICU admission; pregnant patients; Drug overdose patient; Trauma or burn injury; Immunocompromised patients. During this period, we collect data using data collection sheet. The primary outcome was to evaluate the rate of compliance with SSC guidelines 2021 before and after intervention. The secondary outcomes were to assess the ICU morbidity and mortality before and after intervention. All statistical analysis was performed by using software Microsoft Excel and SPSS 20.0.
Results: A total of 161 patients with sepsis or septic shock were included, 77 patients in the pre-intervention group and 84 patients in the post-intervention group. The two groups were similar on term of baseline characteristics, and the severity of illness assessed by APACHE II score, SOFA score and requirement of organ support. In the pre-intervention group, the compliance to SSC guidelines was 35.1% (27 patients) versus 77.4% (65 patients) in the post-intervention group with $p < 0.001$. During ICU stay the complications was significantly higher in the pre-intervention group compared to post-intervention group (44.2% versus 23.8%; $p = 0.006$). The rate of ICU mortality during pre-intervention group was 28.6% (22 patients) versus 15.5% (13 patients) in the post-intervention group with $p = 0.044$ (OR, 0.45; 95% CI, 0.21–0.98). During ICU stay, the DNR decision was activated in 27 patients (35%) of the pre-intervention group versus 17 patients (20.2%) of the post-intervention group with $p = 0.035$.
Conclusions: Appropriate intervention induces significant improvement of compliance to SSC guidelines with significant reduction of ICU morbidity and mortality.

Prognosis survival score at admission for subarachnoid haemorrhage

L. Simón Miguel[1], B. Dopazo López[1], M. Mourelo Fariña[1], M. Sanchez De La Iglesia[1]
[1]Intensive Care Medicine, [CHUAC] University Hospital of A Coruña, A Coruña, Spain
Correspondence: L. Simón Miguel
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000611

Introduction: Spontaneous subarachnoid haemorrhage is a rare cause of stroke, but it causes high mortality. Other studies describe a variable long term survival, using predicting models which doesn´t count on physiological variables. The aim of this study is to develop a risk stratification survival score for HAS.
Methods: Retrospective study of 536 patients diagnosed with SAH admitted to the ICU of the University Hospital A Coruña 2003–2013.
Results: The middle age of the patients was 56.9 ± 14.1 years old. An aneurismatic lesion (A-SAH) was diagnosed in the 73.9% of the patients. The light discapacity of the patients after 6 months had middle values in the Glasgow Outcome Scale (GOS) and Rankin (mRS) around 4.3 ± 0.9 points and 1.5 ± 1.4 points respectively, and with a favorable recovery at 12 months GOS 4.6 ± 0.8 and mRS 1.0 ± 1.4). A 16.3% of the patients discharged from the hospital passed away later.
The survival score developed is composed by the variables independently associated with the survival: older age ($HR = 1.02$; $p = 0.001$), Fisher score (Fisher 3 $HR = 1.82$; $p = 0.033$) (Fisher 4 $HR = 2.25$; $p = 0.001$), APACHE II at 24 h ($HR = 1.03$; $p = 0.047$), and SOFA at day 0 ($HR = 1.1$, $p = 0.07$). For global survival after hospitalisation, based on the multivariant model, a nonogram was developed for predicting, in a patient admitted due to SAH, the estimated survival at 30 days, 6 months, 1 year, 5 years and 10 years after the episode.
The model showed an adequate discriminant capacity, with a C index of 0.797 and a corrected C index of 0.791. Likewise, it showed a good calibration at short-middle time but infraestimating the survival after 1 and 5 years.
Conclusions: One month after hospitalisation, two thirds of the patients were alive, and more than a half at 10 years. The main mortality cause during the first year was related with SAH, with a change from that moment to non related causes. The mortality was associated with older age, higher risk of complications in admission Fisher score, a higher severity for APACHE II in the first 24 h and SOFA at day 0, and the presence of rebleeding during ICU stay. The long term survival predictive model developed with the described variables has an adequate discrimination and calibration. That model doesn't require a previous etiological diagnosis and considers the initial organ disfunction impact.

Impact of diesel exhaust particles on the evolutive phenotype of acute respiratory distress syndrome

A. Gaudet[1], P. De Nadai[2], G. Piga[1]
[1]Intensive Care, CHU Lille - Center for Infection and Immunity of Lille, LILLE, France; [2]U1019 Team 13, Pulmonary Immunity, University of Lille - Center for Infection and Immunity of Lille, Lille, France
Correspondence: A. Gaudet
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000613

Introduction: The impact of diesel exhaust particles (DEP) on late-stage acute respiratory distress syndrome (ARDS) remains unknown. Published data suggest that prior exposure to DEP may increase the risk of progression to fibrosis in ARDS (1, 2).
Methods: After intranasal administration of DEP (10µg) at a rate of 3 times/week for 1 week, C57BL/6 male mice aged 6 to 8 weeks were exposed to LPS at a dose of 5 mg/kg (3) by intratracheal route. Three weeks after exposure to LPS, the alveolar inflammatory response was assessed by the count of immune cell populations in the bronchoalveolar lavage fluid (Figure 1). Mice exposed to PBS instead of DEP or LPS were used as controls.
Results: Macrophages represent most immune cells found in BAL for all mice. We find a higher value for BAL macrophages in mice exposed to DEP and LPS, compared than in mice exposed to DEP and PBS, or PBS and LPS (Figure 2).
Conclusions: Our preliminary results suggest a possible effect of pre-exposition to DEP on alveolar inflammation. We plan to conduct further explorations, including automated measurements of histological lung fibrosis (4) and evaluation of lung regional elasticity by atomic force microscopy (5), to complete these results.

Introduction: Lung and diaphragmatic injury can be related to an excessive respiratory drive during mechanical ventilation (MV) (1). Usually, it is assessed by the airway occlusion pressure (Pocc) or by the esophageal pressure (2).
Objectives: To evaluate a new approach for monitoring the respiratory drive that utilizes the muscle pressure (Pmus) signal generated by equation motion (EM). This signal allows us to identify the real neural inspiratory time (3). For our purpose, we designate, T0: Tonset effort, T1: Tonset of inspiratory flow. We hypothesized, therefore that T0-T1 is indicative of isometric muscle (Figure 1); and it could be useful to measure D pressure at 100 ms (P100) continuously, without the inconveniences due to occlusions and esophageal catheter. Our goal was to compare the measurement of Pmus, at 100 ms with the data obtained from the Pocc.
Methods: We studied a group of mechanically ventilated patients during the weaning time, with different levels of support, instrumented with esophageal/gastric/tracheal, airway pressure (Paw) and flow. Pmus was calculated applying the equation of motion (EM) by means of respiratory mechanics, calculated using standard methods. 200 cycles was analysed. We chose the maximum sensitivity of the trigger allowed by the ventilator. After an occlusion manoeuvre was performed, Pocc 100 was measured in Paw signal between 0 and 300 ms (ms) after the occlusion, in which the regression of the Paw every 100 ms, obtain the highest slope and $R2 > 0.95$ (Figure 1). Ten consecutives regular cycles prior to occlusion were analyzed to measure the Pmus 100 between T0-T1, carry out by regressions every 50 ms, searching for the optimal slope with $R2 > 0.95$; and compared with the data obtained from an occlusion. Demographics data was recording. The results are expressed as mean ± SD, median (IRQ), or percentage. The comparisons by t-student. Bland–Altman and linear regression analyses were performed (Figure 2).
Results: Patients N 27. Age: 64.22 ± 8.10 years. Males 74.2%. PaO_2/FiO_2 265.72 ± 121.47. Diagnosis: SARS-COV2 8. ARDS-pneumonia 4. Lung transplant 4. Cardiac Surgery 2. Abdominal sepsis 3. Trauma 4. Others 2. Days MV 6 (1.74–15). Inspiratory pressure 10.55 ± 5.22; PEEP 7.56 ± 1.95 cmH_2O. Elastance (Ers): 22.99 ± 6.45 cmH_2O/L; Total resistances (Rrs): 14.69 ± 4.45 $cmH_2O/L/s$.
Conclusions: The measurement of the respiratory drive by means of the Pmus signal is precise, and non-intrusive, and allows its continuous monitoring. This method can be incorporated into the ventilator monitoring.
Table (abstract 000614) Agreement of the measurements of P100 between the both methods: Pmus vs Pocc. Note no significant differences and high correlation between both methods

P100, cmH_2O		Mean (SD)	P	Means Difference (SD)	Limits agreement, CI 95%	R^2
All Data	Pmus	4.69 (2.81)	0.696	-0.14 (0.21)	-0.57 a 0.28	0.99
	Pocc	4.83 (2.29)				
High PSV	Pmus	3.35 (1.76)	0.761	-0.15 (0.22)	-0.58 a 0.28	0.98
	Pocc	3.49 (1.82)				
Middle PSV	Pmus	3.34 (1.76)	0.125	-0.17 (0.21)	-0.59 a 0.25	0.99
	Pocc	4.12 (1.82)

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000615

Introduction: Stroke is one of the leading causes of mortality and disability worldwide. Stroke severity measured by the baseline National Institutes of Health Stroke Scale (NIHSS) is a strong predictor of clinical outcomes in acute ischemic stroke (AIS). On the other hand, alterations in glucose (GLC) have been associated with stress and outcomes in AIS. In a Latin American population, we analyzed the percentage change in NIHSS (%ΔNIHSS) and glucose (%ΔGLC) at 24 h as a prognostic tool to predict hospital survival.
Objectives: This study describes the demographic characteristics, clinical outcomes and prognostic utility of %ΔNIHSS and %ΔGLC at 24 h in patients treated with intravenous thrombolysis within 4.5 h of AIS.
Methods: A retrospective cohort of patients admitted between 2007 and 2022 in Bogotá, Colombia, was studied. Subjects diagnosed with AIS and treated with intravenous alteplase who required Intensive Care Unit (ICU) were included and baseline characteristics, etiology, and in hospital outcomes were measured. %ΔNIHSS was defined as ([admission NIHSS score − 24 h NIHSS score] × 100/admission NIHSS score] and %ΔGLC as ([admission GLC − 24 h GLC] × 100/admission GLC]. Receiver operating characteristic curve (ROC) analysis was done in order to establish cut-points for %ΔNIHSS and %ΔGLC values. Descriptive and inferential statistics were performed as well as survival analysis techniques (Kaplan–Meier survival estimation and Cox-Proportional Hazard Model).
Results: We analyzed the outcome in 254 patients. The median age was 71 years, 128 (50.3%) were females. Significant demographic variables found were age, chronic kidney disease, heart failure, atrial fibrillation, carotid stenosis, and Charlson comorbidity index ($p < 0.005$). All patients were admitted to the ICU. The median duration of hospital stay in patients who survived was 8 days (interquartile range—IQR—6–14), in those who did not survive, it was 6 days (interquartile range—IQR—4–12). ROC curve comparison AUC 0.8776 showed that a %ΔNIHSS > 20 was a predictor for survival (HR: 0.109; 95% CI 0.03–0.33 $p < 0.001$) (Figure 1). In a multivariate model, the %ΔNIHSS > 20 continued to be an excellent predictor for survival (HR: 0.117; 95% CI 0.03–0.36 $p < 0.001$), compared to the %ΔGLC > 2 AUC 0.6113 (HR: 0.538; 95% CI 0.21–1.34 $p = 0.184$) (Figure 2). The Kaplan–Meier curve shows a statistically significant difference in survival probability between %ΔNIHSS ≥ 20 and %ΔNIHSS ≤ 20 (Figure 3).
Conclusions: This study demonstrates the prognostic value of the %ΔNIHSS > 20 for AIS. To our knowledge, this is the first description in the literature of the %ΔGLC as a potential prognostic value in AIS. Prospective and bigger studies are required to address the true added value of the %ΔGLC. %ΔNIHSS is a useful, feasible, and a universal prognostic tool for AIS.

Improving emergency airway planning on a district general hospital intensive care unit: results and barriers

J. Gibson[1], N. Botting[2]
[1]Critical Care, East Surrey Hospital, Redhill, United Kingdom; [2]Critical Care, Worthing Hospital, Worthing, United Kingdom

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000619

Introduction: The fourth National Audit Project of the Royal College of Anaesthetists and the Difficult Airway Society evidenced that approximately one-quarter of major airway complications occur outside of the theatre environment, in areas that include the intensive care unit [1]. When major airway events occurred, they commonly led to death or severe neurological disability. Recommendations were made that included planning and documentation for 'inadvertent tracheal tube or tracheostomy displacement or obstruction' in critical care [1].
Objectives: We sought to establish whether the creation of a dedicated electronic form improves documentation of emergency airway management plans for patients with a tracheal tube or tracheostomy in the critical care environment. Barriers to completion were considered.
Methods: An initial audit of emergency airway plan documentation was performed for all patients with a tracheostomy admitted to the critical care unit of a district general hospital over a three-year period (February 2019–January 2022). Subsequently, an emergency airway management form was created (Figure 1) on the hospital critical care information system (IntelliSpace Critical Care and Anaesthesia, Philips). A re-audit was undertaken to establish completion rates of this emergency airway management document for all patients with a tracheal tube or tracheostomy.
Results: Pre-intervention, zero percent of patients (0 of 62) cared for with a tracheostomy over a three-year period had documented plans for emergency airway management. Following the creation of the dedicated electronic emergency airway management plan form, accompanied by education and inclusion of the form in the daily safety huddle, completion rates increased to 26.8% (36/134) for patients with tracheostomies or tracheal tubes.
Conclusions: Documentation of an emergency airway management plan remained low, despite education and the creation of a dedicated electronic form. This continues to expose patients to unnecessary risk in the event of a major airway complication occurring during their admission to this district general hospital critical care unit. Possible explanations are numerous, but locally may include the rotation of critical care trainees every few months, inadequate teaching intervals and the burden of electronic documentation. Suggested ways to improve completion rate include regular educational refresher sessions to critical care staff members, inclusion of the form during the induction of new critical care staff and making the electronic form compulsory at the time of critical care admission, given completion of forms is improved in other areas of healthcare when these are made compulsory [2, 3]. These simple interventions may greatly improve emergency airway planning and reduce the risk of preventable morbidity in the event of a major airway emergency.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000620

Introduction: Respiratory rate is an important indicator of respiratory failure, however, upon increased respiratory loading, changes in tidal volume (TV) precede increases in respiratory rate (1). TV measurement in non-intubated critically ill patients is challenging given the need for accurate flow measurements. We hypothesized that measurement of diaphragm excursion (DE) could serve as surrogate for TV.
Objectives: The aim was to determine the relationship and correlations between changes in TV and DE within healthy volunteers and patients on invasive mechanical ventilation (IMV).
Methods: Patients with tracheostomy, BMI > 35 kg/m^2, exacerbation of obstructive lung disease, neuromuscular disease or diaphragm paralysis were excluded. This prospective study was executed in two hospitals in the Netherlands after ethical approval. TV-DE relationships were investigated using a linear mixed model with DE as fixed effect with a random intercept per participant. Simultaneous measurements of TV and DE were obtained in ≥ 3 breaths per participant. The right hemidiaphragm was visualized using subcostal ultrasound in M-mode. To determine TV, healthy volunteers were breathing through a mouthpiece with flow sensor connected to a signal acquisition system while wearing a nose clip. In patients on IMV measurements were performed during CPAP (5 cmH_2O).
Results: IMV patients (N = 21) and healthy volunteers (N = 20) yielded 471 analyzable breaths. The models indicated an excellent association *within* participants (R2 = 0.96 in IMV patients, R2 = 0.90 in healthy volunteers, Figure 1). The TV-DE ratio was 201 (161–240) mL/cm in IMV and 361 (294—428) mL/cm) in healthy volunteers. However, the variability of the DE and TV relationship *between* participants was considerable. Estimation of absolute TV by DE using the models showed large differences between observed TV and TV predicted by the model, illustrated with Bland–Altman analysis in Figure 2.
Conclusions: The difference in TV-DE ratio between IMV patients and healthy volunteers may be explained by a smaller distribution of TV in IMV patients. Also, underlying Ventilator-induced Diaphragmatic Dysfunction (2) possibly decreased the TV-DE ratio in IMV patients compared to healthy volunteers.
Despite a strong relationship between changes in DE an TV *within* participants, the large variability in the data precludes a reliable estimation of TV from the absolute value of DE. Possibly, consecutive measurements of DE to monitor changes in DE within patients with respiratory failure may indicate clinical deterioration. Since diaphragm motion is multidimensional (3), the novel speckle tracking technique could enable better measurement of DE by quantifying diaphragm motion in multiple dimensions (4).

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000621

Introduction: The ultimate goal of fluid challenge (FC) is to reduce tissue hypoxia which would be confirmed by an increase in oxygen consumption (VO_2) following oxygen delivery (DO_2) after FC. Microvascular reactivity was assessed non invasively by near-infrared spectroscopy (NIRS) with a vascular occlusion test (VOT) at bedside. We aimed to evaluate whether the change of microvascular reactivity was related to an increase in VO_2 after FC.
Methods: Circulatory shock patients with atrial catheterization (mean arterial pressure (MAP) < 65 mmHg or the need of a vasopressor to maintain MAP ≥ 65 mmHg with ≥ 1 sign of poor tissue perfusion (oliguria, alteration of consciousness, cold clammy skin, lactate levels ≥ 2 mmol/L)) who required FC (250 ml of crystalloid for 10 min) within the first 24 h were included. A cardiac index (CI) rating was obtained by pulse contour analysis (Hemosphere®, Edwards). Hemodynamic variables, lactate levels, central venous oxygen saturation ($ScvO_2$), capillary refill time (CRT) (index finger, contra lateral site of NIRS), thenar muscle oxygen saturation (StO_2) (FORE-SIGHT Elite®, Edwards) and VOTs were obtained before and after FC. VOTs were performed by inflating an arm-cuff to a pressure of 40 mmHg above systolic blood pressure for 3 min. The descending (Desc) and ascending (Asc) StO_2 slopes were calculated. Patients were divided by the function of ΔCI and $\Delta VO_2 \geq 15\%$.
Results: 28 shock patients were included. 26 of the 28 patients (93%) had septic shock and a SOFA score of 11 (9–14). 11 of the 28 patients (39%) were fluid responders. All patients received norepinephrine with a median dose of 0.2 (0.1–0.6) mcg/kg/min. The time of inclusion was 3 (3–7) hours and the amount of fluid resuscitation before inclusion was 3.4 (2.0–5.9) L.
Before FC, only CI was greater in the fluid responders (FRs) than in the non fluid responders (non-FRs) (Figure 1). There were no differences in baseline hemodynamic variables, DO_2, VO_2, CRT, $ScvO_2$, StO_2, Asc and Desc StO_2 slopes between the VO_2 responders and the VO_2 non responders (Figure 1).
Comparing the FRs and non-FRs after FC, CI, DO_2 and CRT increased only in the FRs (Figure 1). Among the FRs, only Asc slope increased in the VO_2 responders (Figures 1, 2). There was no correlation between baseline hemodynamic variables, $ScvO_2$, lactate, CRT, StO_2, Asc, Desc StO_2 slope and baseline VO_2.
Conclusions: In shock patients, microvascular reactivity increased after FC only in VO_2 responders.

Introduction: The atmospheric pressure and air-oxygen percentage in highland regions vary with changes in altitude. Differences in environmental conditions may affect precision instruments within HFNC devices, which influences the temperature, humidity, flow rate, and oxygen concentration of the delivered gas. Therefore, it is important to determine whether HFNC devices are influenced by different ambient temperatures, ambient humidities, and altitude conditions, which could inform the selection of suitable devices based on environmental conditions.
Objectives: This study aimed to investigate the clinical performance of high-flow nasal cannula (HFNC) oxygen therapy devices in different simulated environments with various ambient temperatures, humidity levels, and altitudes.
Methods: Four representative regions were selected with various combinations of ambient temperatures, humidities, and altitudes. The temperature accuracy, flow rate accuracy, oxygen concentration accuracy, and humidification ability of four types of HFNC devices were tested in a multi-parameter environment simulation cabin. Then, an HFNC clinical evaluation scoring system was used to evaluate the clinical performance of the HFNC devices in different environments. Moreover, to measure the volume of accumulated condensate in the HFNC devices within different simulated environment. The HFNC devices were continuously operated for 6 h in three simulated environments with different altitudes but identical ambient temperature and humidity levels. Finally, the possibility to establish an environmental correction algorithm using test results was demonstrated.
Results: We found that the temperature accuracy, flow accuracy, oxygen concentration accuracy, and humidification ability of all HFNC devices were influenced by simulated high and extreme altitude environments, with differences in the clinical performance stabilities across the different types of HFNC devices. Additionally, all HFNC devices showed significant abnormal changes in the condensate volume in the simulated high and extreme altitude environments. The volume of accumulated condensate more then 100 ml at a simulated altitude of 3000 m and 4000 m in three HFNC devices. The test results were used to derive a temperature correction formula applicable to altitudes of up to 3000 m above sea level for correcting the actual temperatures of gas delivered by the HFNC devices.
Conclusions: Taken together, changes in the clinical performance of different HFNC devices showed complex differences according to the simulated environment. HFNC devices and their parameter settings should be selected based on the external environment and individual characteristics of each device.
The experimental process and test method.

Impact of implementing multidisciplinary daily rounds in a Brazilian poorly resourced public ICU on clinical outcomes: a retrospective study

H. Sousa Bastos[1], G. A. Lisboa Oliveira[1], A. M. Clayton[1], M. N. Caroline[1], D. L. Oliveira Da Silva[1], V. Freire Pereira[1], V. Freitas Neto[1], P. De Carvalho Bacelar[1]

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000623

Introduction: Intensive Care Units (ICUs) are critical areas of the hospital that require intensive and complex care. In low-resource hospitals, the quality of care in the ICU may be impaired due to a lack of resources and qualified personnel. In this context, the implementation of a multidisciplinary quality program can improve the quality of care in the ICU. The aim of this study is to evaluate the impact of implementing a multidisciplinary quality program in the ICU of a low-resource hospital.
Objectives: Evaluate the outcomes as risk-adjusted mortality rate and length of stay on care in the ICU one year before and after the implementation of the multidisciplinary quality program.
Methods: We conducted a population-based retrospective cohort study of medical patients admitted in our unit (N = 652) from January 1, 2021, to December 31, 2022. We analyzed 12 months before and 12 months after the implementation of a multidisciplinary quality program in the ICU. Multivariate logistic regression was used to determine the independent relationship between daily multidisciplinary rounds on mortality and length of stay.
Results: A total of 652 non-COVID patients in a non-dedicated ICU were included in the final analysis, with a mean predominance of males (67% before and 70.9% after, p = 0.52), maintaining a mean occupancy rate (96% before and 99.5% after, p = 0.29) and mean age (45.9 before and 47.2 after, p = 0.25) similar, but with greater mean severity (SAPS3) in the post-intervention group (40.2 before and 61.8 later, p = 0.001). Despite the greater severity in the post-intervention group, the mean standardized mortality was significantly lower (3.7 before and 0.8 after, p = 0.001 [95% CI, −4.3 to −1.6]), as well as in the mean time using mechanical ventilation (10 before and 7 after, p = 0.03 [95% CI, −5.0 to −0.1]), but with an increase in the mean number of days using devices such as a bladder catheter (166 before and 210 after, p = 0.02) and central line catheter (85 before and 161 after, p = 0.04), with no impact in the regression on mean length of stay (11 before and 12.5 after, p = 0.77).
Conclusions: The implementation of daily rounds by a multidisciplinary team seems to be associated with lower mortality among ICU patients, showing the potential benefit on survival and others clinical outcomes with simple actions like the daily presence of an intensivist physician staffing and a multidisciplinary team, even in a public intensive care unit with low resources.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000627

Introduction: Right heart failure is an entity that is rarely diagnosed in intensive care units in Mexico, reporting a prevalence of 14–18%; however, it is potentially lethal and is the cause and/or consequence of different common critical illnesses (ARDS, pulmonary embolism, acute myocardial infarction, and postoperative cardiac surgery). Right ventricular dysfunction is a common problem in critically ill patients and has been associated with increased mortality rates.
The gold standard for the assessment of right ventricular-pulmonary artery coupling requires invasive pressure–volume loop recordings to measure the end-systolic/arterial elastance ratio (Ees/Ea). Echocardiographic measurement of the relationship between TAPSE and PASP is a simple, non-invasive parameter that has shown good correlation with invasively estimated coupling (< 0.31 mm/mmHg, sensitivity: 87.5%, specificity: 75.9%, for predicting mortality); however, its use is currently still controversial.
Objectives: To evaluate the association of the TAPSE/PASP index at a cut-off point of 0.31 mm/mmHg and mortality in patients admitted to the Critical Care Unit who received levosimendan.
Methods: A retrospective cohort was carried out, in which a total of 49 patients were included, older than 18 years and who used levosimendan; without considering any comorbidity (diabetes, kidney disease, cancer, etc.); excluding patients who had a life expectancy of less than 48 h, whose baseline characteristics were described, grouping them into two groups (TAPSE/PASP index greater or less than 0.31 mm/mmHg), to determine if there was a difference, X2 was applied, a simple logistic regression was subsequently performed to determine if other factors, such as age, sex, etc., had an impact on the outcome; to finally adjust for the variables with the greatest impact in a multiple logistic regression.
Results: Of the patients analyzed, 30 (61.2%) were men with a median age of 72 years (58.25, 78.5) and had a median TAPSE/PASP index of 0.34 mm/mmHg (0.30, 0.48). Preliminary results indicate that mortality in the studied population was 31.8% (14) for the group with the best prognosis according to the index under study; however, it is important to mention that it is still necessary to adjust the results for variables such as: the severity of the patients, comorbidities and time of evolution.
Conclusions: Preliminary results indicate that it will be possible to determine whether there is an association between the TAPSE/PASP index and mortality for critically ill patients receiving levosimendan.

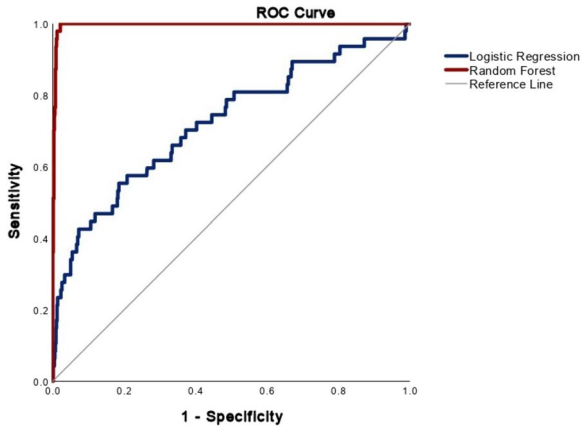
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000628

Introduction: Intermediate ward has been established for less severe critical-ill patients to alleviate the burden on the intensive care unit (ICU). However, patients transferred to the ICU after intermediate ward admission demonstrate worse outcomes. This study was conducted aiming to develop a machine learning model to predict ICU transfer among patients admitted in the intermediated ward.
Objectives: Our study aimed to develop and validate prediction model using machine learning to predict ICU transfer among patients admitted to the intermediate ward.
Methods: We conducted a retrospective study to develop prediction models for ICU transfer using both statistical model of logistic regression and the machine learning approach, a random forest model. The models were trained and tested using several variables measured within 24 h before admission, including patient demographics, vital signs, laboratory tests. Performance of the models were evaluated using the area under the receiver-operating characteristic curve (AUROC), sensitivity, positive predictive value accuracy and F-score.
Results: Total 1973 patients were included in the study, 1286 for training dataset and 705 for testing dataset. Of these, 132 patients (6.7%) were transferred to the ICU. Random forest demonstrated the excellent performance to predict ICU transfer, with an AUROC of 0.997, positive predictive value (PPV) of 76.7%, sensitivity of 97.9%, accuracy of 97.9%, and an F1 score of 0.86 in testing dataset. The most contributed variables in the random forest model included blood pressure, heart rate, using of $FiO_2 > 0.5$, serum creatinine levels, respiratory rate, serum sodium levels, and body temperature. In contrast, the statistical logistic regression had an AUROC of 0.722, PPV of 10.3%, sensitivity of 78.7%, accuracy of 50.8%, and an F1 score of 0.18 in the testing dataset. For logistic regression model, age, underlying of cerebrovascular disease, admission from the general wards, diagnosis of pneumonia, body temperature, blood pressure, respiratory rate, Glasgow coma score, requiring mechanical ventilator, using of $FiO_2 < 0.5$, and serum bicarbonate levels were included in the final model.
Conclusions: The machine learning approach using random forest demonstrated a noteworthy performance to predict ICU transfer among patients admitted in the intermediate ward. The findings of our study demonstrated the potential of machine learning in the triage process, especially when physician decisions are controversial.



The Receiver-Operating Characteristic (ROC) curve of the test sets.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000629

Introduction: Coronavirus Disease 2019 (COVID-19) has clinical similarity with other flu-like syndromes. Owing to the similarity of symptoms, there are chances of misdiagnosis of patients with other respiratory viruses as COVID-19 or chances of missing out upon viral co-infections in patients with COVID-19.
Objectives:: Here we report etiologic pattern of respiratory tract infections, especially of the viral etiology, diagnosed at Yashoda Hospital, Hyderabad, a tertiary care hospital of Hyderabad, Southern India, during period of the pandemic.
Methods: The patients presenting with the respiratory symptoms were tested for presence of other respiratory tract pathogens. At admission, we sent samples, nasopharyngeal swab for COVID real-time reverse transcriptase PCR (RT-PCR) and nasopharyngeal swab or Bronchoalveolar lavage (BAL), depending on the clinical profile, for multiplex PCR BioFire FilmArray Pneumonia panel or Respiratory panel (BioFire Diagnostics; bioMérieux, Marcy l'Étoile, France). These Biofire panels allow detection of 33 respiratory pathogens with a run time of 1 h.
We retrospectively reviewed clinical and microbiologic records generated via routine clinical practice (ethical approval not required) from 490 consecutive patients (336 males; median age, 53 years; range, 14–93 years), with respiratory symptoms who were screened with FilmArray and RT-PCR for COVID-19, over 28 months months, from 1st June 2020 to 30th September 2022.
Results: We included nasopharyngeal swabs (229/490, 46.9%), and BAL (261/490, 53.1%) samples. SARS-CoV-2 RNA was detected in 315 (64.8%) of 490 samples, while FilmArray showed presence of other viruses in 54/490 (10.9%). FilmArray results showed 27/54 samples (50%) had multiple viruses, and were as follows: Rhinoviruses/Enteroviruses (24/54, 44.4%), Influenza A virus, Coronaviruses and rhinovirus (each 9/54, 16.6%). One nasopharyngeal swab in a 61-year old COVID-19 patient showed presence of rhinovirus/enterovirus and Influenza A and was mildly symptomatic, but no secondary cases were found among her contacts. Our data are consistent with results from other studies on co-infection, showing low prevalence of other respiratory virus co-infection in SARS-CoV-2 patients, in range of 1.6–6.5%. Several phenomena like viral interference, common receptor usage, different inoculum size or simply resource competition might explain why dual or multiple concurrent viral respiratory infections are rare among COVID-19 patients.
Conclusions: A multiplex PCR system for rapid diagnosis of respiratory infections revealed that there is low prevalence of concomitant viral infection in patients positive for SARS-CoV-2. Moreover, with the spread of SARS-CoV-2, occurrence of other respiratory pathogens has undergone a sharp decline.

SAMPLES		Total number of samples	COVID-19 positive	COVID-19 Negative
Bronchoalveolar lavage (BAL)		261	150	111
	Viral co-infection present		6 (4%)	21 (19%)
	Viral co-infection absent		144	90
Nasopharyngeal swab		229	164	65
	Viral co-infection present		12 (7.2%)	15 (22%)
	Viral co-infection absent		152	50

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000633

Introduction: Acute respiratory distress syndrome and sepsis are heterogeneous syndromes comprised of various diseases. The heterogeneity of these two syndromes signifies that our understanding remains incomplete despite numerous efforts and may explain why randomized controlled trials of numerous drugs and treatment methods have not achieved groundbreaking results in these syndromes. In the case of COVID-19 infection, it is a disease caused by a single virus, which is expected to exhibit relatively similar characteristics. However, it is also true that the disease progression varies among patients. Therefore, this study aims to elucidate the sub-phenotypes present in a cohort of severe COVID-19 patients, as observed in their clinical progression.
Methods: We conducted a retrospective multicenter cohort study of severe COVID-19 patients admitted to the intensive care units of 26 university hospitals in South Korea from January 2020 to August 2021. To identify sub-phenotype groups, we utilized latent class analysis modeling. We employed initial data variables following cohort enrollment as factors for sub-phenotype classification. Subsequently, we examined the differences between subgroups and clinical outcomes and analyzed the effects of each treatment.
Results: We analyzed a total of 1114 patients. The latent class analysis revealed that the two-class model best described the sub-phenotypes within the cohort. Of the 1114 patients, 823 belonged to the type 1 sub-phenotype, and 291 belonged to the type 2 sub-phenotpye. The type 2 sub-phenotype was associated with higher mortality, higher usage of vasopressors, mechanical ventilation, continuous renal replacement therapy, extracorporeal membrane oxygenation, longer ICU length of stay, higher serum inflammatory markers (WBC, CRP), higher initial FiO_2, and lower PF ratio. No significant difference in steroid use was observed between the two groups.
Conclusions: We identified two sub-phenotypes in severe COVID-19 patients, which were associated with more severe hyperinflammation, shock, metabolic acidosis, and worse clinical outcomes. In this study, we were able to classify subgroups in severe COVID-19 patients, which could potentially aid in patient stratification and inform future treatment approaches.

Introduction: Head trauma is the main cause of death and disability in people under 40 in industrialized countries (1).
It has been estimated that 70–90% of all head traumas evaluated in Emergency Departments (EDs) are mild (2). Mild Head Injury (MHI) is defined as any blunt trauma to the head presenting at the time of evaluation a Glasgow Coma Scale (GCS) score of 13 to 15 (3).
Early diagnosis of intracranial lesions through Computed Tomography (CT) scan is the aim of the emergency physician, but multiple studies have demonstrated that only a small percentage of such lesions requires surgery (1.5% in some cases) (4).
Objectives: The aim of this study is to evaluate the impact of head CT scans on the clinical management of patients suffering MHI.
Methods: Patients older than 18 admitted to the ED of the Novara University Hospital reporting a MHI and able to express an informed consent were consecutively enrolled in this prospective observational study. They were clinically evaluated at the time of admission and then 6, 24, 48 and 72 h later, as long as they were still in the ED. A telephone follow-up was performed at 90 days.
The primary composite endpoint was a change in patients' management decided by the emergency physician after finding a post-traumatic intracranial lesion on a CT scan. Component endpoints were admission to an ordinary ward (such as Neurosurgery), modifications in pharmacotherapy (reversal of anticoagulation, prolonged withdrawal of antithrombotic drugs, anti-edema treatments) or invasive treatments (invasive ventilation, surgery).
Results: This preliminary analysis includes 248 patients recruited between June 2021 and December 2022.
At least 1 CT scan was performed in 87.9% of cases, and the first CT scan revealed an intracranial lesion in 18.1% of them. At least another CT scan was repeated in the first 24 h in 70 patients; a delayed lesion was observed in 1 case only, but finding it had no clinical impact on the patient's management.
The cumulative number of CT scans performed throughout the study was 309, but only 20 of them (6.5%) had a clinical impact. In particular, 17 patients were hospitalized, and among them 1 patient also received reversal therapies for ongoing anticoagulation, 2 patients also received anti-edema treatments, and in 1 patient antithrombotic treatment was also withdrawn. In the remaining 3 out of 20 patients, the CT scan induced the physician to withdraw anticoagulation. None of the patients underwent neurosurgery. Two patients died, but only one because of an intracranial injury.
Out of the 53 patients reached so far at follow-up, only 4 reported a transient limitation in daily-life activities after the event, but they all got back to their pre-event condition within 90 days.
Conclusions: These preliminary data support the need to move the attention of the emergency physician from finding intracranial lesions as such, to finding clinically significant intracranial lesions, thus reducing the number of useless CT scans and improving both patients' and resources management.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000635

Introduction: Children requiring extracorporeal membrane oxygenation (ECMO) experience malnutrition and significant functional impairment. Nutritional adequacy in relation to functional impairment in children receiving ECMO has not been reported.
Objectives: This pilot study aimed to describe the nutritional adequacy, muscle changes and functional outcomes in children requiring ECMO.
Methods: Children admitted to a tertiary mixed pediatric intensive care until (PICU), requiring ECMO between January 2018 and December 2020 were included in this study. Energy and protein intake for the first 7 days of ECMO were collected. Energy and protein requirements were determined using the Schofield equation and 1.5 g/kg/day, respectively. Intake adequacy was determined as a percentage of requirements. Muscle changes were assessed using ultrasound of the rectus femoris cross sectional area (RFCSA) at ECMO initiation, ECMO decannulation, and PICU discharge. Function was assessed using the functional status scale (FSS) at baseline, PICU discharge and hospital discharge. Functional impairment was defined as an increase in FSS score by ≥ 3 from baseline. Presence of gross motor impairment at hospital discharge was assessed using the Test of Infant Motor Performance (TIMP) (0–4 months), Peabody Developmental Motor Scales-II (PDMS-2) (4 months–5 years) through gross motor quotient scores, or 6-min walk distance test (6MWT) (> 5 years).
Results: Sixteen children [median age 1.31 years (Interquartile range (IQR) 0.03–3.52)] were included. All required venous-arterial ECMO. 11 (68.8%) patients survived to hospital discharge. Median energy and protein intakes were 31.4% (IQR 19.9–53.3) and 24.2% (IQR 6.0–37.9), respectively. Median RFCSA change was 7.69% (IQR −11.88–23.23) during ECMO, and −0.33% (IQR −15.42–8.48) from ECMO decannulation to PICU discharge. Functional impairment was present in 8 (50%) children.
Gross motor impairment was assessed in 10 patients (90.9%). 1 participant had a below average TIMP score, and 7 patients had very poor to below average [70 (IQR 55–83)] PDMS-2 scores. 6MWT distance of 2 patients > 5 years of age were less than 3rd centiles of age-normative values for Asian children. 3 patients required long-term physiotherapy review more than 6 months.
Total energy [27.9% (IQR 27.8–51.5) vs. 35.5% (IQR 16.2–58.0), $p = 0.921$] and protein adequacy [19.7% (IQR 19.0–44.4) vs. 17.1% (IQR 3.6–52.1), $p = 0.630$] were similar between those with and without PICU functional impairment. There was no correlation between RFCSA change and energy [Pearson's $r = -0.027$, $p = 0.938$] or protein adequacy [Pearson's $r = -0.06$, $p = 0.858$] during ECMO.
Conclusions: Functional impairment and gross motor delay rates were high in children requiring ECMO. Nutritional adequacy was low. Energy and protein intakes were similar between children with and without functional impairment. Energy and protein adequacy were not correlated with RFCSA. Larger cohort studies are required to validate these findings.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000637

Introduction: Peer support is a promising intervention to reduce psychological morbidity and improve social support and self-efficacy for ICU survivors and their caregivers. Our prior systematic review demonstrated there are few well-designed and rigorously reported trials. In one of the first international pilot randomised controlled trials, this study aimed to establish the feasibility of an in-person, co-designed, peer support model—in both the early and late post-hospital phases of recovery.
Methods: Prospective, randomised, single-centre pilot trial with blinded outcome assessment. Community-dwelling ICU survivors (and their nominated caregiver if designated), > 18 years of age, able to speak and understand English and participate in phone surveys, were eligible.
Participants were randomised to attendance at the in-person peer support group (six sessions, fortnightly or usual care). Two models were piloted: 1. Early (baseline outcome measurement within 2 weeks post-hospital discharge; intervention commencing 2–3 weeks post-hospital discharge, follow-up at 15–17 weeks post-hospital discharge); 2. Late (baseline outcome measurement within 3–4 weeks post-hospital discharge, intervention commencing 4–6 weeks post-hospital discharge with follow-up 17–20 weeks post-hospital discharge). Outcomes included post-traumatic growth, resilience, social support, anxiety and depression, post-traumatic stress disorder, and quality of life. The primary outcome was feasibility of implementing the peer support model, as measured by participant recruitment, intervention attendance, and outcome measurement completion.
Results: Of 231 eligible patients, 80 participants were recruited. The early phase pilot recruited 38 participants, (28 patients, 10 carers; 18 singles, 10 dyads), with an average (SD) age of 59.8 (17.9) years, 55% female. Twenty-two (58%) were randomised to intervention. The primary outcome (Impact of Events Scale) was completed by 20 (53%) participants at baseline and 14 (37%) at follow-up. The early intervention group attended a median (IQR) of 0 (0 to 1) sessions (total 24 sessions).
The late phase pilot recruited 42 participants (32 patients, 10 carers; 22 singles, 10 dyads), with an average (SD) age of 60.4 (15.4) years, 50% female. Twenty-one (50%) were randomised to intervention. The primary outcome was completed by 41 (98%) participants at baseline, and 29 (69%) at follow-up. The late intervention group attended a median (IQR) of 1 (0 to 5) sessions (total 44 sessions).
Conclusions: In this proof of concept trial, an in-person peer support model delivered in the late post-hospital phase of recovery, appeared to be more feasible than an early model. Further research, should investigate alternative modes of intervention delivery to improve uptake and reduce barriers to attendance.

Preoperative malnutrition is risk factor for unplanned postoperative reintubation in patients who undergoing abdominal surgery

D. Choi[1], S. Lee[1], K. Park[1], K. Y. Lee[1], J. Y. Jang[1]
[1]General Surgery, National Health Insurance Service Ilsan Hospital, Goyang-si, Republic of Korea
Correspondence: K. Park
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000638

Introduction: Postoperative reintubation in patients who extubated after surgery under general anesthesia is associated with poor prognosis, longer hospital stay and increase of medical expenditure. Accurate extubation timing is critical for patient safety and intensive care unit (ICU) resource management. Therefore, this study aimed to identify preoperative malnutrition is a risk factor for postoperative reintubation in patients undergoing abdominal surgery.
Objectives: To identify preoperative malnutrition is a independent risk factor for postoperative reintubation in patients undergoing abdominal surgery.
Methods: We retrospectively analyzed medical charts of patients who extubated after abdominal surgery under general anesthesia between January 2017 and June 2022 at the National Health Insurance Service Ilsan Hospital.
Results: Among 9917 patients, unplanned postoperative reintubations were occurred in 42 patients. There were significant difference in age, sex, operation time, amount of red blood cell transfusion, blood loss in operating room, operation time, underlying disease (hypertension, cardiac disease, Chronic obstructive pulmonary disease and cancer), ASA score, preoperative and postoperative sequential organ failure assessment (SOFA) scores, and preoperative malnutrition between reintubation group and non-reintubation group. Logistic regression analysis preoperative malnutrition (OR 3.578 95% CI 1.426–8.98) were independent risk factors for unplanned reintubation. The area under the ROC curve for this model was 0.9496.
Conclusions: Pre-operative malnutrition is a risk factor for unplanned postoperative reintubation in patients undergoing abdominal surgery.

Open abdominal management (OAM) and intensive care improve prognosis in cases of lower colonic perforation with septic shock

Y. Minami[1], C. Watanabe[2], H. Masui[1]
[1]Department of surgery, Yokosuka Kyōsai Hospital, 横須賀市, Japan; [2]Emergency and Critical Care, Yokosuka Kyōsai Hospital, 横須賀市, Japan

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000639

Introduction: OAM has long been selected as a damage control surgery for severely injured patients, but in recent years, it has also been applied to severe non-traumatic conditions (1). According to reports, OAM in severe non-trauma peritonitis patients is feasible and safe as surgical strategy management without increasing mortality, length hospital of stay, or complications (2).
Since 2019, our hospital has performed OAM for lower colonic perforation cases with septic shock. In the first surgery, only the cause of shock was removed, and intensive care was performed in the ICU with the abdomen open. After the general condition has improved, create an intestinal anastomosis or colostomy and close the abdomen.
Objectives: In this study, we investigated the treatment results of OAM for patients with colonic perforation with septic shock in our hospital.
Methods: 31 cases were underwent surgery from 2017 to October 2022. We examined perioperative factors between two groups, one that underwent OAM and received intensive care (OAM group) and one that underwent primary abdominal closure and received intensive care (PC group), and examined the short-term results after surgery.
Results: OAM was performed in 13 of 31 patients. There was no significant difference in patient background between the two groups. APACHE2 score and SOFA score did not show any significant difference between the two groups. The initial operation time in the OAM group was significantly shorter than that in the PC group (104 vs 208 min, $p = 0.000$). In the OAM group, an average of 3 surgeries were performed until abdominal closure. There was no difference in postoperative complications between the two groups, but in the PC group, 4 died of multiple organ failure associated with infection and 1 died of respiratory failure associated with ARDS. There were no deaths in the OAM group, mortality was significantly lower in the OAM group ($p = 0.050$). In cases excluding death cases, the number of days of ventilator management and ICU stay tended to be longer in the OAM group, but there was no significant difference. There was no significant difference in postoperative length of stay between the two groups (43.3 vs. 36.5 days, $p = 0.531$).
Conclusions: In patients colonic perforation with septic shock, the prognosis could be improved by selecting OAM and improving the general condition first by intensive care.

Association of preoperative prognostic nutritional index and postoperative acute kidney injury in patients undergoing on pump coronary artery bypass grafting

D. Z. Alih[1]
[1]Critical Care Medicine Division, Philippine Heart Center, Quezon City, Philippines
Correspondence: D. Z. Alih
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000640

Introduction: Acute kidney injury (AKI) is documented to occur at 12 to48.5% after coronary artery bypass graft (CABG) surgery. Prognostic nutritional index (PNI) has been related to clinical outcomes in post-surgery patients and is documented as an independent predictor of AKI. In this study, we aimed to investigate the association of PNI with AKI after elective on-pump CABG operations.
Objectives: To determine the association of prognostic nutritional index with post-operative acute kidney within 48 h of surgery, in patients undergoing elective coronary artery bypass graft.
Methods: A total of 66 consecutive patients who underwent elective on-pump CABG were enrolled in this prospective study. Prognostic nutritional index was computed based on the laboratory tests taken during their admission prior to surgery. AKI was defined as occurrence of creatinine changes within the first 48 h after CABG surgery based on the Kidney Disease: Improving Global Outcomes (KDIGO)criteria. The patients were then grouped into an AKI (−) and an AKI (+) group.
Results: A total of 66 patients were included in the study with a mean age 58.04 ± 9.28 years predominantly male (80.3% men vs 19.7% female). Of the 66 patients, a total 5 patients (8%) developed AKI. PNI did not show association with the development of AKI after elective on-pump coronary artery bypass surgery.
Conclusions: In our study, PNI was not associated with the development of AKI after elective on-pump coronary artery bypass surgery.

Hs-troponin-T on day of extubation is associated with extubation failure

C. Groenland[1], A. Siemers[1], E. J. Wils[2], E. Dubois[1], L. Heunks[1], V. Baggen[1], H. E. Endeman[1]

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000641

Introduction: Accurate timing of readiness for extubation in patients with COVID-19 is challenging, since the extubation failure rate is reported to be up to 20% (1, 2). Extubation failure is associated with higher mortality, morbidity, ICU length of stay, and healthcare costs (3, 4). To date, clinical and respiratory variables are used to predict extubation failure. Data on the value of cardiac and inflammatory biomarkers in this setting is limited.
Objectives: The aim of this study is to investigate whether cardiac and selected inflammatory biomarkers (NT-proBNP, high sensitive troponin-T (hs-TnT), procalcitonin, and IL-6) on the day of extubation are associated with extubation failure in mechanically ventilated patients with COVID-19.
Methods: This was a single-center retrospective cohort study. From march 2020 until march 2022, 602 mechanically ventilated patients with COVID-19 were screened for eligibility. Patients were eligible for inclusion if they were extubated for the first time, according to a weaning protocol including a spontaneous breathing trial. The primary endpoint was extubation failure (i.e. reintubation or mortality within 7 days). Logistic regression was performed to investigate the relation between biomarkers on day of extubation and extubation failure. Biomarkers were log2 transformed and associations were adjusted for age and SOFA score on day of extubation.
Results: In total 298 patients met the inclusion criteria. Median age was 60 years [IQR, 51–67], and 70.1% was male. The primary endpoint occurred in 20.8% patients. Patients with extubation failure had a higher SOFA score on the day of extubation (5 [IQR, 3–7] versus 3 [IQR, 2–4], $p < 0.001$) and a longer duration of mechanical ventilation prior to extubation (11.5 days [IQR, 7.3–15] versus 8 days [IQR, 6–11.3], $p < 0.001$) (Table 1). Of the four evaluated biomarkers, log2 hs-TnT was independently associated with extubation failure (adjusted OR, 1.38 (95% CI, 1.03–1.88), but NT-proBNP, procalcitonin and IL-6 were not (Figure 1). The AUC of the ROC curve was 0.76 (95% CI, 0.63–0.90), with a sensitivity and specificity of 73 and 72%, respectively.

Table 1 (abstract 000641) Baseline characteristics

Characteristics	All patients N = 298	Patients without extubation failure N = 236	Patients with extubation failure N = 62	P-value
Age (years)*	60 [51–67]	59 [51–67]	64[55–68]	0.051
Male, sex, N (%)	209 (70.1%)	164 (69.5%)	45 (72.6%)	0.751
BMI (kg/m^2)*	28.9 [25.9–32.9]	28.94 [26.3–33.1]	28.06 [24.5–30.9]	0.078
SOFA score on the day of extubation*	3 [2–5]	3 [2–4]	5 [3–7]	< 0.001
Days of MV prior to extubation*	9 [6–13]	8 [6–11.3]	11.5 [7.3–15]	< 0.001
Biomarkers levels on the day of extubation				
NT-pro-BNP (pmol/l)*	26.9 [12.4–62.2]	25.2 [12.1–58.7]	36.1 [15.2–77.1]	0.066
Hs-TnT (ng/L)*	13.9 [9.8–25.0]	12.9 [9.0–21.7]	19.2 [12.1–45.9]	< 0.001
Procalcitonin (ng/mL)*	0.10 [0.06–0.20]	0.09 [0.06–0.19]	0.18 [0.10–0.34]	< 0.001
IL-6 (pg/mL)*	73.5 [20.0–209.5]	76.0 [20.0–207.5]	67.5 [23.8–248.3]	0.860

*Values are presented as median, [Interquartile Range]

Conclusions: In mechanically ventilated patients with COVID-19, hs-TnT was independently associated with extubation failure. This association was not found for NT-proBNP, procalcitonin, and IL-6. Prospective cohort studies are needed to further investigate this association.

Benefits of "Analgesia Nociception Index" guided fentanyl administration in critically ill patient: a pilot study and randomized controlled trial

C. Plukmonton[1], P. Theerawit[2], Y. Sutherasan[3], S. Morakul[1]
[1]Anesthesiology and Critical Care Medicine, Faculty of Medicine Ramathibodi Hospital, Mahidol University, Bangkok, Thailand; [2]Critical Care Medicine, Faculty of Medicine Ramathibodi Hospital, Mahidol University, Bangkok, Thailand; [3]Pulmonary and Pulmonary Critical Care Medicine, Faculty of Medicine Ramathibodi Hospital, Mahidol University, Bangkok, Thailand
Correspondence: C. Plukmonton
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000642

Introduction: Mismanagement of analgesic and sedative drugs in mechanically ventilated and sedated ICU patients can lead to adverse outcomes. The use of the Analgesia Nociception Index (ANI) has been proposed as a reliable biomarker to monitor nociception in critically ill patients. We hypothesize that using ANI monitoring to guide fentanyl administration in mechanically ventilated and sedated ICU patients can reduce the total fentanyl doses administered at 48 h.
Objectives: To assess the benefit of analgesia nociception index to guide fentanyl administration in mechanically ventilated and moderate to deep sedated ICU patient.
Methods: We conduct a randomized controlled trial to compare the total fentanyl doses administered in patients who receive ANI-guided fentanyl administration to those who receive standard care. We monitored ANI and fentanyl doses every 4 h for 48 h to evaluate the effect on total fentanyl doses and patient outcomes.
Inclusion Criteria:

1. Age ≥ 18 years
2. Receiving mechanical ventilation through an endotracheal tube or tracheostomy
3. Admitted to the medical or surgical ICU
4. Indicate moderate to deep sedation with the analgesic drug for more than 48 h.

Exclusion criteria:

1. Patients with an unstable hemodynamic required a high dose of vasopressor or inotrope
2. Patients with a history of cardiac arrhythmia, on pacemaker, autonomic dysfunction, and chronic opioid use
3. Patients who have contraindications to study drug
4. Patients with a respiratory rate lower than ten breaths per minute
5. Patients who were expected to undergo sedation for less than 48 h after the start of the study.
6. Patients refused to participate in the research program or withdrew from the research.

Withdrawal Criteria

1. Patients desire to stop the study
2. Inability to participate until the end of the trial namely hemodynamic instability required a high dose of vasopressor during study and a new onset of cardiac arrhythmia.
3. Patients have adverse reactions to the study drug
4. Physician decision to stop sedation or study drug before 48 h

Results: 15 out of 39 patients were included in the study, and the mean dose of fentanyl administered was lower in the ANI-guided group compared to the control group (42.25 ± 12.21 vs 65.11 ± 33.15, 95% confidence interval 0.349–0.686, P = 0.08). ANI was associated with significantly lower fentanyl dose when using Linear mixed model estimated mean difference 0.52 mcg/kg/h (P < 0.001, 95% CI 0.35 to 0.69). The mean ANI scores were higher in the ANI-guided group 71.71 ± 3.7 compared to 61.5 ± 4.62 (95% CI − 23.11 to 2.67, P = 0.11). No significant differences were observed in the RASS score, BIS, and BPS score. There were no significant differences in the length of hospital and ICU stay, ventilator days, the occurrence of adverse events, and 28-day mortality between the two groups.
Conclusions: The dose of fentanyl administered over time was lower in the ANI-guided group compared to the control group in mechanically ventilated and sedated ICU patients. Our study suggests that the use of ANI may be a promising tool for guiding analgesia-based sedation in mechanically ventilated patients.

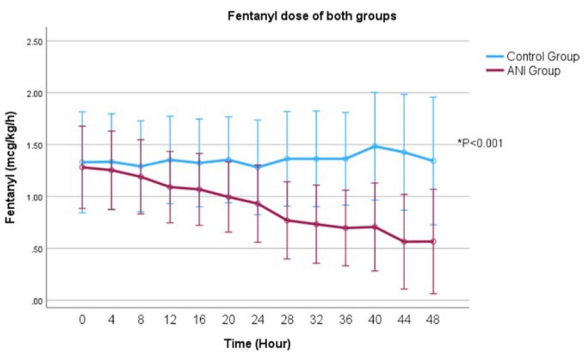

Figure 6 (abstract 000642) Fentanyl dose of both groups
Mean fentanyl dose of both groups are significantly different with p value < 0.001 and 95% CI 0.35 to 0.67

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000643

Introduction: Antibiotic dosing is not optimal in the ICU. Our recent trial investigated the effect of model-informed precision dosing (MIPD) of beta-lactam antibiotics and ciprofloxacin and showed no significant differences in clinical outcomes.
Objectives: This study aimed to identify subgroups of patients in which MIPD of these antibiotics could be beneficial for clinical outcomes.
Methods: We analyzed data from the DOLPHIN randomized controlled trial, which compared MIPD to standard dosing of beta-lactam antibiotics and ciprofloxacin in 388 ICU patients. We divided patients into subgroups based on baseline characteristics and assessed the effect of MIPD on 28-day mortality, 6-month mortality, delta-SOFA, and ICU length of stay (LOS).
The following subgroups were deemed to be of interest: obese patients (BMI $\geq$ 30 kg/m^2), male patients, patients with high renal clearance, younger patients, the use of renal replacement therapy (RRT), low Sequential Organ Failure Assessment (SOFA) score, lack of positive microbiology, and patients with sepsis (defined using the Sepsis III criteria). Patients who received a dose recommendation within 24 h after initiation of the study antibiotic and those that received ceftriaxone were also analyzed as separate subgroups. Groups that were based on continuous variables were divided based on their median value.
For 28-day and 6-month mortality, a binary logistic regression was used, displaying the odds ratio (OR). For the change in SOFA score between day 0 and day 5, a linear regression was used and displayed as estimate. For ICU LOS the associations between MIPD versus standard dosing treatment using a negative Poisson regression was examined and reported as incidence risk ratio (IRR). All data is displayed with corresponding 95% confidence intervals (95% CI).

Results: In total, 450 patients were randomized in the DOLPHIN trial. Due to meeting exclusion criteria between randomization and the first study intervention, 62 patients were excluded from analyses. This leaves 388 patients in total, of which 189 patients are in the MIPD group, and 199 patients in the standard dosing group. The subgroups and their respective cohort sizes are shown in Figure 1.
Patients with a SOFA score below 8 at T0 had a decreased 28-day mortality when randomized to the MIPD group (11% MIPD vs 24% standard dosing; OR 0.40; 95% CI 0.17–0.88) (Figure 2). On the contrary, patients with a SOFA score above or equal to 8 show increased 28-day mortality (39% MIPD vs 25% standard dosing; OR 1.94; 95% CI 1.07–3.59) and 6-month mortality (52% MIPD vs 35% standard dosing; OR 2.04; 95% CI 1.16–3.62) when randomized to MIPD.
Applying MIPD only for ceftriaxone showed a decreased delta-SOFA score (-3 MIPD vs -3 standard dosing; estimate 1.85; 95% CI 0.02–3.67). However, dose recommendations within 24 h resulted in a trend towards increased delta-SOFA score for all antibiotics (-4 MIPD vs -2 standard dosing; estimate -1.19; 95% CI -2.98–0.60).
For both beta-lactams and ciprofloxacin, patients with a SOFA score below 8 at T0 had an increased ICU LOS when randomized to the MIPD group (12 MIPD vs 6 standard dosing; IRR 1.36; 95% CI 1.01–1.83). Early dose recommendations within 24 h showed a trend towards a decreased ICU LOS in MIPD (5 MIPD vs 8 standard dosing; IRR 0.77; 95% CI 0.52–1.16). Using MIPD for only ceftriaxone results in an increased ICU LOS (7 MIPD vs 4 standard dosing; IRR 1.76; 95% CI 1.24–2.51). All other subgroups showed no major differences.
Conclusions: ICU patients with a SOFA below 8 using MIPD had an increased ICU LOS as they had a decreased mortality. In addition, fast dose recommendations using MIPD of beta-lactam antibiotics and ciprofloxacin may be beneficial in ICU patients.

Introduction: Admission to an Intensive Care Unit (ICU) can have major consequences on well-being and quality of life after discharge. ICU-survivors and family members can both develop persistent problems (1–3) which has consequences for their social functioning (4).
The needs of survivors for care after ICU discharge are often significant (2), making it arduously for them to reassume their role within the family. Family members may experience the pressure of being an informal caregiver while at the same time feeling the need to return to their former lives. To what extend this affects the family relationships is largely unknown.
Objectives: To gain insight in the way ICU-survivors and their family members experience their health in the physical, emotional and social domain, three months after ICU discharge and to explore whether this affects family relationships.
Methods: A cross-sectional qualitative study with an exploratory design using semi-structured interviews was conducted at the ICU of the University Medical Center Groningen (UMCG) in the Netherlands.
All patients with unplanned admission to the ICU between November 2018 and September 2019, with a length of stay of 48 h or more, and their family members, were eligible to participate. Survivors were asked for their consent and for permission to approach family members by telephone. Participants of whom we expected communication problems and participants who did not live in the northern part of the country were excluded.
Participant demographics were retrieved from the Electronic Patient File and collected in the interviews. Interviews with ICU-survivors and family members were conducted at participants' homes three months after ICU admission by four experienced ICU nurses. An interview guide was used with seven open and impartially formulated questions, based on the Research And Development 36-item Health Survey (RAND-36). Furthermore, two quantitative questions on Quality of Life (QoL) were asked by using a 10-point Numeric Rating Scale (NRS). The audio-recorded interviews were transcribed verbatim and subsequently analysed using Atlas.Ti version 22, according to the steps of thematic analysis (5).
Results: A total of 138 patients were eligible for participation. Interviews were conducted until data saturation was reached, resulting in ten survivors and ten family members participating in the study. Mean age was 63 (Standard Deviation [SD] 10) and 64 (SD 6) respectively. Eight of the survivors were male and of the family members five were male. Seven dyads participated, who were interviewed separately from each other. The median ICU Length Of Stay (LOS) was 4.5 days (IQR: 3.2–6).
Five of the survivors evaluated their QoL three months post-ICU lower than before their ICU admission, whereas four of them genuinely rated their QoL higher, with a median of 7 (IQR: 6–7.7) on the NRS. Family members rated their QoL lower than before or equally (median: 8, IQR: 6–8).
The qualitative data of this study are now being analysed and the findings will be presented during the conference.
Conclusions: Five out of ten of the ICU-survivors rated their QoL three months post-ICU lower than before admission, however four out of ten evaluated their QoL higher. The family members rated their QoL lower or the same as before. The qualitative results may provide more insight into the origin of this findings, which may be of use to healthcare professionals in improving ICU-aftercare.

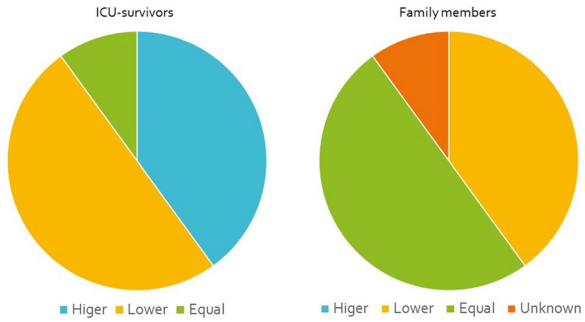

Figure 1 (abstract 000644) Experienced QoL of ICU survivors and family members, three months post-ICU compared to the experienced QoL pre-ICU

Introduction: One of the common causes of COVID-19 related death is acute respiratory distress syndrome (C-ARDS) [1, 2]. Dexamethasone is the cornerstone in the treatment of C-ARDS and reduces mortality probably by suppressing inflammatory levels in ICU patients [3]. Its anti-inflammatory effects may be concentration-dependent. However, no pharmacokinetic studies of dexamethasone have been conducted in ICU patients.
Objectives: The aim of this study is to design a population pharmacokinetic study to gain a deeper understanding of the pharmacokinetics of dexamethasone in critically ill COVID-19 patients in order to identify relevant covariates that can be used to personalize dosing regimens.
Methods: Blood samples from critically ill patients receiving fixed-dose intravenous dexamethasone (6 mg/day) for the treatment of COVID-19 were sampled in a retrospective pilot study. The data were analyzed using Nonlinear Mixed Effects Modelling (NONMEM) software for population pharmacokinetic analysis and clinically relevant covariates were selected and evaluated.
Results: A total of 51 dexamethasone samples from 18 patients were analyzed and a two-compartment model fit the data best. The mean population estimates were 2.85 L/h (inter-individual-variability 62.9%) for clearance, 15.4 L for the central volume of distribution, 12.3 L for the peripheral volume of distribution and 2.1 L/h for the inter-compartmental distribution clearance. The covariate analysis showed a significant negative correlation between dexamethasone clearance and CRP.
Conclusions: Dexamethasone PK parameters in ICU COVID patients were substantially different from those from non-ICU non-COVID patients, and inflammation may play an important role in dexamethasone exposure. This finding suggests that fixed-dose dexamethasone over several days may not be appropriate for ICU COVID patients.

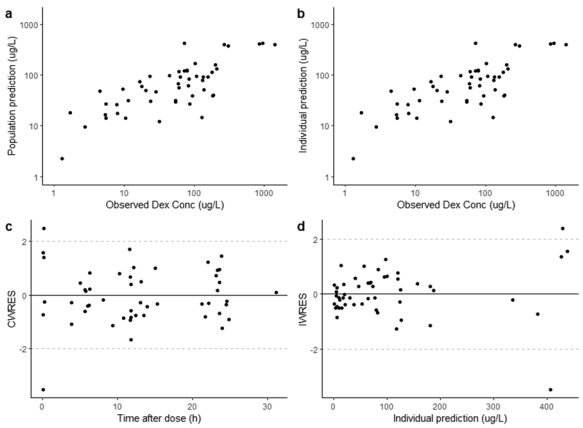

Figure 2 (abstract 000645) Basic goodness of fit plots for the final model: population predictive concentration versus observed concentration (DV) (upper left); individual predictive concentration versus observed concentration (DV) (upper right); time after dose versus individual weighted residuals (IWRES) (lower left); time after dose versus conditional weighted residuals (CWRES) (lower right). CWRES: conditional weighted residuals, DV: dependent variable, IWRES: individual weighted residuals

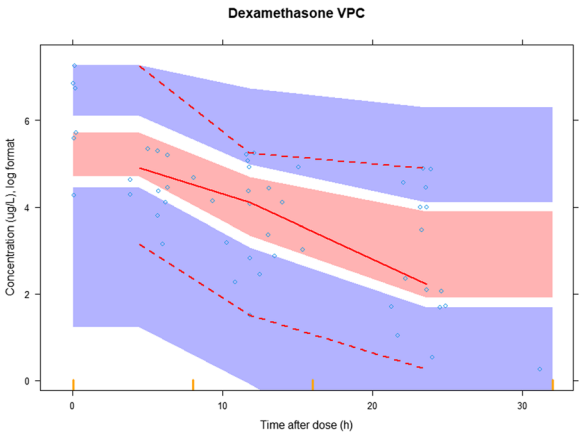

Figure 3 (abstract 000645) The visual predictive check (VPC) of dexamethasone in the final. The x-axis is time after dose (h) and y-axis is concentration of dexamethasone in log transformed format. VPC: visual predictive check

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000646

Introduction: Insertion of a gastric tube (GT) is a routine procedure in the intensive care unit (ICU). For immediate position control, the injection of air through the GT with simultaneous auscultation of the epigastrium is probably the most simple and common clinical method. Quality reviews show auscultation finding is misinterpreted by tracheal, bronchial, or pleural secretion, and mispositioning may remain undetected [1–3]. In the worst case, hyperosmolar tube feeding occurs via the misplaced tube into the lungs or pleural space causing subsequent severe pneumonia, pleuritis, and often fatal patients' outcome (##). Recent data from NHS UK over a five-year period describe 95 unrecognized misplaced gastric tubes in 3 million with a mortality of 30% [4].
In contrast to similar procedures in the ICU, like installation of central venous catheters or endotracheal intubation, no uniform standards for forensic GT position verification exists.
Objectives: The work examines the sensitivity of (1) pH measurement of gastric tube aspirate, point of care ultrasound (POCUS) (2) without and (3) with parallel performed bubble test, as compared with chest X-ray (CXR) as gold standard for GT position control.
Methods: Following ethical approval, study registration (Deutsches Register für Klinische Studien, ID: 00029309), and consent by the patient or legal representative, 300 consecutive ICU patients older than 18 years with indication for GT insertion were included. GT was inserted according to the in-house standard and checked by means of auscultation and CXR. In addition, secretion was aspirated via GT and pH tested, if successful, and a POCUS including bubble test was carried out.
Results: A total of 303 patients with 321 ET placements were included (12 patients received multiple GTs). All patients received a routine CXR, in 239/321 (74.45%) cases exclusively to check GT position. Aspiration was successful in 277/321 (86.3%). Although all patients were treated with proton pump inhibitors for stress ulcer prophylaxis, 207/277 (74,7%) tests showed a pH-Value below the cut off value of 5,5. POCUS allowed a clear position check in a high number of cases (Table 1), and the additional bubble test was successful in all 39 patients, in whom no GT was identifiable in the POCUS alone.

Table 1 (abstract 000646) .

	Test performed	Success rate single test	Success rate combined test A	Success rate combined test B
pH-Test	321/321	74,7%	100%	
POCUS		87,9%		100%
POCUS bubble test		88,5%		
Chest X-ray		100%		

Conclusions: Combination of pH-value measurement and POCUS with bubble test provide a highly sensitive position control of GT and can significantly reduce CXRs solely performed for GT position control. This single center study was not powered to test the specificity of the tests.

Increased hyaluronan synthesis by overexpression of HAS2 improves pulmonary microvascular endothelial barrier function in ARDS

X. Lu[1], A. Liu[2]
[1]Department of Critical Care Medicine, Zhongda Hospital, School of Medicine, Southeast University, Nanjing, China; [2]Department of Critical Care Medicine, Zhongda Hospital, School of Medicine, Southeast University, Nanjing, Jiangsu, China

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000652

Introduction: Increased lung permeability due to impaired pulmonary microvascular barrier function is the main pathological change in ARDS. The glycocalyx plays an important role in maintaining the function of the pulmonary endothelial barrier. Since hyaluronic acid synthesized by HAS2 is an important component of the glycocalyx. Altered HAS2 expression in pulmonary microvascular endothelial cells in ARDS may be important for endothelial barrier function disruption.
Objectives: This study wanted to explore the effect of hyaluronic acid synthesis by HAS2 in pulmonary microvascular endothelial cells on pulmonary microvascular barrier function in ADRS.
Methods: 1. From September 2009 to August 2022, 34 patients with ARDS and 15 patients with severe illness caused by non-infection were enrolled in the department of Intensive Care at Zhongda hospital affiliated to Southeast University, and 10 healthy adult volunteers were recruited. The peripheral blood of ARDS patients was collected on D1 and D3 after admission, and the peripheral blood of non-infection severe group and healthy group was collected on D1 after admission, to compare the correlation between HA content in peripheral blood and the severity and prognosis of ARDS patients, non-infection-induced severe patients and healthy adults.
2. ALI/ARDS Mouse model was established by cecal ligation and puncture (CLP). The expression of HAS2 in lung tissue and the content of HA in lung tissue and plasma were detected, and the relationship between the expression of HAS2 and inflammatory reaction, lung endothelial injury, lung permeability were observed.
3. The expression of HAS-2 and the content of HA in the supernatant of mouse pulmonary microvascular endothelial cells were observed before and after LPS stimulation. A stable transgenic strain of mouse lung microvascular endothelial cells with HAS2 gene overexpression/low expression was constructed, to observe the changes in permeability of endothelial cells with different HAS2 expression levels before and after LPS stimulation.
Results: 1. The content of HA in peripheral blood of Ards patients on D1 and D3 was significantly higher than that of non-infection severe patients and healthy adults ($p<0.0001$). The content of HA in peripheral blood of ARDS patients was positively correlated with PEEP and SOFA score of invasive mechanical ventilation (Rho: 0.51, 0.61; $P=0.0024$, <0.001). The patients were divided into two groups according to the median value of HA content in peripheral blood of ARDS patients on D3 (134.4 ng/ml), the difference of survival analysis between the two groups was statistically significant ($p=0.01$).
2. HA content in lung tissue of CLP mice was lower than that of Sham group ($P=0.0038$). HA content in plasma of CLP mice was higher than that of Sham group ($P=0.0233$). MPO level in lung tissue of CLP mice was higher than that of Sham group ($P=0.0082$). The wet/dry ratio of lung tissue in CLP group was lower than that in Sham group ($P=0.026$). The expression of HAS2 mRNA and protein in lung tissue of CLP mice were significantly lower than that of Sham group ($P=0.021$, 0.0197). The fluorescence intensity of CD31/HAS2 co-localization in lung endothelial cells of CLP mice was lower than that of Sham group ($p<0.05$).
3. After LPS stimulation for 24 h, the expression of HAS2 mRNA and protein in the lung Endothelium was down-regulated compared with the control group ($p=0.0018$, 0.0014), and the content of HA in the supernatant of the lung Endothelium stimulated by LPS was increased compared with the control group ($p=0.0117$) After overexpression low expression of HAS2 gene in mouse lung Endothelium, the control group was cultured in Trans-Well chamber and the lung Endothelium were treated with LPS for 24 h, the results showed that the permeability of the Endothelium with HAS2 overexpression was lower than that of the control group ($p=0.0036$), and that of the Endothelium with HAS2 overexpression was higher than that of the control group ($p=0.047$).
Conclusions: Down-regulation of HAS-2 expression in ARDS leads to a decrease in HA synthesis, which increases endothelial permeability. Overexpression of HAS2 can increase HA synthesis and improve pulmonary microvascular endothelial barrier function.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000653

Introduction: The Belgian multicentric CONFIDENT RCT has shown a reduced day-28 mortality in C-ARDS patients treated with CP. As COVID-19 patients are immunologically heterogeneous, we hypothesized that immunologically similar COVID-19 clusters may differ in their treatment responses to convalescent plasma.
Methods: We measured 20 cytokines, chemokines and cell adhesion markers using a multiplex Luminex technique in patients at the time of inclusion in the CONFIDENT trial. We performed descriptive statistics, hierarchical cluster analysis and search for association between the identified clusters and CP effect on day-28 mortality. Ethics Committee of the University Hospital of Liège CE 2020/239. Clinicaltrials.gov NCT04558476.
Results: 384 patients out of 475 included in CONFIDENT were sampled. Missing samples were completely at random because several centers did not sample for this sub-study.
Age 64 [56–72] years, BMI 30 [26–35] kg/m^2, delay from hospital admission 4.6 [2.7–7.4] days, SOFA 6 [4–8], PEEP 10 [10–12] cmH_2O, FiO_2 65 [50–80]%, CRP 123 [66–192] mg/L, steroids 98%.
Median [IQR] levels of the biomarkers in pg/mL: MIP-1α = 4.1 (2.3–10.3), IL-1β = 1.6 (1.6–17.4), IL-4 = 18 (13–27), IP-10 = 127 (48–275), IL-6 = 16 (10–124), IL-8 = 13 (5–26), IL-10 = 3.4 (1.6–9.3), IL-12p70 = 14 (8–69), IL-13 = 3.4 (3.4–7.2), IL-17A = 4.2 (2.9–12.7), IFNγ = 10 (10–26), GM-CSF = 12 (12–12), TNFα = 16 (10–30), MIP-1β = 76 (44–134), IFNα = 0.8 (0.8–3.2), MCP-1 = 240 (103–3962), P-Selectin = 192,818 (3781–356,545), IL-1α = 2.3 (1.3–3.8), ICAM-1 = 199,975 (127,457–313,908), E-selectin = 29,943 (18,869–43,647).
Unsupervised learning analyses identified 3 clusters of participants. The most contributing biomarkers to distinguish cluster 1 (n = 181, 47.1%) from cluster 2 (n = 99, 25.8%) are IL-1 β, IL-12p70, IL-6, IFN α, and IL-17A (CTLA-8) and cluster 3 (n = 104, 27.1%) IL-6, MCP-1 (CCL2), IL-8 (CXCL8), IL-10, IP-10 (CXCL10), MIP-1 α (CCL3). The treatment effect of convalescent plasma was found in cluster 2 with those receiving the CP having a significant lower likelihood of mortality at D-28, OR = 0.42 (95% CI: 0.19–0.95).
Conclusions: In a population of patients with COVID-19 induced ARDS during the first days of invasive mechanical ventilation, we identified 3 sub-phenotypes of immune profile with different response to convalescent plasma.

Association between the body mass index and short- and long-term mortality in Korean septic patients: a retrospective cohort study

I. Park[1]
[1]Department of Anesthesiology and Pain Medicine, Seoul National University Bundang Hospital, Seongnam-si, Republic of Korea
Correspondence: I. Park
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000654

Introduction: Sepsis is a major contributor of the intensive care unit (ICU) patient mortality in many countries, including Korea. The "obesity paradox" in critical illness has raised a great consideration in the scientific community, and a number of studies have also explored the association between obesity and mortality in patients with sepsis and septic shock using the body mass index (BMI) as a representation of the patient's body fat. Obesity is reported to exhibit a protective effect on the survival of septic patients, but the results have been inconsistent.
Objectives: We investigated the association between obesity and 30-day and 1-year mortality in septic patients.
Methods: This retrospective study included patients with either sepsis or septic shock who were admitted to the ICU between November 2013 and May 2017. Based on the BMI, patients were categorized as underweight (< 18.5 kg/m^2), normal weight and overweight (18.5–25.0 kg/m^2) and obese (≥ 25.0 kg/m^2) in accordance to the Asia–Pacific World Health Organization guidelines. Primary endpoints were the 30-day and 1-year mortality from the date of ICU admission. Risk factors were analyzed via Cox proportional hazard regression analyses. The Kaplan–Meier survival curves were compared via a signed log rank test.
Results: Out of the total 834 patients, 207 (24.8%), 478 (57.3%), and 149 (17.9%) patients were underweight, normal weight and obese, respectively. Obesity was associated with lower 30-day (HR 0.61, 95% CI 0.41 to 0.89, P = 0.012) and 1-year mortality (HR 0.75, 95% CI 0.57 to 0.98, P = 0.037). Being underweight had no effect on the 30-day mortality (P = 0.683) but was associated with higher 30-day mortality (HR 1.44, 95% CI 1.17 to 1.77, P = 0.001). The 1-year survival was longest in obese patients followed by normal weight and underweight patients (Ps < 0.032). The 30-day survival was not different among the three groups (Ps > 0.05).
Conclusions: Obesity was associated with lower 30-day and 1-year mortality in septic patients. Being underweight showed no difference in 30-day mortality but higher 1-year mortality.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000656

Introduction: Cardiac injury is frequently reported in Corona virus disease 2019 (Covid-19) patients. Yet, many reports rely on elevated cardiac biomarkers to diagnose the myocardial involvement and few have focused on detailed echocardiographic findings.
Objectives: We aimed to comprehensively describe the cardiac function in mechanically ventilated (MV) Covid-19 Acute Respiratory Distress Syndrome (ARDS) patients, using 2D/4D echocardiography.
Methods: We prospectively evaluated the cardiac function in consecutive MV Covid-19 ARDS patients (04/2020–09/2021, University Hospital of Larissa, Greece) during the first 48 h of ICU admission. Patients with 1. severe pre-existing cardiac/lung disease and 2. pulmonary embolism, were excluded. Increased pulmonary afterload was considered if patients presented: Pulmonary Artery Systolic Pressure (PASP) > 38 mmHg, Pulmonary Acceleration Time < 90 ms, a notch in the ascending part of the (velocity time integral in the right ventricular outflow tract)\\VTI*RVOT* envelope.
Results: One hundred and sixty one patients were assessed. The mean age was 65.57 ± 0.92, (117 male, 72.7%), were intubated on the 10.8 ± 0.4 day from Covid-19 symptom onset. Comorbidities included: arterial hypertension (117, 72.7%), diabetes mellitus (43, 26.7%), Coronary Artery Disease [without heart failure, (13, 8%)], mild

Chronic Obstructive Pulmonary Disease (16, 9.9%), smoking habitus (24, 14.9%). The RV was dilated [RV End-Diastolic Area/Left Ventricular End-Systolic Area (RVEDA/LVEDA): 0.91 ± 0.03]. RV systolic function was also impaired: Right Ventricular longitudinal strain (RV-LS) was severely reduced [RV-LS − 13.02 ± 0.46%. RV-LS < 20% in was present in almost the whole cohort 146/155 (94.2%) patients measured], while RV-LS ≤ 17 (average value reported in severe Covid-19 patients) was present in 122/155 (78.7%). Tricuspid Annular Plane Systolic Excursion, (TAPSE) ≤ 16 mm was present in 49/177 (27.68%) and RV Fractional Area Change, RVFAC ≤ 35% in 97/184 (52.72%), while RV ejection Fraction (RVEF) ≤ 44% was present in 71/93 (76.34%) of patients.
Increased Pulmonary Vascular Resistances (PVRs) were present in 120/143 (83.9%) and right ventriculoarterial coupling (VACR) was excessively decreased (0.57 ± 0.04 mm/mmHg). Although the mean Ejection Fraction (EF) was almost normal (55.21 ± 1.07%), LV-LS was severely decreased (− 13.15 ± 0.46%). Troponin levels were increased in 51 patients (0.93 ± 0.15 ng/ml) and correlated to RV function and LVEF. Mild (< 10 mm) pericardial infusion (in diastole) was present in 59/161 (36.64%) patients.
Conclusions: The myocardial function is affected in MV Covid-19 ARDS patients. Increased RV afterload was documented, while conventional echocardiography may fail to depict the effects on LV systolic function which were mainly unraveled with longitudinal strain imaging.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000657

Introduction: Heat stroke (HS) is a clinical syndrome characterized by the rapid rise of body core temperature (> 40.5 °C) caused by exposure to high temperature environment. Central nervous damage inflammation plays an important role in the occurrence and development of heat stroke. The polarization state of microglia is closely related to the inflammation of the central nervous system. Previous studies have indicated that mesenchymal stem cells (MSCs) could protect against inflammation and brain injury in heat stroke. However, whether MSCs exosome activated microglia from M1 to M2 phenotypes under heat stress conditions is still unknown.
Objectives: In this study, we focused on microglial phenotypic modulation to investigate the mechanisms underlying the anti-inflammatory effects of MSCs exosome in vivo and in vitro.
Methods: Exosomes were extracted from human umbilical cord mesenchymal stem cells, and characterized by transmission electron microscopy, nanoparticle tracking analysis and western blotting. The expression of long non-coding RNAs in exosomes was detected by high-throughput sequencing and verified by qRT-PCR. In vitro and in vivo models of heat stroke were compared with whether LncRNA-VIM-AS1 was overexpressed or not treated with exosomes from human umbilical cord mesenchymal stem cells. The expression of M1/M2 microglia genes and proteins was detected by qRT-PCR and western blot. The proliferation rate of M1/M2 microglia was detected by flow cytometry. The concentration of pro-inflammatory and anti-inflammatory factors in the medium was detected by Elisa, and the interaction between lncRNAs, microRNAs and mRNA was detected by luciferase reporter assay.
Results: Exosomes from human umbilical cord mesenchymal stem cells promote functional behavioral recovery by transferring microglial polarization from M1 to M2 phenotype in vivo and in vitro. High-throughput sequencing results showed that LncRNA-VIM-AS1 was most enriched in human umbilical cord mesenchymal stem cell exosomes, and may be involved in human umbilical cord mesenchymal stem cell exosome-mediated microglial polarization. LncRNA-VIM-AS1 upregulation promotes microglial M1/M2 polarization by inhibiting miR-34a-5p and promoting Per2 expression, and was confirmed by a series of gain and loss-of-function experiments.
Conclusions: We demonstrate that lncRNA-VIM-AS1-enriched exosomes from human umbilical cord mesenchymal stem cells can inhibit microglial inflammation by down-regulating miR-34a-5p and promoting Per2 expression, which can shift microglial polarization from M1 to M2, providing neuroprotection and functional improvement after heat stroke.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000658

Introduction: Acute kidney injury (AKI) is one of the most prevalent organ dysfunctions present in a critical patient. The management of patients with AKI is mainly supportive, with continuous renal replacement therapy (CRRT) used in patients with severe kidney injury or its complications. CRRT often requires effective anticoagulation of the extracorporeal circuit in order to prevent filter clotting, improve the efficacy of CRRT and prolong filter life. Despite being the suggested choice for anticoagulation by the KDIGO guidelines, regional citrate anticoagulation (RCA) is still not the most used worldwide compared to systemic anticoagulation with unfractionated heparin (SUH). This results from the perception that RCA is a complex technique, difficult to monitor and with a significant number of potential side effects. In order to avoid these misconceptions, our ICU developed an ubiquous RCA for CRRT protocol, in partnership with intensivists and nephrologists, without any exclusion criteria. Both the medical and nursing staff were comprised of stable, well trained and meticulous teams, extremely attentive and experienced in extracorporeal techniques that replace kidney function.
Objectives: This study aims to do a retrospective evaluation of the quality and safety of the protocol instituted for CRRT in our peripheral Portuguese ICU between 2018 and 2022.
Methods: We performed a retrospective study on all the patients who underwent renal replacement therapy in our ICU between 1 January of 2018 and 31 December of 2022.
Results: Among the 101 patients enrolled, 65,4% were male, the mean age was 65,45 (±12,35) years old, the mean weight was 75,8 kg and the mean BMI was 26,76. The baseline value of serum creatinine was 1,89 mg/dL, a previous history of chronic kidney disease was present in 26,73% of the patients and 9,90% were already under a dialysis program. The mean APACHE score was 29,09, the mean SAPSII was 58,81 and the mean maximum renal SOFA score was 3,61. The day before the start of CRRT the mean serum creatinine was 4,97 and the mean urine output was 0,415 mL/Kg/h. The most common indications to start CRRT were the patient's incapacity in managing volume, severe nitrogen retention and severe acidosis (or alkalosis).
Of the patients enrolled, in 91,51% was used RCA, in 2,83% was used SUH and in 5,66% no regional or systemic anticoagulation was initiated. The mean dialysis dose was 1841,38 mL (approximately 23,68 mL/kg), the mean pump velocity was 110,34 mL/min and the mean citrate concentration was 2,78 mmol/L The CCRT was considered effective, as shown by the decrease of serum creatinine levels—a decrease of 54,89% after 48h of CRRT and of 61,89% after 72h. Also, in the patients who needed CRRT because of severe acidosis, we documented an increase of the mean pH—7,257 at the beginning of CRRT,

7,301 24h after the start, 7,331 48h after and 7,343 after 72h. To control de safety of the protocol, we used calcium compensation as an initial surrogate of citrate toxicity. After 24h of CRRT, 7.32% of patients had an increase in calcium compensation, number that rose to 7.81% and 8%, respectively at 48h and 72h. In those patients a total calcium to ionized calcium ratio was obtained, and only 2.17% of the patients showed toxic levels that forced citrate to be switch to other type of anticoagulation.

Conclusions: AKI is a frequent diagnosis in the ICU, despite only a small fraction develop the need to CRRT. In our retrospective evaluation, we found that the majority of our patients underwent RCA for CRRT and only a negligible percentage needed other types of anticoagulation. Our data shows that the protocol that we developed and instituted in our ICU was always adhered to, without frequent need to adjust our strategy. It also shows that RCA is safe regarding the extremely low percentage of patients that developed citrate toxicity and needed to switch to other means of anticoagulation. The results of our study also confirm the inexistence of absolute contraindications to RCA for CRRT—because RCA showed to be safe in the vast majority of patients, regardless of medical history and reason of admission at the ICU. This shows that under cautiously developed protocols, RCA is relatively easy to use, being safer, cheaper and with lesser associated complications compared to other means or the lack of anticoagulation.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000659

Introduction: The inflammatory, metabolic, and hemodynamic disturbances observed in sepsis can lead to the development of sepsis-associated encephalopathy (SAE), a condition characterized by diffuse brain dysfunction that presents on a spectrum ranging from delirium to coma. As SAE is frequently observed in critically ill patients, understanding its impact on clinical outcomes is important.

Objectives: To explore the association between SAE and mortality in patients with sepsis.

Methods: This nationwide, prospective cohort study analyzed patients with sepsis admitted to 20 tertiary hospitals between September 2019 and December 2021. SAE was defined as a Glasgow coma score (GCS) < 15 in patients without neurologic infection; those with preexisting neurological disease (stroke, epilepsy, encephalitis), metabolic encephalopathy, and dementia were excluded. The primary outcome of in-hospital mortality was analyzed by logistic regression adjusted for key prognostic factors.

Results: Of the 5723 patients included in the study, 2634 (46%) developed SAE, and a total of 2657 (46.4%) were admitted to the intensive care unit (ICU). Significant differences in terms of comorbidities, sequential organ failure assessment scores, and laboratory values were observed between patients with SAE and those without. SAE was associated with both higher in-hospital mortality (adjusted odds ratio [aOR], 1.66; 95% confidence interval [CI], 1.46–1.9) and ICU mortality (aOR, 1.7; 95% CI, 1.39–2.09). In addition, patients with SAE who survived until discharge had a longer length of stay in the ICU (5 [3–10] vs 4 [2–7] days; $P < 0.001$) and were less likely to be discharged to home (1,043 [63.9] vs 1,940 [82]; $P < 0.001$). When stratified according to SAE severity, higher 28-day mortality was observed in patients with lower GCS scores ($P < 0.001$, log-rank test) (Figure 1).

Table 1 (abstract 000659) Clinical outcomes according to SAE status

Variables	Non-SAE (N = 3089)	SAE (N = 2634)	*P*-value	Adjusted OR (95% CI)*
In-hospital mortality	723/3089 (23.4)	1001/2634 (38)	0.05	1.66 (1.46–1.9)
ICU mortality	230/1231 (18.7)	443/1426 (31.1)	0.37	1.7 (1.39–2.09)
Hospital LOS, days				
Survivors	14 (8–26)	15 (9–26)	0.28	
Non-survivors	12 (4–28)	7 (2–19)	< 0.001	
ICU LOS, days				
Survivors	4 (2–7)	5 (3–10)	< 0.001	
Non-survivors	5 (2–12)	4 (1–11)	0.08	
Discharge location				
Home	1940 (82)	1043 (63.9)	< 0.001	
Other hospital	426 (18)	590 (36.1)		

Values reported as *n* (%) for categorical variables and median (IQR) for continuous variables

CI confidence interval, *ICU* intensive care unit, *LOS* length of stay, *OR* odds ratio, *SAE* sepsis-associated encephalopathy

*Adjusted for age, sex, BMI, diabetes mellitus, malignancy, Charlson Comorbidity Index, clinical frailty scale, non-neurologic Sequential Organ Failure Assessment score, septic shock, and lactate

Conclusions: SAE is a common complication of sepsis that is associated with adverse clinical outcomes.

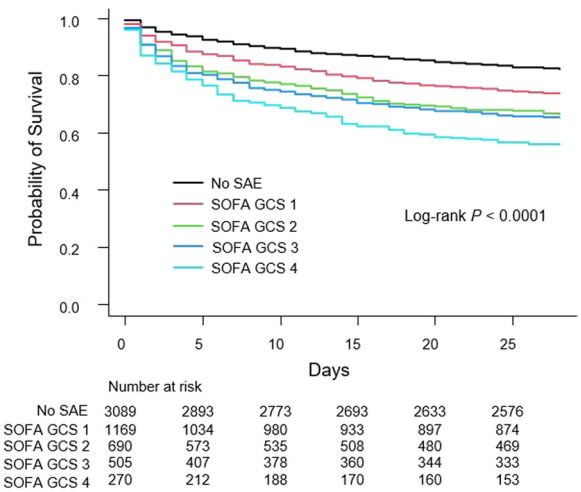

Figure 1 (abstract 000659) Kaplan–Meier estimates of 28-day mortality according to SAE severity. For each time interval, the survival probability was calculated as the number of patients who survived divided by the number of patients at risk

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000660

Introduction: Accurate choice of tools guiding fluid management of critically ill patients is crucial since excessive volume expansion and hyperhydration have been shown to increase morbidity and mortality.
Objectives: To compare the effectiveness and accuracy of different invasive and noninvasive dynamic tools in the prediction of fluid responsiveness, in relation to an actual volume challenge (500 ml) monitored by invasive Peripherally inserted continuous cardiac output (PICCO) as a gold standard in shocked mechanically ventilated adult patients.
Methods: 40 critically ill shocked adult patients, on controlled mechanical ventilation (MV) with Tidal volume 8 ml/kg, sinus rhythm. Exclusion criteria; arrhythmia, spontaneous breathing, and valvular heart disease. Noninvasively tools monitored by Doppler/Echo: Inferior vena cava distensibility index (IVC-DI), delta velocity time integral (ΔVTI) of the left ventricular outflow tract. Invasive tools monitored by PICCO: stroke volume variation (SVV), pulse pressure variation (PPV), end-expiratory occlusion (EEO) test, passive leg raising (PLR) test, and the actual volume bolus (500 ml) challenge. A truly positive or truly negative result of each tool was considered if it coincided with the result of the gold standard actual volume bolus. Sensitivity (Sens), Specificity (Sp), Accuracy (Acc.) were calculated. Area under the curve (AUC) was withdrawn from ROC curves, correlations ® were determined.
Results: PLRT showed (r = 0.614, P 0.001, AUC 0.815, ACC. 75.0%, Sens. 85.0%, SP70.0). SVV (r = 0.380, P 0.015, AUC 0.775, ACC 70.0%, Sens 79.0%, SP62.0%). PPV (r = 0.299, P 0.019, AUC 0.743, ACC 71.0%, Sens 77.0%, SP64.0%). IVC-DI (r = 0.405, P 0.009, AUC 0.693, ACC 54.0%, Sens 60.0%, SP50.0%). EEOT (r = 0.170, P 0.09, AUC 0.61, ACC 52.0%, Sens 55.0%, SP50.0%). ΔVTI (r = 0.068, P 0.675, AUC 0.63, ACC 53.0%, Sens 58.0%, SP49.0%).
Conclusions: PICCO monitored PLR test is the most accurate and correlating tool for predicting fluid responsiveness in shocked mechanically ventilated patients, followed by SVV, PPV AND IVC-DI. On the other hand, EEOT and ΔVTI were not significantly correlated.

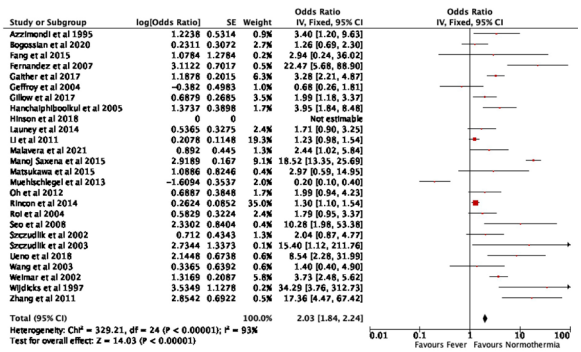
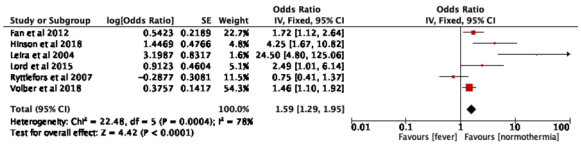
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000661

Introduction: Fever is a common condition in intensive care unit (ICU) patients, with an incidence between 30 and 50% in non-neurological ICU patients and up to 70–90% in neurological-ICU patients [1, 2]. It is known that fever has some potential protective functions [3]. Despite it, fever shows several detrimental effects, especially in patients with neurologic injuries, correlating with increased ICU mortality, longer ICU stay, and worse neurological outcomes [4–6].
Objectives: A systematic review and meta-analysis of current literature on the impact of fever on neurological outcomes and mortality of acute brain injury (ABI) patients (not including cardiac arrest patients).
Methods: We searched MEDLINE and SCOPUS following the recommendations of the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) statement, and we included both retrospective and prospective observational studies, interventional studies, and randomized clinical trials that had data on body temperature during ICU admission and outcome (mortality, neurological outcome, stroke progression, neurological/radiological deterioration). There were no language restrictions. This study was registered in PROSPERO (CRD42020155903).
Results: 68 studies from 15.236 records identified after the initial search were included in the final analysis, for a total of 56.049 patients. The level of evidence in most studies was low to moderate. All studies had a low overall risk of bias. Fever/hyperthermia increased the chance of death (pooled OR 2.03 [95% CI 1.84–2.24], I2:93%), unfavorable neurological outcome (pooled OR 1.84 [95% CI 1.74–1.96], I2:86%), neurological deterioration (pooled OR 1.59 [95% CI 1.29–1.95], I2:78%) and risk of stroke progression/DCI (pooled OR 2.19 [95% CI 1.88–2.55], I2:57%).
Conclusions: Fever/Hyperthermia is associated with poor neurological outcomes and mortality in patients with acute brain injury. Normothermia should be targeted in the management of neuro critically ill patients.

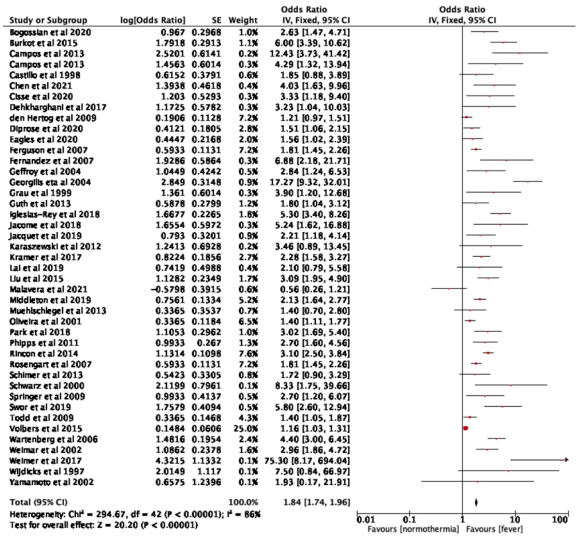


Fever and mortality
Odds-ratio for fever or hyperthermia and mortality.

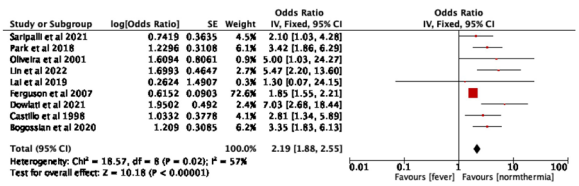


Neurological deterioration
Odds-ratio for fever or hyperthermia and neurological deterioration.

Odds-ratio for fever or hyperthermia, and mortality or neurological deterioration.



Fever and UO
Odds-ratio for fever or hyperthermia and unfavorable outcome.



Stroke progression
Odds-ratio for fever or hyperthermia and stroke progression.

Odds-ratio for fever or hyperthermia, and unfavorable outcome or stroke progression.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000662

Introduction: ICU survivors' quality of life (QoL) is generally lower than that of the general population. Additionally, with survival rates of critical illness increasing, patient reported outcomes, such as QoL, are becoming an important factor in decisions regarding ICU treatment. However, as most studies do not take pre-ICU QoL into account, it is unknown to what extent this reduced QoL is attributable to critical illness.
Objectives: To better understand the effects of critical illness on QoL, we explored QoL before and one year after ICU in different subgroups of ICU patients.
Methods: Data from an ongoing prospective multicenter cohort study, the MONITOR-IC, were used. Patients admitted to the ICU in one of the eleven participating hospitals between July 2016 and June 2021 were included. Patients completed questionnaires regarding their QoL before hospital admission and one year after ICU admission. Outcome was defined as change in QoL, measured using the EuroQol five-dimensional (EQ-5D-5L) questionnaire, and calculated by subtracting the EQ-5D-5L score at baseline from the EQ-5D-5L score one year after ICU. Based on the minimal clinically important difference, an improvement in QoL was defined as an increase in EQ-5D-5L score of ≥ 0.08, a deterioration in QoL as a decrease of ≥ 0.08, and an unchanged QoL as a delta EQ-5D-5L score < 0.08. Patients were grouped by admission diagnosis, using the Acute Physiology and Chronic Health Evaluation (APACHE) IV diagnosis system, resulting in 6 main groups and 22 subgroups.
Results: 3913 (50.6%) of included patients completed both baseline and follow-up questionnaires. 25.2% (n = 989) of patients reported a deterioration in QoL one year after ICU admission, while 39.4% (n = 1540) reported an improvement, and 35.4% (n = 1384) returned to their pre-ICU QoL. After ICU admission due to trauma, 56.5% (n = 104) experienced a deterioration in QoL, while after cardiovascular surgery this was true for 19.7% (n = 289). The largest increase in QoL was seen in patients admitted due to respiratory disease (mean 0.17, SD 0.38), whereas the largest decrease in QoL was observed in trauma patients (mean −0.13, SD 0.28) (Table 1). The lowest QoL one year after ICU was observed in the group admitted due to obstructive pulmonary disease (EQ-5D-5L score 0.64, IQR 0.37–0.76). Notably, before hospital admission 92.3% (n = 36) of these patients experienced limitations in their daily activities. One year after ICU, this was true for 84.6% (n = 33) (Figure 1). In the total group, the most-affected dimension of the EQ-5D-5L was pain, with 61.3% (n = 2398) of patients reporting symptoms of pain before hospital admission, and 59.3% (n = 2320) one year after ICU admission.

Table 1 (abstract 000662) Changes in quality of life one year after ICU for 6 main groups of ICU patients, based on APACHE IV diagnosis

Admission diagnosis	EQ-5D-5L score before hospital admission Median (IQR)	EQ-5D-5L score 1 year after ICU admission Median (IQR)	P value*	Delta EQ-5D-5L score Mean (SD)
Cardio-vascular (n = 587)	0.82 (0.59–0.96)	0.82 (0.70–0.91)	< 0.01	0.07 (0.30)
Cardiovascu-lar surgery (n = 1464)	0.83 (0.70–0.91)	0.86 (0.78–1.00)	< 0.001	0.07 (0.22)
Respiratory (n = 675)	0.68 (0.31–0.88)	0.81 (0.67–0.89)	< 0.001	0.17 (0.38)
Neurological (n = 186)	0.82 (0.55–0.91)	0.80 (0.62–0.89)	0.55	0.01 (0.36)
Trauma (n = 184)	1.00 (0.82–1.00)	0.82 (0.61–0.89)	< 0.001	-0.13 (0.28)
Other (n = 817)	0.81 (0.60–0.89)	0.82 (0.74–0.91)	< 0.001	0.08 (0.26)

*Comparison of EQ-5D-5L score before and 1 year after ICU, using wilcoxon signed rank test

Conclusions: One year after ICU, the majority of survivors returned to, or exceeded their pre-ICU QoL, while patients admitted after trauma experienced a significant decrease in QoL.

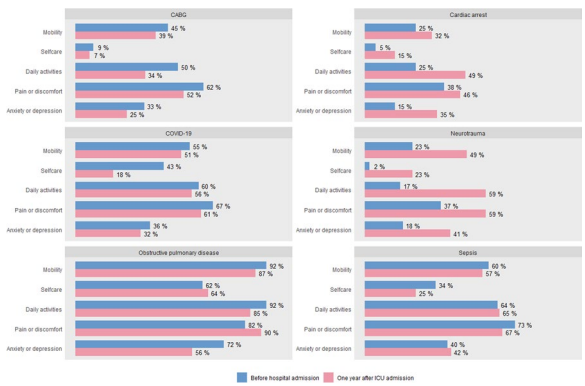

Figure 1 (abstract 000662) Percentage of patients reporting limitations in each dimension of the EQ-5D-5L, before hospital admission and one year after ICU admission for 6 subgroups of ICU patients

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000663

Introduction: Soft tissue infections result from microbial invasion of the skin and its supporting structures. Management depends on severity of the infection and the patient's comorbidities. Sepsis cand multiple complications can be associated, requiring admission to ICU. Survival will depend on early identification and treatment, severity and response to treatment. Patients require empirical polymicrobial antibiotic coverage and surgical evaluation for possible debridement of the infection focus.
Objectives: To analyze the evolution and survival of patients with severe soft tissue infections that require admission to the ICU.
Methods: Retrospective observational study carried out in a regional hospital. Data have been obtained from the HGG ICU Admissions Database for 10 years period (2013–2022). All patients with severe soft tissue infection were included. Final cohort: 28 patients.
Results: The mean age was 66 years, 79% being male. Medium–high comorbidity (average Charlson of 3). Average GMA (adjusted morbidity group) of 3.7/5. High BMI was observed with mean of 28.8. Type of infection: 45% cellulitis, 24% fasciitis and 31% gangrene. 82% presented multi-organ dysfunction syndrome (MODS). In the fasciitis group 100% presented MODS, 89% in gangrene group and 63% in cellulitis group. Diagnosis and microorganism: blood cultures were performed in 100% of patients, these being negative in 71%. Cultures of the infectious focus were performed in 89.28% of the patients, 16% were negative. Among the positive cultures we found *E. coli* (28%), *S. aureus* (20%), *S. anginosus* (8%), *S. epidermidis* (8%). The patients took 3 days to consult since the start of symptoms. Diagnosis took an average of 15.7 h of delay since the emergency room visit. 64.28% of the patients required urgent surgery. Cellulitis group was the one with the least indication for surgery, indicated only in 18.2%, versus 87.5% and 100%, in the cases of fasciitis and gangrene. Once indicated, surgery took an average of 4:30 h to be performed. Mean hospital stay of 40 days (median 29.5 days). Mean ICU stay 14.75 days and post-ICU 24 days. Average Apache II on ICU admission: 16. Therapeutic measures used in ICU stay are shown in Table 2.

Table 2 (abstract 000663) .

	VAS%	CRRT%	MV%	PRONE%	TRACHEO%
Cellulitis	90	45	55	0	27
Fasciitis	100	50	63	25	37
Gangrene	78	11	55	0	0
% Total	89	36	68	7	29

VAS: vasoactive support. CRRT: continuous renal replacement therapy. MV: mechanical ventilation. PRONE: prone position. TRACHEO: tracheostomy

32% of all patients died. Death rate in cellulitis group 45.5%, in fasciitis group 33% and finally 11% in gangrene group

Conclusions: Soft tissue infections can be life-threatening and remain a diagnostic and therapeutic challenge for clinicians. In many cases, they require multidisciplinary management involving intensive care providers, surgeons and infectious disease specialists. Early recognition is essential in order to start broad-spectrum empirical antibiotic treatment and perform debridement of the focus of infection as soon as possible.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000664

Introduction: Most published prediction models for Coronavirus Disease 2019 (COVID-19) were poorly reported, at high risk of bias, and heterogeneous in model performance. Unreliable outcome predictions could cause more harm than support, discouraging the use of these models in clinical practice. We aimed to provide an approach how to tackle important methodological challenges faced in previous prediction studies, using the Intensive Care Unit (ICU) as a proxy, and to investigate whether this results in better mortality prediction.
Methods: The Euregio Intensive Care COVID cohort included COVID-19 patients admitted to seven ICUs in Belgium, Germany, and the Netherlands. The 4C Mortality and Spanish Society of Infectious Diseases and Clinical Microbiology (SEIMC) scores were selected as promising prognostic models from an external validation study. Five predictors could be estimated for updating and extending based on cohort size. We adhered to the transparent reporting of a multivariable prediction model for individual prognosis or diagnosis (TRIPOD) guideline. Logistic regression analyses with the linear predictor, Acute Physiology and Chronic Health Evaluation score, and country were performed with and without a restricted cubic spline (RCS) function. Bootstrapping with backward selection was applied to select variables for the final model, using a p-value of 0.1, and, together with multiple imputation in each bootstrap sample, to assess optimism. Model discrimination was displayed as optimism-corrected areas under the receiver operating characteristic curve and calibration by calibration slopes and plots. Shrinkage was performed using the optimism-corrected calibration slope.
Results: Between March 2 and August 12, 2020, 551 patients were included. The mortality rate was 36%. For the 4C Mortality score and the SEIMC score, discrimination after updating and extending increased from 0.70 to 0.74 and 0.70 to 0.73, respectively. Calibration plots improved compared to the original models.
Conclusions: Mortality prediction can be improved after updating and extending promising models. Instead of spending much time, effort, and money on developing new models, we show how to adapt available or future prediction models to a new target population and setting, resulting in more reliable and robust predictions for clinical decision-making.

Equality of care—a review of patients with learning disabilities admitted to ICU

J. Donachie[1], E. Harlow[1], H. Butler[1], T. De Beer[1]
[1]Critical Care, Royal Cornwall Hospital, Truro, United Kingdom
Correspondence: J. Donachie
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000665

Introduction: Learning disabilities (LD) affect 2.2% of adults in the UK (1). NICE defines an LD as "a significantly reduced ability to understand complex information (impaired intelligence); a reduced ability to cope independently (impaired social functioning); a condition which started before adulthood, and has a lasting effect" (2).
LDs are associated with poorer physical and mental health, and reduced life expectancy compared to those without (3, 4). Deaths from avoidable causes are more common in this group (49%) than in the general population (22%) (3). This can be propagated by impaired communication: 50–90% of LD patients have communication difficulties, resulting in 'softer signs' of acute illness and delayed recognition (5).
Patients with learning disabilities are at risk of delayed escalation to ICU, impairing their chance of survival and extending their length of stay. It is important to ensure LD patients are identified early and are adequately supported throughout their ICU admission.
Objectives: This project aims to audit current practices at a DGH ICU through review of quantitative data, and to develop a standard operating procedure to guide future practice and facilitate subsequent audit cycles. This study used NHS England's LD improvement standards; LD guidance from The Royal College of Physicians; and GPICS standards of care to determine research parameters (5–7).
Methods: Patients with an LD admitted to ICU between April 2017–April 2022 were identified through central admissions software.
A local ICU database provided quantitative data; these parameters were compared to the non-LD patients admitted to ICU over the same time period.

Results:

Table 1 (abstract 000665) Comparison of LD patients vs non-LD patients in ICU cohort

	LD n = 90	Non-LD n = 4384	Total n = 4474	Mann Whitney U
Time from hospital to ICU admission, days Median (IQR)	1 (0–2)	0 (0–1)	0 (0–1)	p 0.023
ICNARC score Median (IQR)	21 (14–27)	15 (10–22)	15 (10–23)	p < 0.001
LOS, days Median (IQR)	1.9 (0.7–4.7)	2 (1–4.3)	2 (1–4.3)	p 0.159
Unit mortality, n (%)	4 (4.4%)	529 (12.1%)	533 (11.9%)	
Time from ICU to hospital discharge, days Median (IQR)	4 (0–9)	4 (1–10)	4 (1–10)	p 0.437
Delay from request to discharge, minutes Median (IQR)	393 (199–657)	406 (175–668)	406 (175–667)	p 0.669

Conclusions: There was a statistically significant difference in the time from hospital to ICU admission and the median ICNARC score, though this did not translate into a significantly higher ICNARC predicted risk of death (p 0.368) nor longer length of stay. We plan to perform qualitative analysis of this dataset via manual review of electronic notes, focusing on whether LD was recognised by clinical teams and referred to the LD support team, and reasons for delayed admission to ICU. Involving the MDT and stakeholders, we will then develop a standard operating procedure to guide clinical management and facilitate reaudit in one year.

Redefining SOFA categories to maximize predictive performance using Bayesian optimization—a pilot study

J. Helleberg[1], A. Sundelin[2], O. Rooyackers[3], J. Mårtensson[4]
[1]Perioperative Medicine and Intensive Care, Karolinska University Hospital, Stockholm, Sweden; [2]Department of Physiology and Pharmacology, Section of Anesthesia and Intensive Care Medicine, Karolinska Institute, Stockholm, Sweden; [3]Department of Clinical Science, Intervention and Technology, Karolinska Institute, Stockholm, Sweden; [4]Department of Physiology and Pharmacology, Section of Anaesthesia and Intensive Care Medicine, Karolinska Institute, Stockholm, Sweden
Correspondence: A. Sundelin,
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000666

Introduction: SOFA score has been in clinical use since the expert consensus 1996, but the standard of care in the ICU has improved significantly. Best practice of e.g., continuous renal replacement therapy and vasoactive support has changed. It is possible that the categories could be changed to better reflect the present. Such a revision could also be aimed to make SOFA score a better tool for measurement of illness severity. A data-driven approach based on large data sets could be of use in such work.
Objectives: To test whether Bayesian Optimization could be used to define cut-offs in the variables of the SOFA components that are both easy to remember, and maximize the ability of a modified SOFA score (mSOFA) to predict 30-day mortality.
Methods: An electronic algorithm was developed and validated to calculate SOFA score from variables extracted from a Patient Data Management System (PDMS). The algorithm aggregates values for GCS, Mean Arterial Pressure (MAP), PaO_2/FiO_2-index (PFI), Norepinephrine dose, Urine output, Creatinine, Bilirubin and Platelets according to the original SOFA score definition. Patients admitted to the ICU at the Karolinska University Hospital 2015–2018 were included in the study. The patients were split into a development cohort and a holdout cohort. Bounds for cut-offs for each variable and category in a modified SOFA (mSOFA) were fed into a Bayesian optimization process which attempted to maximize the area under the ROC curve with maximum mSOFA score up to ICU day 7 as predictor and 30-day mortality as outcome. Five-fold cross-validation was used to define variable cutoffs. The process was halted when no improvement in ROC curve greater than 0.001 could be found. The predictive performance of the mSOFA score was compared to standard SOFA score in the holdout set, using Delong's method for comparison of ROC curves.
Results: The Bayesian optimization procedure was terminated after 20 epochs due to lack of further improvement. In the holdout set, the AUC for standard SOFA score (highest during the first week) was 0.777 (95% CI: 0.7523–0.8032), the modified SOFA score had an AUC of 0.822 (95% CI: 0.7979–0.8462), p = 0.013 (Fig 1).

Table 1 (abstract 000666) Best performing scoring, mSOFA

Score	Central nervous system (GCS)	Coagulation (platelets 10^9/L)	Renal (creatinine µmole/L; urine output mL)	Hepatic (bilirubin µmole/L)	Circulation (MAP mmHg; norepinephrine µg/kg/min)	Respiratory (PFI kPa)
1	< 9	< 40	> 150 or < 2000	> 170	< 55 or > 0.23	< 60
2	< 8	< 30	> 300 or < 1500	> 340	< 50 or > 0.46	< 45

Score	Central nervous system (GCS)	Coagulation (platelets 10^9/L)	Renal (creatinine µmole/L; urine output mL)	Hepatic (bilirubin µmole/L)	Circulation (MAP mmHg; norepinephrine µg/kg/min)	Respiratory (PFI kPa)
3	< 7	< 20	> 450 or < 1000	> 510	< 45 or > 0.69	< 30
4	< 6	< 10	> 600 or < 500	> 680	< 40 or > 0.92	< 1

Conclusions: This study shows that SOFA score could be redefined, using the same variables and number of categories, to retain its human interpretable quality and simple arithmetic, but with better correlation with higher score to mortality. Any such undertaking should involve both expert consensus and data-driven methods using large data sets to best capture the standard of care in the ICU in the 2020s.

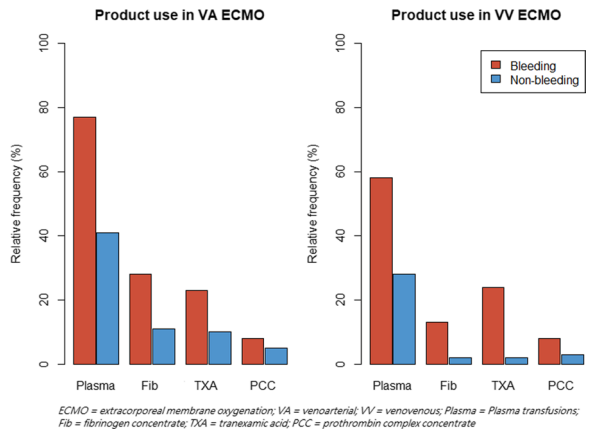
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000667

Introduction: To achieve optimal hemostatic balance in patients on extracorporeal membrane oxygenation (ECMO), a liberal transfusion practice is currently applied despite clear evidence.
Objectives: We aimed to give an overview of the current use of plasma, fibrinogen concentrate, tranexamic acid (TXA) and prothrombin complex concentrate (PCC) in patients on ECMO.
Methods: This was a prespecified subanalysis of an international, multicenter (16 intensive cares) retrospective study. Venovenous (VV) and venoarterial (VA) ECMO are analyzed as separate populations, comparing patients with and without bleeding and with and without thrombotic complications.
Results: Of 420 VA ECMO patients, 59% (n = 247) received plasma, 20% (n = 82) fibrinogen concentrate, 17% (n = 70) TXA and 7% (n = 28) PCC. Fifty percent (n = 208) suffered bleeding complications, 27% (n = 112) thrombotic complications. More patients with than without bleeding complications received plasma (77% vs. 41%, $p < 0.001$), fibrinogen concentrate (28% vs. 11%, $p < 0.001$) and TXA (23% vs. 10%, $p < 0.001$). More patients with than without thrombotic complications received TXA (24% vs. 14%, $p = 0.02$, OR 1.75) in VA ECMO, where no difference was seen in VV ECMO. Of 205 VV ECMO patients, 40% (n = 81) received plasma, 6% (n = 12) fibrinogen concentrate, 7% (n = 14) TXA and 5% (n = 10) PCC. Thirty-nine percent (n = 80) of VV ECMO patients suffered bleeding complications, 23% (n = 48) thrombotic complications. More patients with than without bleeding complications received plasma (58% vs 28%, $p < 0.001$), fibrinogen concentrate (13% vs 2%, $p < 0.01$) and TXA (11% vs 2%, $p < 0.01$). Of the plasma transfusions in ECMO patients without bleeding complications, 89% (VV ECMO) to 90% (VA ECMO) was transfused with an INR below 3.0.
Conclusions: The majority of patients on ECMO receive transfusions of plasma, procoagulant products or antifibrinolytics. In a significant part of the plasma transfused patients, this was in the absence of bleeding

or prolonged INR. This poses the question if these plasma transfusions were administered for another indication or could have been avoided.



ECMO = extracorporeal membrane oxygenation; VA = venoarterial; VV = venovenous; Plasma = Plasma transfusions; Fib = fibrinogen concentrate; TXA = tranexamic acid; PCC = prothrombin complex concentrate

Plasma transfusion, fibrinogen concentrate, tranexamic acid and prothrombin complex use in extracorporeal membrane oxygenation (ECMO). ECMO = extracorporeal membrane oxygenation; VA = venoarterial; vv = venovenous; Plasma = Plasma transfusions; fib = fibrinogen concentrate; TXA = tranexamic acid; PCC = prothrombin complex concentrate

Pursuing the real midazolam clearance during continuous renal replacement therapy in ICU patients with COVID-19: are midazolam and metabolites dialyzable?

T. Smeets[1], H. de Geus[2], A. Valkenburg[3], B. Koch[1], D. Gommers[4], H. E. Endeman[5], N. Hunfeld[6]

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000668.

Introduction: Midazolam based continuous intravenous (iv) sedation in patients admitted to the intensive care became prominent during the COVID-19 pandemic. However, benzodiazepine based sedation is associated with a high incidence of benzodiazepine-related delirium and an increased number of days spent in coma. Given the high midazolam dose requirements and the impaired renal clearance (CL) of the active (10% potency compared to midazolam) metabolite 1-OH-midazolam-glucuronide, ICU patients with COVID-19 and continuous renal replacement therapy (CRRT) may be at risk of prolonged sedation. Several factors like CRRT modality, downtime and filter patency may influence and determine the delivered clearance of midazolam and its metabolites.
Objectives: The aim of the case serie was to study CRRT related factors that could influence the CL of midazolam and metabolites in critically ill COVID-19 patients with CRRT.
Methods: Pre-filter blood samples and ultrafiltrate samples were collected simultaneously. Midazolam, 1-OH-midazolam and 1-OH-midazolam-glucuronide plasma samples were analyzed by means of a validated UPLC-MS/MS method. The prescribed renal dose was corrected for downtime therapy and filter integrity by means of a filter urea ratio. CL of midazolam and metabolites were calculated by the delivered renal dose and saturation (Sd) coefficient.
Results: We included 3 patients with CVVHD and 2 patients with CVVHDF (see Table1). The delivered renal dose ranged from 10.3 mL/kg/h to 33.3 mL/kg/h and the corrected delivered renal dose ranged from 8.8 mL/kg/h to 29.3 mL/kg/h. The urea ratios were in 4 patients > 0.80 and in 1 patient < 0.80. Midazolam, 1-OH-midazolam and 1-OH-midazolam-glucuronide concentrations ranged from below of quantification to 6070 µg/L, below of quantification to 295 µg/L and 1727 to 39,000 µg/L, respectively. Sd ranged from 0.02 to 0.03 for midazolam, 0.05–0.06 for 1-OH-midazolam and 0.23–0.43 for 1-OH-midazolam-glucuronide. The CL by the delivered renal dose was 0 mL/min to 1.7 mL/min for midazolam, 0 mL/min to 3.5 mL/min for 1-OH-midazolam and 4.0–27.7 mL/min for 1-OH-midazolam-glucuronide.
Conclusions: Midazolam and 1-OH-midazolam are not removed efficiently by CRRT and 1-OH-midazolam-glucuronide approximately up to 43%. Type of CRRT, filter integrity and downtime of CRRT affect the CL of midazolam and metabolites. Our results have implications for more personalized titration of midazolam in COVID-19 patients with CRRT, mainly to avoid oversedation.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000669

Introduction: Severe COVID-19 pneumonia is associated with significant morbidity and mortality and often requires intubation and invasive mechanical ventilation (MV). Weaning from MV is a difficult issue in this patient population, leading to extubation failure and/or tracheostomy. This contributes significantly to the prolonged ICU stay with its known negative effects.

Objectives: To investigate the incidence and consequences of successful and failed extubation and tracheostomy in ICU patients with COVID-19 pneumonia.
Methods: A retrospective observational study was performed in a Greek ICU from April 2021 to November 2021. We collected data from a total of 55 critically ill patients with severe laboratory-confirmed COVID-19 pneumonia. We excluded 19 patients who died without extubation attempt or direct tracheostomy. Demographic and baseline data, MV parameters and laboratory results, and sedation management data were collected at day 1, 3 and 7 after ICU admission. We also recorded all data from the day of extubation, re-intubation, or tracheostomy, general in-ICU events such as ventilator-associated pneumonia (VAP) and tracheobronchitis (VAT), and in-ICU, in-hospital, 28-day, 3-month, and 6-month mortality.
Results: Included 36 patients were males in 58.3%, had a mean age of 59.8 (SD ± 9.4) years, mean CCI 1.8 (SD ± 1.3) (arterial hypertension in 52.8%), mean APACHE II score 13.7 (SD ± 3.8) and mean LIS score 2.95 (SD ± 0.37). 17 (47.2%) patients underwent an extubation attempt on average day 10. Among them, 2 (11.8%) extubation failures were recorded with respiratory failure as the main cause. Patients with extubation failure displayed a longer length of ICU stay (39 vs 13 days), a longer MV duration (29 vs 10 days) and a higher in-ICU (50% vs 0%), in-hospital (50% vs 20%), 28-day (50% vs 13.3%), 3-month (50% vs 20%), and 6-month (50% vs 20%) mortality rate compared to patients with successful extubation (Figure 1). 19 (52.8%) patients underwent tracheostomy without extubation attempt on average day 14 with expected long duration of MV as the main cause. Patients with direct tracheostomy (mean APACHE II score 13.9 ± 3.8, LIS score > 2.5) displayed a longer length of ICU stay (31 vs 16 days), a longer MV duration (27 vs 12 days) and a higher in-ICU (47.4% vs 5.9%), in-hospital (47.4% vs 23.5%), 28-day (47.4% vs 17.6%), 3-month (52.6% vs 23.5%), and 6-month (52.6% vs 23.5%) mortality rate than patients with an extubation attempt (success and failure) (mean APACHE II score 13.5 ± 3.9, LIS score > 2.5). Patients with direct tracheostomy experienced more VAP (68.4% vs 23.5%) and VAT (10.5% vs 5.9%) events compared to patients with an extubation attempt (Figure 2).
Conclusions: In critically ill patients with severe COVID-19 pneumonia, extubation failure (11.8%) was found to be similar to the general ICU population (10.4%) according to current literature. Extubation failure and direct tracheostomy are associated with unfavorable outcomes.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000670

Introduction: COVID is likely to become endemic in several regions. Europe has vaccinated a large proportion of its citizens, and effective preventive and therapeutic interventions for earlier disease stages are becoming available (1–5) it is important to assess the resource consumption associated with COVID-19 infection, and factors that may influence it.
Objectives: To compare resources used to care for patients requiring ICU admission with SARSCoV-2 infection and stratified by disease severity (ie: severe or critical COVID-19 vs nonsevere disease).
Methods: Retrospective chart review of all patients requiring ICU admission with with PCR-proven SARS-CoV-2 infection between February, 1 and April, 30, 2022 with follow-up until hospital discharge, in 11 Portuguese hospitals.
Results: 305 patients were recorded. 194 (63.6%) had severe or critical COVID-19 (S/C) and 111 had non-severe (NS) disease and were admitted due to other conditions. ICU LOS in S/C patients was more than double that of NS (13.7 vs 6.6 days); hospital LOS was also longer (27.8 vs 17.9 days). Data on ventilatory support is presented in Table 1.

Table 1 (abstract 000670) .

	HFNO use n (%)	Duration of HFNO—days (AVG; range)	NIV use n (%)	Duration of NIV—days (AVG; range)	IMV n (%)	IMV duration days (AVG; range)
Global (n = 278*) * Data missing in 27	118 (42.4)	4.84 [0–36]	108 (38.8)	4.93 [1–36]	114 (41.0)	15; [1–61] * Data missing in 2
Covid S/C (n = 194)	105 (54.1)	5.03 (n = 105) [0.5–36]	94 (48.6)	4.90 (n = 94) [1–36]	91 (46.9)	16.28 (n = 90) [1–61]
Covid NS (n = 84)	13 (15.5)	3.0 (n = 13) [1–10]	14 (16.7)	5.0 (n = 14) [1–27]	23 (27.4)	9.68 (n = 22) [1–35]

Of 83 S/C patients submitted to iMV, with known vaccination status, 26 (31,3%) were non-vaccinated (NV) and without prior SARS-CoV-2 infection. Duration of MV was similar in both groups: NV 17,88 days vs 16,77 days.
Prone positioning was used in 77 patients. Of these 75 were in the S/C group and 71% were vaccinated.
28/277 patients received renal replacement therapy. Of these 24 (20 previously vaccinated) were in the S/C group and duration of treatment was longer in this group (13,5 vs 6 days). Ten patients received VV-ECMO, 8 in the S/C group (6 unvaccinated), for an average of 23 days.
Tracheostomies were done in 21 patients of whom 17 were critical COVID-19 cases.
A first episode of ICU-acquired infection occurred in 98 patients, of which 84 (85.7%) were in the S/C group. The most frequent foci were respiratory (n = 67) and urinary (n = 17). 40 had positive blood cultures (34 in C/S group).
Overall hospital mortality was 28.5% (37.1 in S/C vs 17.9 in NS); survivors were discharged to home in 72% of cases (equal in SC and NS pts).
Conclusions: With ~90% of the Portuguese population vaccinated, roughly two thirds of patients admitted to intensive care with documented SARS-CoV-2 infection still had severe disease. Resource consumption is significant with S/C patients more frequently requiring respiratory support and prone positioning. Duration of invasive mechanical ventilation was markedly prolonged. Extracorporeal organ support also appeared to be used more often although the numbers are quite small.
The high resource consumption may be, in part, driven by a higher incidence of nosocomial infection.

Flow versus pressure-controlled ventilation (FCV vs PCV) in postoperative cardiothoracic surgery patients on the ICU; a physiological prospective pilot study

J. P. van Oosten[1], H. E. Endeman[1], D. Gommers[1], A. Jonkman[1]
[1]Department of Intensive Care, Erasmus University Medical Center, Rotterdam, Netherlands

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000672

Introduction: The mechanical power (MP) unifies variables known to be related to the development of ventilator-induced lung injury (VILI) and is independently associated with ICU mortality [1]. Flow controlled ventilation (FCV) is a ventilation mode that uses a constant flow during both in- and expiration [2]. In a mathematical model the dissipated energy during FCV was lower compared to standard modes of controlled mechanical ventilation (CMV; being VCV and PCV) [3]. So far only Grassetto and colleagues compared the MP between CMV modes and FCV in ICU patients, however these results are hard to interpret since airway pressures were measured at different levels (the valve in CMV and intratracheal in FCV) [4]. Therefore, we conducted a physiological pilot study comparing FCV and PCV in patients requiring CMV at the ICU, whereby all airway pressures and flows were measured intratracheally.
Objectives: To assess the difference in MP and dissipated energy between FCV and PCV.
Methods: Post-cardiothoracic surgery patients requiring CMV in the ICU were enrolled. Intratracheal pressure and flow were measured continuously using dedicated equipment (BIOPAC Systems, Inc.) and stored for offline analysis. Patients were ventilated on PCV (t = 0) and then switched to FCV at the same PEEP and FiO_2 while Ppeak and flow of the FCV were optimized aiming for a stable tidal volume and ETCO2. After 30 min, FCV was further optimized in terms of driving pressure aiming for the highest dynamic compliance (not exceeding tidal volumes of 10 ml/kg IBW) and continued for 90 min. Arterial blood gasses were collected at start and then every 30 min. The MP, comprised of the resistive and elastic dynamic work but not static elastic work (Fig 1), and the dissipated energy (area within P–V loop) were calculated breath-by-breath for an 8-min stable period at t = 0 (PCV) and t = 90 (optimized FCV). Average values were compared using the paired-samples t-test or the Wilcoxon matched-pair signed-rank test (for not normally distributed data).
Results: 10 patients were included (7 males; age 66y (IQR 63–68); BMI 30.5 kg/m^2 (IQR 27.5–34.8)). Figure 1 shows a representative P–V loop with corresponding calculations. FCV resulted in a lower MP and dissipated energy while the minute volume (MV) decreased but the $PaCO_2$ and P/F ratio remained stable (Table 1).

Table 1 (abstract 000672) .

Variables	PCV (t = 0m) Median (IQR)	FCV (t = 90m) Median (IQR)	P-value
MV (L/min)	8.0 (6.5–8.4)	4.8 (4.3–7.2)	**0.005**
$PaCO_2$ (kPa)	5.4 (5.1–6.2)	5.3 (5.1–5.9)	0.264
P/F ratio	324 (240–365)	300 (273–369)	0.683
MP (J/min)	11.0 (8.4–12.8)	7.6 (5.7–11.4)	**0.013**
Dissipated energy (J/L)	0.34 (0.21–0.43)	0.20 (0.16–0.27)	**0.003**

Conclusions: FCV resulted in a significantly lower MP and dissipated energy compared to PCV with a lower MV but a stable gas exchange.

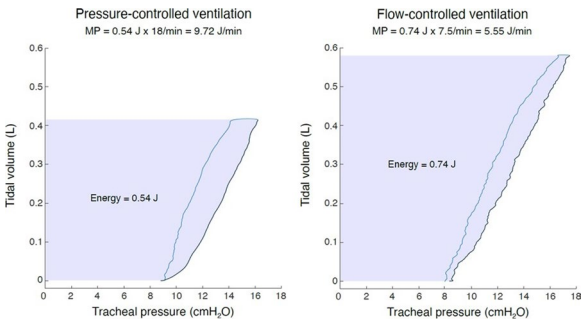

Figure 1 (abstract 000672) A representative P–V loop with corresponding MP calculations during PCV and FCV

Introduction: ICU-acquired weakness (ICUAW) is a long-recognised phenomenon, featuring a prevalence of 25–80%. Early mobilisation is an accepted intervention that may attenuate ICUAW and improve outcomes [1–4].
Objectives: Analyse, through a prospective observational study in a polyvalent ICU, the effect of early rehabilitation (eRHB) on the functional quality of life of patients one year after discharge (D/C).
Methods: During the COVID-19 pandemic, an early mobilisation protocol was started, working with the rehabilitation and physiotherapy department. Following its implementation, we conducted a prospective observational study in a polyvalent ICU analysing the effect of early rehabilitation (eRHB) on the quality of life of critically ill SARS-CoV2 positive patients one year after discharge (D/C); between March 2020 and July 2022.
Our study cohort included patients who did not receive early RHB (NO-eRHB group; programme was not yet in place) and patients who did receive early RHB (YES-eRHB group). All patients had (a) SARS-CoV2 pneumonia and (b) required invasive mechanical ventilation > 24 h. Demographic and clinical data were collected, and a telephone survey was conducted one year after D/C. We assessed the quality of life measured by: CFS on ICU admission (T1), Barthel at ICU discharge (T2), Barthel at hospital discharge (T3), and CFS/Barthel/SF36 one year after hospital discharge (T5). Statistical analysis was performed between subgroups: Pearson's Chi-square test or Mann–Whitney U test to find significant differences.
Results: We included 99 patients; 64.6% belonged to the YES-eRHB group (n = 64). In the raw data analysis (NO-eRHB group vs. YES-eRHB group), we observed statistically significant differences in SAPS III (59 vs. 53, p = 0.001) and SOFA on ICU admission (5 vs. 3; p < 0.001). Given the possibility that this statistically significant difference could impact the results obtained in the surveys, a propensity score (matching according to severity scales, age, and sex) was performed. Thus, we got 35 patients from the YES-eRHB group with demographic characteristics very similar to those from the NO-eRHB group. We observed only one death in the YES-eRHB group during the study period.
Demographic data and survey results are shown in Tables 1 and 2, respectively. Patients who belonged to the YES-eRHB showed a higher prevalence of respiratory comorbidities, required more often non-invasive mechanical ventilation after extubation, and showed longer hospital length-of stay. Regarding survey results, there were no statistically significant differences except for social functioning and self-reported health transition.
Conclusions: The assessment of interventions in critically ill patients is often complicated, given the close relationship between many factors, some of which are uncontrollable. Despite not having found statistically significant differences in most of the items assessed, we should highlight that patients who received early rehabilitation reported a clear positive impact on their social life and on the self-reported health transition item (higher vitality recovery, better pain control, and physical functioning). These results encourage and push us to continue improving critical patient care from a multidisciplinary point of view. Our goal is to get our patients back on their feet and back to their baseline life (or at least to a state of health they are satisfied and happy with).

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000674

Introduction: Facing the problem of multidrug-resistant bacteria (MDR-B) increasing, in our Intensive Care Unit (ICU) screening for MDR-B is carried out on admission from all patients with risk factors (RF) for them within the "Zero Resistance" project (1).
Objectives: To analyse patients admitted to our ICU who have RF for colonization by MDR-B, the RF rate, colonized patients and isolated MDR-B, assessing their evolution before and after COVID-19 pandemic.
Methods: A retrospective descriptive observational analysis of MDR-B RF and colonizations of patients admitted to our ICU in the pre-COVID (preC) and post-COVID (posC) period, from May 2018 to February 2020 and from November 2021 to March 2023. Screening for MDR-B is carried out by collection of oropharyngeal (OP) and rectal swabs on admission from all patients with risk factors (RF) for them within the "Zero Resistance" project (1). It is a multipurpose ICU with 12 beds, which increased to 24 beds during the pandemic.
Results: In the preC period, 912 patients were admitted to our ICU, of which 147 (16.12%) had RF for MDR-B; 77 (52.38%) had one RF and 57 (38.77%) 2 RF. The most frequent RF being previous admission (73.47%), followed by previous antibiotic treatment (61.9%). OP and rectal samples were collected from 114 patients (77.5%), of which 30 (26.32%) presented colonization by MDR-B, being rectal 25 (83.33%) and OP 8 (26.66%). The most frequent germs in rectal colonization (RC) were 12 (48%) extended spectrum betalactamase-producer *Gram-negative bacillus* (ESBL-GNB), followed by 5 (20%) *Acinetobacter baunmanii* imipenem-resistant, 4 (16%) methicillin-resistant *Staphylococcus aureus* (MRSA), 4 (16%) vancomycin-resistant *Enterococcus* (VRE) and 4 (16%) other GNB (1 carbapenemase). Three patients (12%) were colonized by more than one MDR-B. The most frequent germ in OP colonization (OPC) was MRSA in 5 (78.5%).
In the posC period, 701 patients were admitted, of whom 146 had RF (20.83%); 94 (64.38%) 1 FR and 40 (27.4%) 2 RF. The most frequent RF was previous admission (76.02%), followed by previous antibiotic treatment (44.52%). OP and rectal samples were collected from 108 patients (73.97%), of which 32 (29.63%) presented colonization by MDR-B, 27 (84.37%) RC and 12 (37.5%) OPC. About de rectal samples the most frequent were 13 (48.15%) ESBL-GNB, 7 (25.92%) KPC producing GNB, 4 (14,81%) *Pseudomonas aeruginosa* (PA), 3 (11,1%) *Enterobacter* and 3 (11.1%) MRSA. Five patients (18.52%) had RC by more than one MDR-B. In OP, 4 (33.33%) PA, 4 (33.33%) GNB ESBL and 3 (25%) MRSA; 4 (33.33%) had more than one MDR-B.
Conclusions: There is an increase in the rate of patients presenting RF in the posC period (20.83%) beside preC (16.12%). In both, the most frequent RF was previous admission, followed by previous antibiotic treatment. MDR-B colonization was 26.32% preC and 29.63% postC. The most frequent germs in RC were ESBL-GNB in both periods. In the posC appear KPC-GNB that were not detected the preC, with more patients colonized by more than one MDR-B. In OP, SAMR predominates in preC and GNB in posC.

Introduction: ESKAPE pathogens are increasingly identified as causative microorganisms in hospital acquired infections. The T2MR platform can expedite the identification of such pathogens in whole blood specimens without the prior need of a positive blood culture.
Objectives: To evaluate the feasibility and diagnostic accuracy of the T2 bacteria assay as point of care test in the intensive care unit compared to blood cultures.
Methods: Prospective observational study of consecutive critically ill patients with suspected bacteremia. Data collected included microbiological and T2 bacteria assay reports. Diagnostic accuracy was evaluated considering the blood cultures as the gold standard.
Results: 208 patients were assessed for eligibility and included in the study. All patients had T2 bacteria and blood culture samples sent. The rate of reported blood culture contamination as well as the rate of invalid T2 bacteria reports was 6.73%. 181 patients had valid blood culture and T2 bacteria reports. The mean time from sampling to report availability was 4 days for the blood culture results, and 3 h and 40 min for the T2 bacteria assay. The positive % agreement was 90.5%, the negative % agreement was 62.6%, the positive predictive value was 42.2%, and the negative predictive value was 95.6%.
Conclusions: The T2 bacteria diagnostic assay has high negative predictive value for excluding bacteremia caused by ESKAPE pathogens in a fraction of time compared to blood cultures. The application of this method is feasible as point of care technique in the intensive care. The lower positive predictive value observed can be attributed to higher sensitivity of T2 bacteria compared to blood cultures.

Introduction: Historically, admission of hematological patients in the ICU shortly after the start of a critical illness is associated with better survival rates [1–3]. However, prompt ICU admission cannot always be achieved. Intensive interventions administered by a pre-ICU system as (Medical Emergency Team) MET have an establish role in the management of critically ill patients [4–6]. However, the safety and effectiveness of intensive management of hematological patients in non-intensive wards is unclear [3].
Objectives: Our aim was to evaluate the safety and effectiveness of an intensive treatment trial in the medical ward provided by MET on hematological patients who develop a critical illness.
Methods: This is a monocentric retrospective study. The interventions provided by MET in the pre-ICU setting are mainly helmet CPAP and/or pharmacological cardiovascular support. We considered eligible for the study hematological adult patients (age $\geq$ 18 years) that were referred to MET for an acute clinical deterioration. We excluded patients who were not eligible to the ICU treatment due their clinical condition and poor prognosis defined by a multidisciplinary team composed of hematologists and intensivists. We also excluded those patients who immediately died after MET referral and for which the MET was alerted for the first time for a cardiac arrest.
Results: Between January 2015 and December 2019, our MET was called for advice for 169 hematological patients, 133 of which were considered eligible for data collection and analysis. Of these, 84 (63%) were admitted to ICU, while 49 (37%) were treated exclusively in the hematological ward (Figure 1).
Overall, in hospital mortality was 38%; mortality doesn't increase in patients not immediately transferred to the ICU (Figure 2). Moreover, 37% of patients overcame the critical episode in the hematological ward, thereby avoiding a relocation in a less isolated environment and lifting the pressure on ICU beds. 84 patients were admitted to the ICU, 53 of them (63%) immediately after the first MET referral. Only 3 patients died without a former admission in ICU; in these cases, mortality was not related to the acute illness, confirming the safety of this approach.
Apparently, mortality is not influenced by age age, sex, comorbidity, prior performance status, neutropenia, pharmacological immunosuppression, PaO_2/FiO_2, and degree of cardiovascular failure. Contrarily, patients who died had generally more severe systemic disease at first MET evaluation (SOFA 8.0 vs. 5.9, $p < 0.001$; MEWS 4.9 vs 3.8, $p = 0.007$) than those who survived.
Conclusions: An intensive treatment trial in the medical ward provided with MET support on hematological patients who develop a critical illness may be effective in avoiding ICU admission and safe. SOFA and MEWS were effective tools for prognostication. A prospective and multicentric trial is necessary to confirm our results.

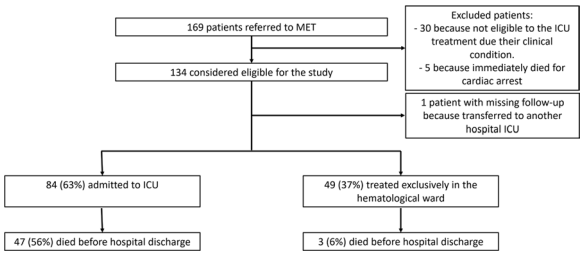

Figure 1 (abstract 000676) Enrollment, exclusion and patients' distribution in the primary analysis

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000677

Introduction: The long-standing effects of Covid-19 disease in physical and mental health are described by the term "post-Covid syndrome". Anxiety, depression, and post-traumatic stress are the most frequent post-Covid psychiatric manifestations. It is crucial to identify the patients at risk for post-Covid mental health sequelae, so that further support is provided, and their quality of life is improved in the long term.
Objectives: We aim to identify risk factors associated with the post-Covid anxiety, depression, and post-traumatic stress; correlate post-Covid symptoms with demographic and clinical characteristics; compare the prevalence of psychiatric manifestations among patients differing in co-morbidity, vaccination status, and Covid-19 severity.
Methods: A prospective cohort study recruited patients at one-, three-, or six- month follow-up after SARS-CoV-2 infection. Their demographic information, medical history, and clinical records during (disease severity, need for hospitalization or oxygen therapy) and after infection (somatic and psychiatric symptoms) were investigated. Symptoms of anxiety and depression were measured by the Hospital Anxiety and Depression Scale (HADS) [1] and symptoms of post-traumatic stress were measured by the Post-traumatic Stress Disorder Checklist-Civilian (PCL-C) [2].
Results: Two hundred and fifty patients were enrolled in the study. Post Covid symptoms varied from 88.3% (3rd month) to 70.1% (6th month). Mild mental health symptoms were common (anxiety 29.4%, depression 24.3%, post-traumatic stress 32.3%). Female sex ($p < 0.01$) and comorbidities ($p < 0.001$) were the strongest predictors of these symptoms, whereas severe or critical Covid-19 disease ($p = 0.001$) and hospitalization ($p = 0.002$) were associated with the presence of post-Covid depressive symptoms. Absent (26.8%) or incomplete (16.4%) vaccination against SARS-CoV-2 virus was associated with severe or critical illness (55.3%, $p < 0.001$) and post-traumatic stress symptoms ($p = 0.05$). Age, body mass index, respiratory support, oxygen therapy, and length of stay were not found to significantly correlate with post-Covid mental health symptoms.
Conclusions: Mental health symptoms are common up to six months after Covid-19 infection, with women and patients with comorbidities being the most vulnerable. Taking into consideration the increasing number of patients with post-Covid syndrome, this study highlights the need for their multidisciplinary evaluation.

Introduction: Hyperinflammation occurs in sepsis, especially in early phase, and it could have both positive and negative effects on sepsis. Previously, we showed that new concept of NF-kB inhibitor, exosome-based super-repressor IkBa (Exo-srIkB) delivery, has beneficial effect on sepsis.
Objectives: To investigate the therapeutic effects of this Exo-srIkB in different severity and phase of the sepsis using animal polymicrobial intra-abdominal infection model.
Methods: We used a rat model of fecal slurry polymicrobial sepsis. First, we determined the survival effects of Exo-srIkB on sepsis according to the severity. We used two different severities of animal sepsis model. Severe model had mortality rate over 50%. Mild/moderate model had less than 30% mortality rate. Second, we administered the Exo-srIkB at various time points (1 h, 6 h, and 24 h after fecal slurry administration) to determine the therapeutic effect of Exo-srIkB at different phase of sepsis. Lastly, we determined the effects of the Exo-srIkB on the arterial blood gas, electrolyte, and lactate.
Results: The survival gain was statistically significant in severe sepsis model when Exo-srIkB was administered 6 h after sepsis. The laboratory data showed that lactate, glucose, and potassium levels were significantly lowered in NF-kB inhibitor group.
Conclusions: Exo-srIkB, exhibited beneficial therapeutic effect when administered 6 h post fecal slurry administration in severe sepsis model.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000679

Introduction: Cell-free DNA (cfDNA)/Neutrophil Extracellular Traps (NETs) are associated with sepsis. NucleoCapture® (Pocard) apheresis is based on recombinant histone H1.3 selective binding to cfDNA/NETs. We previously demonstrated that NucleoCapture® reduced organ dysfunction and improved survival in a porcine sepsis model. We therefore performed a first in human study of NucleoCapture® in ten patients with sepsis in the ICU.
Methods: We enrolled ten adult ICU patients diagnosed with sepsis according to the Sepsis-3 criteria. We aimed to apply NucleoCapture® treatment in conjunction with the Terumo Optia system once daily for 3–5 days depending on the physician's assessment, in addition to standard of care. Efficacy and safety parameters were measured. We used the NuQ H3.1 nucleosome assay (Volition) to measure cfDNA/NETs.
Results: Ten patients underwent a total of 32 treatments with NucleoCapture®. The majority underwent 3 sequential treatments on Days 1 to 3. Each treatment lasted 4.26 (±0.8) hours and 3.7 (±0.4) plasma volumes were processed, Mean (±SD). No saturation of the column was evident with near complete removal (85–100%) of cfDNA/NETs in the extracorporeal circuit at all time points. This resulted in a reduction in the circulating levels of cfDNA/NETs in patient blood from 861.45 (IQR 295.7–1201.4) ng/ml to 211.5 (102.8–275.6) ng/ml from Days 1–3 (Figure 1). There were statistically significant decreases in inflammatory markers (e.g., CRP), organ function biomarkers (e.g., NGAL, Figure 2) and SOFA score (from 5.4 (±2.76) to 3.14 (±2.34), $p = 0.05$) during treatments with NucleoCapture®. The 28-day mortality was 50%. Six patients experienced a total of 12 adverse events, three of which were determined to be serious adverse events (SAEs). The investigators considered the SAEs to be unrelated to treatment with the investigational device.

Conclusions: This first in human study of NucleoCapture® suggests that selective cfDNA/NETs apheresis in sepsis is feasible, safe and has the potential to improve the course and outcomes of the disease. We plan to test this in an upcoming larger pivotal multicentre randomised controlled trial (ClinicalTrials.gov Identifier: NCT05647096).

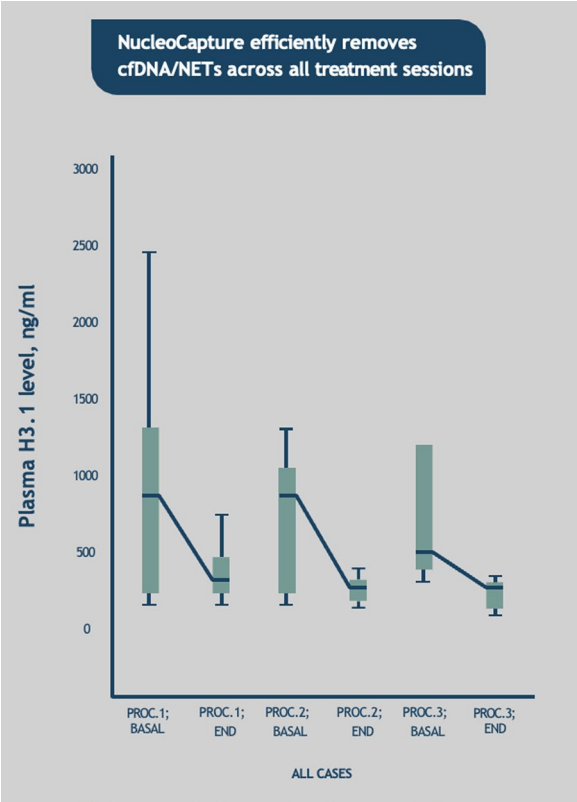

Figure 1 (abstract 000679) Change in plasma cfDNA/NETs over the course of 3 days of treatment with NucleoCapture®. cfDNA/NETs were measured using the NuQ H3.1 ELISA (Volition). Box plot with Min, Max, Median (IQR) values shown

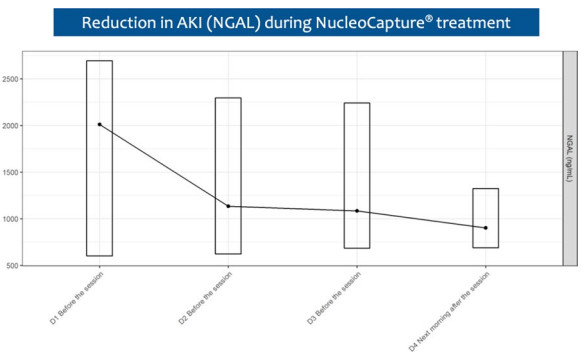

Figure 2 (abstract 000679) Early kidney injury biomarkers during NucleoCapture® treatment: Neutrophil gelatinase-associated lipocalin (NGAL). The plasma level of NGAL gradually decreased during the course of NucleoCapture® treatments, from a median of 2012 ng/mL on day 1 before the 1st session to 902 ng/mL on day 4, the day after the 3rd session, i.e., by 55%. A statistically significant decrease ($p = 0.020$) in the NGAL levels was observed between day 1 before start of the 1st session and day 2 before start of the 2nd session. Median (IQR) values shown

Introduction: Regional collaboration between Intensive Care Units (ICUs) is needed to cope with the increasing demand for ICU care and limited resources in terms of staff, beds and budget.
Objectives: Our aim was to select a consensus-based set of relevant and feasible indicators for monitoring and improving the quality of regional ICU network collaboratives.
Methods: Prior to the Delphi, 85 potentially relevant indicators were identified and listed through a systematic search of (grey) literature and by using the input of a core group of experts. A three-round RAND-modified Delphi study was subsequently conducted in the Netherlands between April and July 2022 (Figure 1). A multidisciplinary expert panel appraised and prioritized the potentially relevant indicators in two rounds of questionnaires with two consensus meetings between both rounds. The RAND/UCLA appropriateness method was used to categorize indicators and synthesize results. The relevance and feasibility of each indicator (in the first questionnaire generally assessed as the degree of appropriateness) were scored on a nine-point Likert scale. In the final questionnaire experts was additionally asked to prioritize the indicators by selecting the 'top 5' of most relevant and feasible indicators. Indicators with a group median ≥ 7, a disagreement index < 1 (indicating agreement) and receiving more than five percent of the maximum possible ranking points were selected for the core set and finally tested in two ICU network collaboratives to assess their measurability.

Results: After three rounds, 24 indicators were deemed as relevant and feasible. Seven indicators (three structure, three process and one outcome) were selected for the core set measuring the standardized mortality rate in the region (n = 1) and measuring the existence, content and/or follow-up of a formal plan describing network structures and policy agreements (n = 3), a long-term network vision statement (n = 1), and network meetings to reflect on and learn from ICU outcome data (n = 2) (Table 1). The practice tests led to minor reformulations.

Table 1 (abstract 000681) List of core set indicators*

A regional ICU cooperation plan is integrated in the policy plan of each ICU in which the tasks, responsibilities and competencies of each hospital/ICU within the network are clearly described (yes/no)
ICU indicator data from NICE** is regionally discussed with a focus on learning and improving (yes/no)
The regional ICU cooperation plan is demonstrably annually evaluated and actualized within the network (yes/no)
Presence of an annual (quality) report of the ICU network describing the network governance structure, actions and outcomes (yes/no)
The number and a description of the nature/types of improvements implemented after regional quality discussion meetings
SMR within the ICU network, expressed as the ratio of the observed and predicted mortality
A long-term vision is formulated in which the role of each ICU within the network is clearly defined (yes/no)

ICU: Intensive Care Unit; SMR: Standardized Mortality Ratio; NICE: National Intensive Care Evaluation Registry

*Indicators selected for the coreset (on the basis of: a median > 7 and DI score < 1 for both relevance and feasibility, and receiving ≥ 5% of the maximum possible ranking points)

**This registry receives monthly batches of data from ICUs extracted from local electronic hospital registries on intensive care patients and their outcomes to monitor and improve the quality of care

Conclusions: This study generated a set of relevant and feasible indicators for monitoring and improving the quality of regional ICU collaborative networks based on the collective opinion of a multidisciplinary group of experts. The indicators can assist those responsible for the governance of regional ICU network collaboratives in the Netherlands and abroad.

Introduction: Excessive patient spontaneous breathing efforts can complicate the transition from controlled to assisted ventilation. During this complex phase the lung may be particularly vulnerable to the injurious effects of high regional transpulmonary pressures. These can result from an unfavorable combination of ventilator delivered pressures and patient's generated muscular pressure. Monitoring transpulmonary pressures, especially in the context of patient's high inspiratory efforts, is of great clinical relevance but it requires the use of esophageal manometry of complex handling and interpretation.
Objectives: Clinical validation of a new method to estimate transpulmonary pressure (PL) in patients on assisted ventilation without the need of an esophageal balloon. The method is based on the combined recording of the diaphragmatic electrical activity (EAdi) and the estimation of the patient's effort contribution during an inspiratory low-assist maneuver (LAM).
Methods: Experimental, physiological, prospective, comparative study performed in patients on assisted ventilation with an adequate spontaneous respiratory drive. Patients were simultaneously monitored with esophageal manometry (Nutrivent®) and an EAdi catheter. After checking the correct positioning and signal of both catheters, three consecutive periods of 30 min using different inspiratory assist levels (clinician-adjusted, under-assist: 50% reduction and over-assist: 50% increase) were performed in a new ventilatory mode called neural-pressure support (n-PSV), a modified PSV mode in which the pneumatic signal is replaced by the EAdi signal for inspiratory trigger and expiratory cycling. A LAM (2 cmH_2O-assisted cycle) was programmed every 3 min. LAM derived PL (PLLAM) was estimated using a correction factor obtained from the ratio between the inspiratory volume during the LAM cycle and the volume of an assisted cycle ensuring that both resulted from breaths with a similar inspiratory drive by confirmed by their respective EAdi. PLLAM was compared with the reference measurement obtained from the esophageal pressure derived PL (PLpes). Correlation (Pearson) and accuracy, precision and percentage error were analyzed using the Bland–Altman test between the two methods.
Results: Preliminary analysis including the first 22 patients of an estimated sample size of 26. Clinician-adjusted PEEP and inspiratory support pressure were $7,2 \pm 1,5$ and $10,5 \pm 2,7$ $_{cmH2O}$ respectively. PLLAM correlated well with PLpes ($R2 = 0.79$) accuracy (Bias of -0.05 cmH_2O) and precision (95% limits of agreement of -3.7 to 3.6 cmH_2O) and a percentage error of 34% independent from the level of assistance.
Conclusions: The proposed method provides good estimates of PL with high accuracy and good precision compared to the reference method in the studied population. If confirmed, PLLAM could be an attractive clinical method to continuously monitor PL during assisted ventilation, without the need to measure esophageal pressure.
