Introduction: During acute respiratory distress syndrome (ARDS), positive end-expiratory pressure (PEEP) might increase pulmonary vascular resistance (PVR). In theory, according to the U-shape of the relationship between PVR and lung volume, which nadir corresponds to the functional residual capacity, PEEP should increase PVR in case of alveolar overdistention and lower PVR if alveolar recruitment predominates. This has never been proven in patients with ARDS.
Objectives: We conducted a prospective observational study to evaluate PVR changes during PEEP modifications depending on the potential of lung recruitability, estimated through the recruitment-to-inflation (R/I) ratio.
Methods: In intubated ARDS patients, monitored by a pulmonary artery catheter, an oesophageal balloon and transthoracic echocardiography, PEEP was lowered by 10 cmH_2O from baseline. At the two levels of PEEP, hemodynamic, echocardiographic and respiratory variables were measured and preload dependence was evaluated through the passive leg-raising test. An $R/I \geq 0.5$ defined high recruitment potential (HRP) and $R/I < 0.5$ defined low recruitment potential (LRP).
Results: Forty-five measurements were performed in 16 patients (2 [1; 3] measures per patient). Demographical and clinical characteristics are presented in Table 1.

Table 1 (abstract 000683) Demographical and clinical characteristics

Variables	Study population (n = 16)
Age, years	66 (11)
Male sex, n. (%)	12 (75)
BMI, kg/m^2	29 (6)
Extra-pulmonary ARDS aetiology, n. (%)	4 (25%)
SOFA score at admission	6 (3)
PaO_2/FiO_2 at diagnosis, mmHg	108 (73–123)
Noradrenaline support at inclusion, n. (%)	16 (100)
Duration of invasive mechanical ventilation, days	8 (4–20)
ICU length of stay, days	11 (7–23)
ICU mortality, n. (%)	6 (38)

The R/I ratio was ≥ 0.5 (0.71 [0.60; 0.89]) in 25 (56%) measurements and there was no difference in the incidence of fluid-responsiveness between HRP and LRP groups ($p = 0.23$). PEEP was lowered from 15 (12; 15) to 5 (2; 5) cmH_2O. By lowering PEEP, the PVR decreased in case of LRP (−23 [−29; −14]%) while they remained unvaried in case of HRP (0 [−10; 13]%, $p < 0.0001$) (Figure 1). The gradient between mean pulmonary arterial pressure (MPAP) and pulmonary arterial occlusion pressure (PAOP) decreased in case of LRP (-7 [−19; −6]%) but increased in case of HRP (9 [0; 19]%, $p < 0.0001$). A similar effect was observed for right to left ventricular end-diastolic area ratio (−16 [−25; −9]% vs. 3 [−9; 17]%, respectively, $p = 0.0003$). An $R/I \leq 0.44$ could predict a decrease in the gradient between MPAP and PAOP with PEEP lowering with an area under the receiver operating characteristic curve of 0.83 (0.68–0.92) ($p < 0.0001$ vs 0.5), a sensitivity of 80 (56–94)% and a specificity of 84 (64–96)% (Figure 2).
Conclusions: Effects of PEEP on PVR in mechanically ventilated patients with ARDS might depend on alveolar recruitment. A

significant risk of PVR increase exists when PEEP leads to pulmonary overdistention. This suggests that the potential of lung recruitment should be considered during PEEP titration, in order to better individualize respiratory support. The study is ongoing.

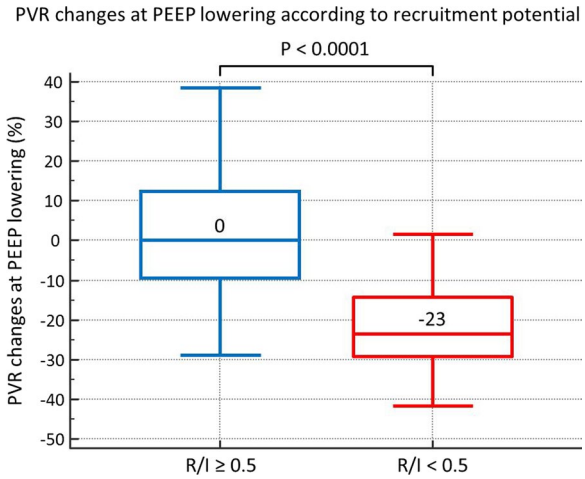

Figure 1 (abstract 000683) PVR changes at PEEP lowering according to recruitment potential

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000684

Introduction: For patients undergoing continuous renal replacement therapy (CRRT) amino acid metabolism is dysregulated, favouring the decrease of amino acid concentration, and promoting negative nitrogen balance. This leads to protein wasting and worse clinical outcomes. For patients undergoing continuous renal replacement therapy (CRRT) amino acid metabolism is dysregulated, favouring the decrease of amino acid concentration, and promoting negative nitrogen balance. This leads to protein wasting and worse clinical outcomes.
Objectives: The aim of this study was to describe the determinants of amino acid concentrations during the 1st and the 3rd day of CRRT.
Methods: This was a prospective study of patients who were admitted to a tertiary referral university hospital ICU. Inclusion criteria were as follows: start of continuous renal replacement therapy (CRRT), mechanical ventilation and compatible with either SEPSIS-3 or SIRS criteria. The patients were evaluated on the 1st and the 3rd day of CRRT. Amino acid (AA) concentration was measured in the systemic circulation with calorimetric assay kit (mmol/l). Possible determinants of amino acid concentration were collected: fat free mass index (FFMI) as a marker of protein storage (kg/m^2), AA loss during CRRT (g/day), SOFA score for disease severity and amount of prescribed daily protein (g/kg). (1) Univariate and multivariate regression analysis for the 1st and 3rd day was conducted.
Results: 60 high mortality risk patients (APACHE II of 22.98 ± 7.87, SOFA score of 12.25 ± 3.61) were included during the period of the study. The AA concentrations for the 1st day were 2.14 ± 1.01 (mmol/l), for the 3rd day were 3.14 ± 2.36 (mmol/l), with a significant increase toward the 3rd day (p = 0.011). In the univariate regression analysis of 1st day AA concentration determinants, the results were as follows: for FFMI (R = 0.313, Beta = 0.084, P = 0.02), for AA loss (R = 0.686, Beta = 0.087, P < 0.001), for SOFA (R = 0.315, Beta = − 0.087, P = 0.016), for daily protein intake (n.s. p = 0.51); in the multivariate regression analysis only the amino acid loss during CRRT prevailed (R = 0.672, Beta = 0.068, P < 0.001). In the univariate regression analysis of 3rd day AA concentration determinants, the results were as follows: for FFMI (n.s. p = 0.468), for AA loss (R = 0.578, Beta = 0.075, P < 0.001), for SOFA (n.s. p = 0.329), for daily protein intake (R = 0.427, Beta = 2.098, P = 0.013); in the multivariate regression analysis both the amino acid loss during CRRT (R = 0.771, Beta = 0.071, P < 0.001) and daily protein intake (R = 0.771, Beta = 2.226, P < 0.08) prevailed.
Conclusions: Amino acid concentrations are low in ICU population on CRRT. The most important determinant of low amino acid concentration is loss through the haemofilter. During the 1st day of CRRT the reserves and the severity of the disease are also effectual, towards the 3rd day the protein load starts to be more impactful.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000685

Introduction: The leukotriene receptor antagonist montelukast and the lipoxygenase inhibitor zileuton have been successfully used in the USA in patients with chronic pulmonary diseases, e.g. asthma. In addition, both agents have been associated with protective effects in other inflammatory conditions, such as inflammatory liver disease, arteriosclerosis and rheumatoid arthritis [1–3]. Since the pathophysiology of the Acute Respiratory Distress Syndrome (ARDS) is rather complex and still insufficiently understood, we tested the leukotriene modifiers montelukast and zileuton regarding potential anti-inflammatory effects in this setting. An uncontrolled infiltration of polymorphonuclear neutrophils (PMNs) into the lung is the main hallmark of ARDS. Thereby, the activation of platelets and the formation of platelet-neutrophil-conjugates (PNCs) play a crucial role in acute pulmonary inflammation. The enzyme lipoxygenase and the leukotriene receptor do have a distinct role in inflammation. However, the effects of leukotriene modifiers in acute pulmonary inflammation and the underlying mechanisms remain unclear.
Objectives: Our systematic investigations in acute pulmonary inflammation will provide new insights in the potential use of montelukast and zileuton for ARDS on intensive care units.
Methods: Acute pulmonary inflammation was induced by lipopolysaccharide (LPS)-inhalation in C57BL/6 mice. Montelukast and zileuton were injected intraperitoneally with a dose of 0.1 µg/µl at 1 µg/g body weight 1 h after LPS inhalation, highlighting the clinical impact of the presented study.
Results: Montelukast and zileuton decreased the LPS-induced PMN-infiltration into all different compartments of the lung (intravascular, interstitial and intra-alveolar) by reduced expression of the involved adhesion molecules and chemokines. Levels of TNF-α, IL6 and CXCL2/3 were diminished by both leukotriene modifiers. Supporting our statement, the corresponding transcription factors ERK1/2 and pCREB were also suppressed on PMNs, lung endothelium and epithelium. Caspase-1 protein expression was decreased in response to both drugs, influencing cleavage and therefore activation of proinflammatory interleukins. Furthermore, our data revealed that both agents inhibited the release of mature PMNs from the bone marrow into the blood, which is a critical step regarding the following PMN-infiltration into the lung. The formation of PNCs, which contributes to an increased neutrophil adhesion and transmigration, was blocked by montelukast and zileuton. Thereby, platelet activation was inhibited by the reduced expression of Txbas1 and P2Y12. To confirm the effects of both modifiers, we examined the expression of leukotriene pathway-related genes. Alox5, CysLTR1, CysLTR2, LTA4H, LTC4S and LTB4R1 were reduced in lung tissue by both modifiers.
Conclusions: Our study revealed formerly unknown anti-inflammatory effects of montelukast and zileuton in LPS-induced lung injury in mice, leading to promising clinical investigations.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000687

Introduction: Presence of multidrug-resistant bacteria (MRD-B) gain importance in our Intensive Care Unit (ICU) and it's necessary to know which MRD-B are rising and monitoring the consumptions of antibiotics. Knowledge about our MRD-B also helps to decide the best initial empiric antibiotic therapy, as it's shown in antibiotic consumption.
Objectives: The main objective of our study is to analyze MRD-B isolations in patients admitted to our ICU (a polyvalent ICU with 12 beds, extended to 24 beds during COVID-19 pandemic period) and to observe which were the antibiotics we mostly used in a defined period of time. We considered MRD-B imipenem resistant *Acinetobacter baumannii* (IRAB), methicillin-resistant *Staphylococcus aureus* (MRSA), extended spectrum beta-lactamase-producing *Kleibsiella pneumoniae* (ESBL-KP), multiresistant *Pseudomonas* (MR-P), vancomycin-resistant *Enterococcus* (VRE) and carbapenem-resistant *Enterobacteriae* (CRE).
Methods: Retrospective descriptive observational analysis of MRD-B isolation and the use of antimicrobials in patients admitted in our ICU from January 1st, 2021 to December 29th, 2022. Microbiological isolation obtained from oropharyngeal and rectal exudates and clinical samples. Antibiotic consumption is expressed in defined daily dose (DDD): consumption (gr) × 100/DDD-WHO × stays, related to 100 stays.
Results: During the study period we had a total of 928 patients admitted in our ICU (420 in 2021 and 508 in 2022). MRD-B isolations were 892, 648 in 2021 and 242 in 2022. Most frequent MRD-B in 2021 were IRAB 374 (41,92%) that was an outbreak without any isolation in 2022, MR-P 134 (20,67%), ESBL-KP 67 (10,33%), CRE 41 (6,32%), MRSA 31 (4,78%) and VRE 1 (0,15%). In 2022, MRSA 113 (46.31%), MR-P 57 (23.36%), ESBL-KP 49 (20.08%), CRE 25 (8.19%) and VRE 0. Total antibiotic consumption in this two years were similar between them, in 2021 antibiotic consumption was 199, 13 and in 2022 was 192,49. Both years the main antibiotic used was Meropenem, with 41, 69 DDD/100 stays in 2021 and 40,26 in 2022. In 2nd place, Linezolid with 27,57 DDD/100 stays in 2021 and 27,03 in 2022. In 2021, Tigecycline ranked 3rd according to the increase of IRAB outbreak (23,52). Same year, the 4th antibiotic was represented by Ceftriaxone (21,44), followed by Levofloxacin (19,53). In 2022, the 3rd mostly used antibiotic was Levofloxacin (20,39), followed by Daptomycin (14,26) and Amoxicillin-clavulanic acid (10,3).
Conclusions: In 2021, we had more MRD-B isolations than 2022, even with similar number of admissions and similar antibiotic consumption. In 2021, we had an increased presence of IRAB due to an outbreak and this made Tigecycline gain importance in this period. Excluding this special situation, most frequent MRD-B were MR-P, ESBL-KP and MRSA. The most used antibiotic were Meropenem in 1st place followed by Linezolid.

Characteristics and outcomes of auto-intoxicated patients admitted to the ICU: a retrospective cohort study

F. Polfliet[1]
[1]Anaesthesiology, Jessa Ziekenhuis, campus Salvator, Hasselt, Belgium
Correspondence: F. Polfliet
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000690

Introduction: Auto-intoxications are responsible for a large number of Intensive care unit (ICU) admissions (1). Literature focusing on characteristics and outcomes of ICU-admitted auto-intoxicated patients is limited.
Objectives: We aimed to describe the characteristics and outcomes of these patients and to calculate the percentage of ICU admissions attributable to auto-intoxications.
Methods: In this retrospective cohort study, all patients admitted to the ICU of JESSA hospital, Hasselt, Belgium with a diagnosis of auto-intoxication between January 1th 2017 and December 31th 2022, were included in the study. We collected data on patient characteristics, comorbidities, type of intoxication and outcomes including the length of ICU and hospital stay and mortality.
Results: In total, 374 patients were included in the dataset, covering 2.66% of all ICU admissions from 2017 to 2022. Baseline characteristics are presented in Table 1. Almost 25% of included patients had a history of previous suicide attempt and more than 40% of previous auto-intoxication. More than 70% of included patients tried to commit suicide versus almost 20% recreational abusers. Toxicological results revealed abuse of more than 1 substance in almost 55% of cases. Outcomes are presented in Table 2. ICU- and hospital mortality were 1.6% and 0.8% respectively. Total mortality at time of dataset closure was 7.2%.
Conclusions: The impact of auto-intoxication on ICU resource utilisation is quite high and the risk of recidivism is substantial. ICU- and in-hospital mortality after auto-intoxication is low but these patients have a substantial risk for death following hospital discharge.

Table 1

	Intoxicated patients ICU n=374
Age (years)	38.00 (26.00, 53.00)
Gender (male/female)	162 (43.3%) / 212 (56.7%)
BMI (kg/m^2)	24.22 (22.09, 26.36)
Comorbidities	
Chronic Liver Disease	31 (8.3%)
Chronic Kidney Disease	5 (1.3%)
Chronic Lung Disease	18 (4.8%)
Cardiovascular Disease	22 (5.9%)

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000691

Introduction: Intensive care unit patients were shown to have poor quality of sleep over the last three decades. However, to improve the sleep distortion in critical patients remains challenging.
Objectives: The aim of this study is to investigate the impact of continuous quality improvement on sleep distortion in critical patients.
Methods: All consecutive patients from 2019 to 2021 in adult ICU were enrolled. The key interventions include novel sacral suspended decompression recumbent care, simple air pressure turning device, remote warning care system and using big data to monitor critical care warning indicators. The patients were divided into three periods: pre-intervention period from Jan to Dec 2019, intervention period from Jan to Dec 2020, and post-intervention period from Jan to Dec 2021.
Results: The sleep assessment ratio improved from 49.0% in the pre-intervention period, to 67.5% in intervention period and to 95.1% in post-interventional period ($p < 0.0001$). The good quality sleep ratio improved from 70.4% in the pre-intervention period, to 74.2% in intervention period and to 87.8% in post-interventional period ($p < 0.0001$). Average ICU stay decreases from 7.9 days to 6.9 days after intervention ($p < 0.05$). The incidence of ventilator-associated pneumonia decreased from 0.7‰ to 0.4‰ ($p < 0.05$). The mortality decreased from 7.6‰ to 5.2‰ ($p < 0.05$).
Conclusions: The study showed that implementation of continuous quality improvement using novel critical care system could increase sleep assessment ratio and good quality sleep ratio, and reduce the average ICU stay. Furthermore, the incidence of ventilator-associated pneumonia and mortality also improved.

Introduction: Long-term functional outcomes after critical COVID-19 are not sufficiently studied.
Objectives: The aim of this study was to describe functional outcome and health-related quality of life (HRQoL) at 3 and 12 months in a cohort of critically ill COVID-19 survivors and to investigate factors associated with good functional outcome and HRQoL at 12 months.

Methods: This prospective multicentre cohort study included critically ill COVID-19 patients admitted to six intensive care units in Sweden between May 2020 and May 2021. Surviving patients were invited to a follow-up at three and 12 months. A good functional outcome was defined as a Glasgow Outcome Scale Extended > 6. HRQoL was assessed by the Short Form-36 item Questionnaire Health Survey version 2® (SF-36v2®). Factors associated with good functional outcome and HRQoL at 12 months were explored by multivariable logistic regression.
Results: Good functional outcome was found in 93/264 (35%) survivors at 3 months and in 138/217 (64%) at 12 months ($p < 0.001$). There was a significant improvement in the physical component summary of the SF-36.v2® between 3 and 12 months (mean 40.2 versus 43.8, $p < 0.001$). The SF-36.v2® mental component summary was within the normal range at three months, with no significant difference at 12 months (mean 46.5 versus 48.4, $p = 0.051$). Age ≤ 65, shorter time on mechanical ventilation and a higher level of education were associated with good functional outcome at 12 months. Low clinical frailty and shorter time on mechanical ventilation were associated with a better physical HRQoL.
Conclusions: A significant improvement in functional outcome and physical aspects of HRQoL was seen between 3 and 12 months, indicating continued recovery up to at least one year after critical COVID-19. Younger age, lower clinical frailty and shorter time on mechanical ventilation were associated with better long-term outcome.

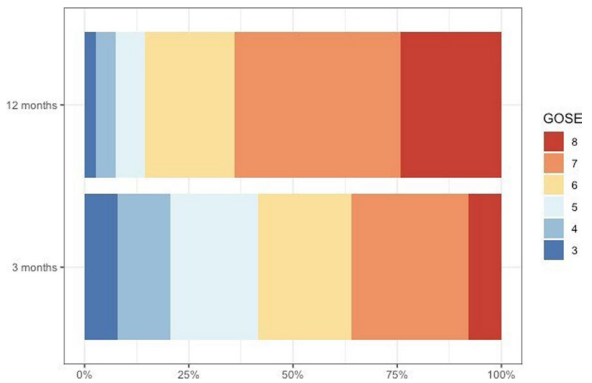

Figure 1 (abstract 000692) Functional outcome measured by Glasgow Outcome Scale-Extended in 217 survivors at 3 and 12 months post critical COVID-19

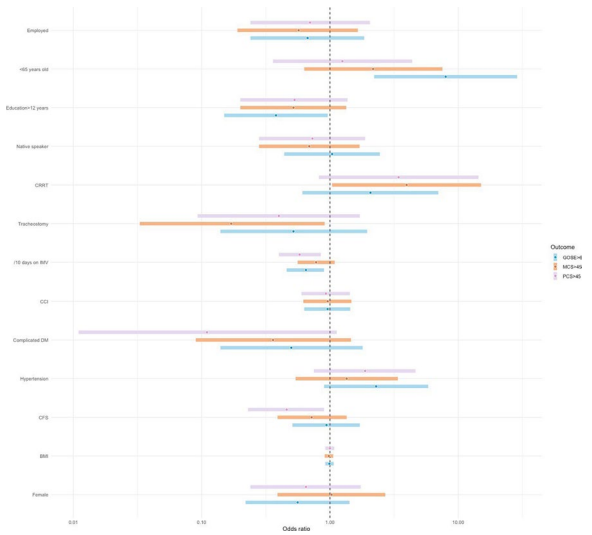

Figure 2 (abstract 000692) Forest plot of good functional outcome GOSE > 6 at 12 months (light blue), good mental HRQoL (mental component Summary > 45 in SF36v2) at 12 months (orange), and good physical HRQoL (Physical component Summary > 45 in SF36v2) (purple) at 12 months. Model based on information on admission and during intensive care stay, with at p-value < 0.1 in the univariate analysis. Demonstrating adjusted/multivariable odds ratio with a 95% CI (demographics, comorbidities, acute physiology, ICU treatments

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000693

Introduction: Analysis of the arterial pressure waveform allows to estimate left ventricle stroke volume (SV). This approach can also be applied for estimation of right ventricle SV (RV-SV) but is less extended in clinical settings. Intrathoracic pressure changes resulting from mechanical ventilation could affect pulmonary artery (PA) pressure waveform (PAPW) and, in consequence, decrease the reliability of its use to estimate RV-SV.
Objectives: To evaluate if correcting the effect of mechanical ventilation on PAPW increases correlation between parameters used to estimate SV and the measured RV-SV.
Methods: Continuous PA pressure and flow were measured simultaneously during two minutes in 5 pigs using a high fidelity microtip catheter and a transonic flow sensor placed at the PA trunk, before and after being subjected to an experimental ARDS model. Animals were ventilated in a volume controlled mode with a PEEP 8 cmH_2O, tidal volume 6 ml/kg, inspiratory/expiratory ratio 1:2, FIO_2 1 and respiratory rate adjusted to keep an end-tidal CO_2 around 45 mmHg. Validated parameters to estimate SV such as pulse pressure (PP), systolic area (SA) and standard deviation (SD) were calculated beat by beat from the PAPW while actual RV-SV was obtained from the PA flow signal. The effect of mechanical ventilation was estimated by creating an artificial continuous signal based on the beat by beat diastolic PA pressure and the relative time position of cardiac beats in the respiratory cycle. This signal was subtracted from the PA pressure signal (Fig 1) and then, corrected PAPW parameters were calculated (cPP, cSA, cSD). Correlation between beat by beat PAPW parameters before and after correction and beat by beat measured RV-SV during the two minutes analysis time was calculated. Two-way ANOVA for repeated measurements was applied to assess whether corrected measurements have a different correlation than uncorrected measurements in the two evaluated conditions.
Results: Driving pressure increased after ARDS, 7 [5–8] cmH_2O vs 19 [19–22] cmH_2O, $p=0.04$. Before ARDS rho between measured RV-SV and uncorrected parameters was: 0.86 ± 0.70 vs PP, -0.11 ± 0.34 vs SD and 0.54 ± 0.14 vs SA while for corrected parameters was: 0.88 ± 0.09 vs cPP, 0.88 ± 0.13 vs cSD and 0.92 ± 0.05 vs cSA. After ARDS rho between measured RV-SV and uncorrected parameters was: 0.75 ± 0.08 vs PP, -0.03 ± 0.26 vs SD and 0.48 ± 0.11 vs SA while for corrected parameters was: 0.85 ± 0.05 vs cPP, 0.84 ± 0.08 vs cSD and 0.93 ± 0.03 vs cSA. A $p<0.05$ was found for the effect of correction in the correlation between measured RV-SV and standard deviation and between measure RV-SV and systolic area.

Conclusions: The effect of mechanical ventilation affected the correlation between RV-SV and the PAPW parameters used for its estimation. In our dataset, this was significant for the standard deviation and the systolic area. These results could be relevant for the bedside implementation of methods to estimate right ventricle SV from PA pressure.

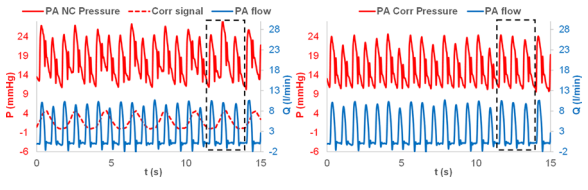

Figure 1 (abstract 000693) Example of the PA pressure before (PA NC Pressure, left) and after correction (PA Corr Pressure, right). A better coherence between pressure and flow amplitudes is seen after the correction (dashed rectangle). Corr signal (dashed red line, left) is the signal used to correct for the effect of mechanical ventilation and is in phase with the airway pressure

Inhaled sedation in COVID-19 acute respiratory distress syndrome: an observational study with a propensity score matching model

I. Cappellini[1], L. Zamidei[1], B. Freschi[1], L. Campiglia[1], G. Consales[1]
[1]Emergency And Critical Care Medicine, Ospedale Santo Stefano, Prato, Italy
Correspondence: I. Cappellini
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000694

Introduction: Patients affected by severe form of COVID-19 induced respiratory failure (C-ARDS) frequently need deep sedation in order to perform adequate ventilator support. Volatile Anesthetics (Vas) are an alternative to intravenous molecules, allowing to obtain the desired level of sedation.
Methods: This is a retrospective single-center nonprofit observational cohort study. We enrolled patients admitted for C-ARDS to the COVID Intensive Care Unit of Santo Stefano Hospital in Prato during the period March 2020-June 2021 who received to invasive mechanical ventilation. Participants were divided in two categories: those who received Sevoflurane and those sedated with intravenous drugs. A propensity score matching model (PSM) was applied to minimize the differences between the two groups. The Mann–Whitney/Wilcoxon test or *t test* was used to analyze continuous variables; for categorical variables, Fisher's exact test or chi-square test was used. Values with $p < 0,05$ were considered significant.
Results: A total of 112 patients were enrolled in the study. 56 patients who received inhaled sedation have been matched with 56 participants who received intravenous sedation by means of PSM. An adequate level of sedation was obtained in both groups. The application of the Wilcoxon test showed an improvement in P/F in the sevoflurane group compared to controls at T2 in respect to T1 (mean: T1 148.31 vs. 208.26 at T2), although this difference was not statistically significant ($p = 0.06$); on the seventh day of ventilation an improvement in the P/F ratio was observed (mean: T0 148.31 vs 182.33 in the sevoflurane group at T3 (*p value* = *0.*10). Static compliance in the "Sevoflurane" population at three days was statistically significantly higher (mean of 42 compared to 39.95 cmH_2O/mL at T1 in the Sevoflurane group) than in the "non-Sevoflurane" population (*p value* = 0.02). At seven days after intubation, static compliance was improved in the "Sevoflurane" population compared to the "non-Sevoflurane" population, but the difference was not statistically significant (p value = 0.1).
Finally, a logistic regression model was applied to the paired sample, relating the *mortality* (dependent variable) to the treatment used (independent variable). The model showed estimate value of −0.9 with a *p value* = 0,02. The *odds ratio* is 0.40, which is a wide 95% confidence interval that does not include the value of 1 (0.18–0.87).
Conclusions: The use of sevoflurane for deep sedation of invasively ventilated CARDS patients is effective and feasible. Sevoflurane sedation induced a relevant amelioration of respiratory mechanics that may have a clinically relevant effect in C-ARDS patients.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000695

Introduction: Protocolised early rehabilitation of critically ill patients may improve long-term outcomes, however, protocolised interventions are poorly described and implementation challenging due to limited staff and resources. We conducted a feasibility study that aimed to deliver a protocolised early rehabilitation program including supine cycling, delivered by a therapy technician, compared with usual care. This study was to inform the protocol design for a future randomised control clinical trial (1).
Methods: Patients were enrolled from 3 UK mixed medical-surgical ICUs. Eligibility criteria were: unplanned medical admissions; intubated and ventilated < 72 h; expected to need continued invasive ventilation for a further 48 h, > 42 years old and functionally independent prior to ICU admission. Randomised participants (1:1) received usual care or usual care plus a protocolised early rehabilitation program consisting of 2 additional 30-min rehabilitation interventions including cycling. Feasibility outcomes included: (1) recruitment at sites; (2) protocol fidelity with > 75% of patients commencing interventions within 72 h of mechanical ventilation, with > 70% interventions delivered; (3) blinded outcome measures recorded at three time points in > 80% of patients.
Results: Recruitment took place between July 2019 and July 2022. Study delivery was impacted by COVID-19 with an interim suspension to recruitment, redeployment of research staff and hospital visiting restrictions. Of 46 patients enrolled, 20 (43%) were female, median age 60, 23 (50%) had pneumonia/COVID pneumonitis with an overall median APACHE II score of 19 (range 9–69). 20 participants received the protocolised rehabilitation. Total ICU mortality was 15/46 (33%) and 16/46 (35%) at hospital discharge and 3 months. Feasibility outcomes (1) Recruitment 0.9 patients/month/site (2) Protocol fidelity 93% patients commencing interventions within 72 h of mechanical ventilation, 70% of study interventions delivered (3) Outcome assessments were completed in 26/31 (84%), 22/26 (85%) and 16/25 (64%) of

patients at the 3 time points. Of these assessments, 12/26 (46%), 10/22 (45%), and 9/16 (56%) respectively were blinded. Interventions delivered were as per table.

	Usual care (N = 22)	Usual care plus protocolise rehabilitation (N = 22)		
		Usual Care therapy	Protocolised therapy	Total therapy Intervention
Time from intubation to randomisation (hrs)	Median: 32 IQR: 18–52		Median: 23 IQR: 19–40	
Time from randomisation to first therapy intervention (hrs)	Median: 24 IQR:16–104	Median: 23 IQR: 18–72	Median: 20 IQR: 2–24	
Total therapy intervention per day (minutes)	Median: 23 IQR: 17–35	Median: 20 IQR:15–35	Median: 35 IQR: 20–60	Median: 48 IQR: 30–74
Total therapy intervention (minutes)	Median: 90 IQR: 70–255	Median: 105 IQR: 35–240	Median: 213 IQR: 88–313	Median: 278 IQR: 170–517

Conclusions: Although feasibility was confounded by COVID-19 restrictions our results suggest careful consideration of staffing resources, which outcome measures should be used, when these data are collected and by whom.

Early admission of oncohematologic patients to the Intensive Care Unit (ICU) improves their prognosis. Prospective observational study

I. Azkarate[1], J. Marin[1], M. Iriarte[1], I. Elosegui[1], I. Quevedo Marcos[1], B. Millan[1], M. Duran[1]
[1]Critical Care Unit, Donostia University Hospital, Donostia, Spain
Correspondence: J. Marin Cortajarena
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000696

Introduction: Survival rates of oncohematologic patients have increased due to advances in diagnosis and treatment in this field. As a result, their admission to the ICU is more frequent due to disease- or management-related complications.

Objectives: To analyze whether the prognosis of oncohematologic patients improves with an earlier admission to the Intensive Care Unit (ICU).

Methods: Prospective observational study conducted over a consecutive 7-year period (1.1.2016 to 12.31.2022) in a 48-bed ICU in a tertiary level hospital, whose Hematology service is the reference for hematopoietic transplantation in the Basque Autonomous Community. Results from 2016, considered as a control year, were analyzed and a protocol for an earlier admission to the ICU was established in the following years.

Results: Over the 7-year period, a total of 197 patients were admitted to ICU (29 in 2016, 36, 19, 36, 36, 18, 22 and 39 in successive years). Patients were predominantly male (69%, in 2016 and 62%, 58%, 53%, 53%, 72%, 77% subsequently), and there was no age difference between years (61, 63, 65, 59, 66, 63 and 60 years). A significant ($p = 0.039$) decrease of SOFA at admission was observed over the years, being 11 in 2016, 8 from 2017 to 2020, and 7 in 2021 and 2022. Mean APACHE significantly ($p = 0.024$) decreased from 2016 to 2022, being 25 in 2016, and decreasing to 24, 23, 24, 23, 22 and 21 in the successive years.

The underlaying hematological diseases did not differ, with leukemia being the most frequently reported (36.4%, acute myeloblastic 35.2%), followed by lymphoma (34.9%, 86.7% was non-Hogdkin's lymphoma). Among a wide range of causes of ICU admission, the leading causes were sepsis, followed by respiratory failure, reported in 43% and 29% of patients, respectively. No significant differences were observed during the 7-year period.

An important amount of patients required vasopressors (72% in 2016, 64%, 68%, 47%, 91%, and 62% subsequently, $p = 0.05$) and mechanical ventilation (62% in 2016, and 28%, 53%, 33%, 33%, 33%, 45% and 30% in successive years, p 0.055). A statistically significant difference ($p = 0.035$) was observed in the percentage of patients in need of renal clearance techniques, being 31% in 2016, and decreasing in the following years (14%, 21%, 22%, 22%, 22%, 17%, 5% and 3%).

ICU mortality decreased significantly (p 0.001) being 59% in 2016, and 28%, 53%, 33%, 33%, 33%, 23% and 11% in subsequent years. Similarly, overall, in-hospital mortality decreased significantly ($p = 0.007$), being 69% in 2016 and 33%, 58%, 44%, 39%, 32% and 24% in the following years.

Conclusions: Oncohematological patients account for a small percentage in ICU, but with high morbimortality and high resource utilization. Sepsis is the most frequent cause of admission. Earlier admission to our ICU, reflected by a significantly lower SOFA, did not lead to a considerable increase in the number of patients but did lead to a significant decrease in both intra-ICU and overall, in-hospital mortality.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000697

Introduction: Recognizing the variables that independently predict death in COVID-19 is of great importance; there is little data regarding the impact of acute gastrointestinal injury (AGI) on outcome in COVID-19 patients.
Objectives: The aim of this study was to analyze the association of acute gastrointestinal injury and mortality in COVID-19 patients admitted to an 18-bed ICU.
Methods: The study was carried out prospectively in a single ICU in northern Greece. Data of all adult patients who were tested positive for SARS-CoV-2 between April 2020 and February 2022 were analyzed. All the patients were intubated due to acute respiratory insufficiency and received invasive mechanical ventilation. Patients' demographic characteristics and clinical data were recorded; development of acute gastrointestinal injury was recorded. AGI was categorized into four grades based on collected clinical and imaging data. Comparison between discrete variables were made using the $\times 2$ test, logistic regression analysis was performed to estimate the relationship between AGI and outcome.
Results: A total of 375 patients were admitted to the ICU during the investigation period. Of those, 239 (63.7%) were male. The patients had a mean age of 64.1 years and had severe ARDS upon admission to the ICU with an average APACHE II of 16.3 and an average length of stay in the unit of 18 days. Overall, the ICU survival was 49.6%, whereas the 28-day survival reached 46.9%. The overall incidence of AGI was 24% in survivors vs. 68.5% in non-survivors, $p = 0.001$ ($\times 2$ test). Logistic regression analysis demonstrated that the presence of AGI grades III and IV was independently associated with higher 28-day and ICU mortality rates.
Conclusions: The development of high-grade acute gastrointestinal injury (AGI) during ICU stay may serve as a prognostic tool to predict outcome in critically ill patients with SARS-CoV-2 infection.

Introduction: With the additional ability to remove endotoxins and inflammatory factors, adsorptive hemofiltration filter (Oxiris) is a novel CRRT filter that has been available in China for five years. There is currently no consensus among experts or advice in the guidelines regarding whether patients will benefit more from oxiris, how to assess the treatment's effectiveness, or how to modify how frequently filters need to be replaced. In an effort to learn more about these issues, we created this survey for experienced oxiris users.
Objectives: Seeking the concepts and concerns of Critical Care physicians with experience with oxiris to help standardize the administration of oxiris.
Methods: Focus on the indication, patient selection, effectiveness assessment, and replacement frequency of oXiris using the QR code questionnaire survey. Target doctors are those who used more than 12 sets of oXiris in the previous year.
Results: 193 hospitals and a total of 493 critical care physicians participated in the survey. There were 8 questions in each survey, and the average response time was 162 s. Depending on the site of infection, 85% of doctors would decide to recommend oXiris for patients in abdominal infection with septic AKI, and then bloodstream infection (73.8%) and lung infection (63.9%).
Diseases with a high inflammatory response are ideal candidates for further investigation, such as acute pancreatitis. Doctors identified the benefits of the efficacy evaluation as a decrease in inflammatory response (97%), a decrease in the demand for vasoactive medications (79%), and an increase in microcirculation (69%). In one course of treatment, 39% of patients in China utilized 3 sets of oxiris, while 49% used 2 sets. A single set typically lasts for 24 h (41% of the time).
It is well accepted that oXiris offer a window of opportunity for surgical or anti-infection intervention (93%).
Conclusions: The appropriate population and oxiris improvement metrics were verified through this survey. The majority of doctors will choose oxiris when treating patients with septic AKI, most frequently an intra-abdominal infection. Following use, the patient's inflammatory condition got better and the drugs that vasoactive drugs were downregulated. According to medical professionals, oxiris offers this opportunity for surgical or anti-infection intervention a therapeutic time window.

Intensive care nurses' experiences in identifying and clarifying potential donors in non-donor hospitals in Norway

A. Haustreis[1], L. Sandnes[2], L. T. Gustad[2]
[1]Helse Nord, Helgelandssykehuset Mo i Rana, Mo i Rana, Norway; [2]Faculty of Nursing and Health Sciences, Nord University, Bodø, Norway
Correspondence: A. Haustreis
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000701

Introduction: The need for transplants is increasing in Scandinavia, but the potential for deceased organ donation in Norway is not being fulfilled. Oslo University Hospital (OUS) has the national responsibility for transplantation in Norway and for the participation in Scandia transplant. However, OUS depends on the work carried out by the 28 donor hospitals and approximately 24 smaller hospitals in Norway (called non-donor hospitals), to find and preserve potential organ

donors to patients on the organ waiting list (1). In difference from a donor hospital, non-donor hospitals don't take a donor all the way to organ removal due to a lack of facilities, staff, training and usually, a lack of a dedicated organ donor team. However, also non-donor hospitals are obliged to start the donor process by identifying potential organ donors, clarifying consent from relatives, contacting the transplant coordinator at OUS and caring for the organ donor until transfer to a donor hospital is possible. Intensive care nurses (ICNs) play a crucial role in identifying potential organ donors and clarifying consent with the donor's family. However, there is a lack of research on ICNs' experiences with this process in non-donor hospitals.

Objectives: Gain insight and describe intensive care nurses' perceptions and experiences with identifying and clarifying potential organ donors in non-donor hospitals. New knowledge can help provide targeted efforts to increase the proportion of organ donation from deceased donors in non-donor hospitals.

Methods: The study has a qualitative, explorative design. Semi-structured interviews were conducted with six intensive care nurses in May 2022. The informants were three men and three women aged 33 to 56, recruited from three intensive care units at non-donor hospitals. All had experience with organ donation at non-donor hospitals. The analysis was conducted by using systematic text condensation (STC) (2).

Results: Two main themes were identified. The assessment of organ donation is non-systematic and dependent on the individual healthcare worker on duty. The ICN experienced insecurity due to lack of training and practice of the procedures. Transferring the potential donor from non-donor hospitals is experienced as a barrier by ICNs'. The transfer of their deceased loved one may affect the relatives' consent negatively. To lay this extra burden on the relatives may also prevent ICN's from proposing organ donation.

Conclusions: The study shows that there is more potential for identifying organ donors in non-donor hospitals. Systematic team training to identify donors and approach relatives for consent would possibly increase donors from non-donor hospitals.

Assessing nutritional targets and the factors that affect those in a tertiary intensive care unit without dietician input

M. Mariyam[1], N. Nikitas[2], M. El-Gazzar[1]
[1]Medical School, University of Plymouth, Plymouth, United Kingdom; [2]Department of Intensive Care Medicine, Derriford Hospital, Plymouth, United Kingdom
Correspondence: M. El-Gazzar
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000702

Introduction: Critically ill patients who do not achieve the recommended nutritional intake are at risk of adverse outcomes such as increased mortality, prolonged ventilation, and longer hospital-stay. Underfeeding and overfeeding compared to recommended targets, suboptimal daily protein intake and defining the optimal nutritional intake in patients with body mass index (BMI) over 30 are the main challenges ICU clinicians face. Evidence-based national and international recommendations exist to help with the management of these challenges (1, 2).

Objectives: This audit's objective was to test the compliance of the local nutritional practices to national and international guidelines (in the absence of national guidelines) and to identify factors that affect this practice in a tertiary intensive care unit without dietician input.

Methods: Single centre, retrospective audit collecting data on all adult medical and neuro-ICU patients who were intubated and enterally fed via nasogastric (NG) tube, over a 4-month period (Oct–Jan 2021). Data was collected from the electronic patient database. Patients' demographics, admission details, total/mean daily caloric intake, total/mean daily protein intake, interruptions in enteral nutrition, reasons for interruptions and total/mean daily propofol intake were collected. Descriptive statistics were used in the data analysis.

Results: Data from 67 ICU participants were collected and analysed. Among audit participants, 63% were male and 37% female, the median age was 58.

When propofol administration-related non-nutritional calories were not included in the analysis the recommended daily caloric intake was not achieved in all participants. When the propofol-related calories were included, 50% of participants with BMI < 30 and 32% of participants with BMI > 30 exceeded the recommended daily caloric intake. Recovery rate enteral nutrition was provided in 38% of participants. Of these, 69% were NG fed for longer than 20 days. In 97% of the participants including those with BMI > 30, the recommended daily protein intake target was not met. Length of stay (LOS) < 5 days led to a median duration of interruptions of 4 h (range: 0–15 h), LOS between 6 and 15 days led to a median duration of interruptions of 10 h (range: 0–54 h), LOS between 15 and 25 days led to a median duration of interruptions of 18 h (range: 0–99 h). The most common indications for interruptions were NG tube dislodgement, high aspirates, and transfers for imaging. In 79% of cases, the interruptions in enteral nutrition were not corrected.

Conclusions: Variable factors affect the achievement of nutritional targets in critically ill patients. These results highlight some of those factors and their effect on ICU nutrition targets. Considering national recommendations, interventions will address these factors and optimise nutritional intake for critically ill patients, being at the same time generally applicable.

Early and dynamic alteration of 2B4 and CD28 on T lymphocytes predicts 30-day mortality of patients with sepsis: a prospective observational study

Q. Liu[1], Y. Yi[2]
[1]Critical Care Medicine, Zhongda Hospital Affiliated to Southeast University, Nanjing, China; [2]Department of Critical Care Medicine, Zhongda Hospital, Southeast University, Nanjing, Dingjiaqiao 87, Nanjing, China

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000703

Introduction: 2B4 and CD28 are important immune checkpoints expressed on T lymphocytes, which are associated with T cell function in sepsis. We aimed to determine the early and dynamic alteration of 2B4 and CD28 expressed on T lymphocytes in patients with sepsis and their association with clinical outcome.

Methods: A prospective observational study included 152 patients with sepsis admitted to the ICU. 2B4 and CD28 expression on T cells were measured on day 1, 3 and 7 in patients with sepsis, and assessed for associations with 30-day mortality. Associations of kinetic changes of 2B4 and CD28 on T cells with clinical outcomes were investigated using time-varying cox proportional hazard regression model.

Results: This study demonstrated that non-survivors (n = 39) had increased 2B4 on CD4+ T cells (p = 0.019) and CD8+ T cells (p = 0.001), and decreased CD28 on CD4+ T cells (p = 0.031) compared to survivors (n = 113). In the multivariate cox regression model, time-varying static %2B4 on CD4+ T cells (p < 0.001) and time-varying static %CD28 on CD4+ T cells (p = 0.012) were associated with 30-day mortality in patients with sepsis. According to the cut-off value of 2B4 and CD28 on CD4+ T cells in predicting 30 day-mortality of septic patients, patients could be split into four groups (2B4hiCD28lo, 2B4hiCD28hi, 2B4loCD28lo and 2B4loCD28hi), in the multivariate cox regression model, the 2B4hiCD28lo pattern was associated with 30-day mortality in patients with sepsis.
Conclusions: Flow cytometric assessment of dynamic alterations in 2B4 and CD28 expression on T cells identifies patients with poor outcomes during sepsis. A dominant 2B4hiCD28lo pattern on day 1 is associated with increased 30-day mortality in patients with sepsis.

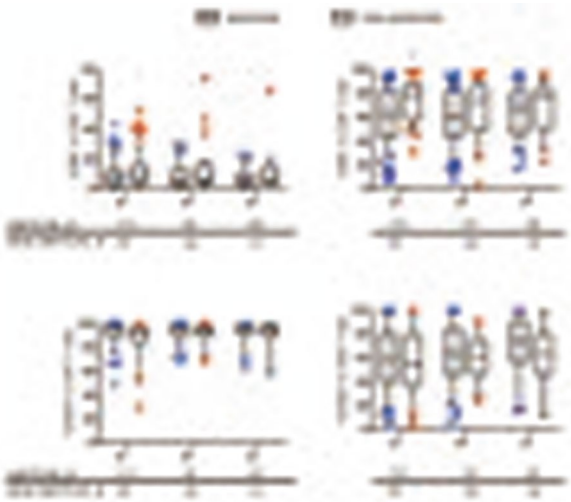

Figure 1 (abstract 000703) Percentage of 2B4 on CD4+ T cells, CD28 on CD4+ T cells, 2B4 on CD8+ T cells, CD28 on CD8+ T cells between non-survivors and survivors of sepsis patients. The percentage of 2B4 on CD4+ T cells, CD28 on CD4+ T cells, 2B4 on CD8+ T cells and CD28 on CD8+ T cells between survivors and non-survivors on day 1, day 3 and day 7 after the admission to the ICU for sepsis. Data are compared using the Mann–Whitney U tests; *p < 0.05, **p < 0.01; ***p < 0.001

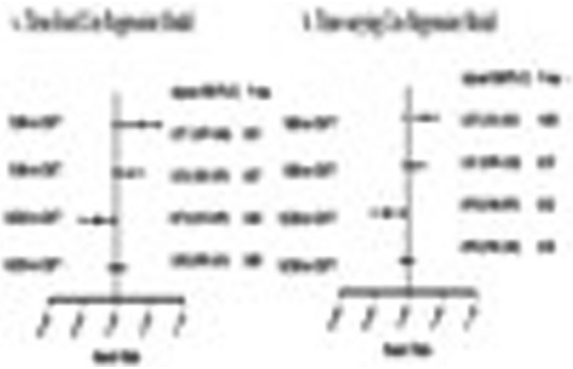

Figure 2 (abstract 000703) Association between 2B4 and CD28 expressed on T lymphocytes and 30-day mortality. (a) Association between 2B4 and CD28 expressed on T lymphocytes and 30-day mortality in time-fixed cox regression model. (b) Association between 2B4 and CD28 expressed on T lymphocytes and 30-day mortality in time-varying cox regression model. Data are expressed with multivariate cox regression

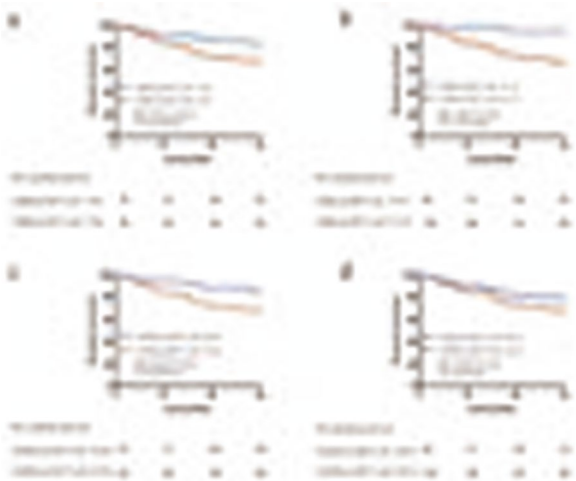

Figure 3 (abstract 000703) Survival analysis. (a–d) Groups are divided according to the cut-off value of 2B4 expression on CD4+ T lymphocytes, CD28 expression on CD4+ T lymphocytes, 2B4 expression on CD8+ T lymphocytes, and CD28 expression on CD8+ T lymphocytes for predicting 30-day mortality of septic patients. Data are compared using Log-rank test and expressed with Kaplan–Meier curves

Formalising echocardiography in critical care—a survey on accreditation status and barriers towards widespread accreditation

H. van Huellen[1], C. Bernard[1], A. Myers[1], T. Samuels[1]
[1]Critical Care, East Surrey Hospital, Redhill, United Kingdom
Correspondence: H. van Huellen
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000704

Introduction: Bedside echocardiography is now an established part of routine critical care. To ensure a consistent approach and reduce inter-operator variability, a variety of accreditation pathways exist. In the United Kingdom these are Focused Ultrasound in Intensive Care (FUSIC) run by the Intensive Care Society (ICS), as well as two levels of competency set out by the British Society of Echocardiography (BSE) (1). Data is lacking regarding which accreditations are favoured by UK intensivists and how many have achieved these.
Objectives: To establish the level of echo proficiency and accreditation status amongst intensivists in Kent, Surrey, and Sussex, as well as ascertaining the perceived barriers to achieving accreditation and how these could be overcome.
Methods: In Spring 2023, intensivists (consultants and trainees) working across the South-East of England were surveyed to find if they

were accredited or working towards accreditation in any of the following: Focused Ultrasound for Intensive Care—Heart (FUSIC Heart) or Haemodynamics (FUSIC HD) and BSE Level 1 or Level 2. They were also questioned regarding barriers to accreditation.
Results: 45 responses were analysed. The majority (36 or 80%) used echocardiography at least occasionally as part of their clinical practice and 17 (37.8%) used it regularly. Less than half (18 or 40%) were formally accredited, with FUSIC Heart accounting for the majority of those (13 or 28.9%). 11 (24.4%) respondents were currently working towards accreditation, with a further 13 (28.9%) planning on doing so in the future. Only 3 respondents (6.7%) were not interested in formal accreditation.
A lack of dedicated time alongside clinical duties was cited as the most common barrier to achieving accreditation (79.1%), followed by scarcity of local mentors (58.1%) or difficulty reviewing scans with them (53.5%). In contrast, unavailability of suitable ultrasound machines was only rarely (2.3%) a problem (Fig. 1).
Availability of echocardiography mentors (73.7%) as well as local echocardiography training (68.4%) were felt to be most beneficial in overcoming these barriers. There was also demand for formal teaching days and peer support groups (65.8% and 42.1% respectively).
Conclusions: This study reflects the increasing importance of critical care echocardiography in the UK, with most participants using it as part of their routine clinical practice. However, growing interest has not yet reliably translated into widespread training and accreditation. Several factors are implicated including a perceived lack of time to complete the accreditation process. These findings are in keeping with data from the Intensive Care Society, who quote that only 34% of those seeking accreditation finished the process in 2014 (2). ICU training and practice is likely to require dedicated echo training sessions or in-house fellowships as standard for intensivists to develop and maintain skills.

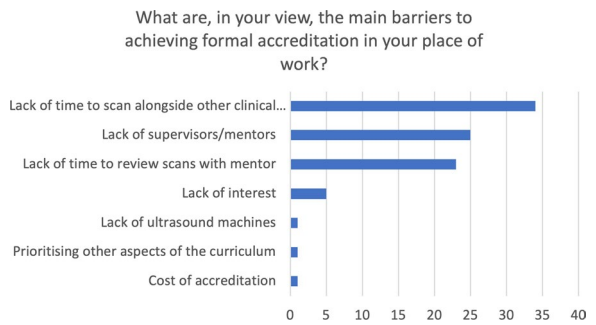

Figure 1 (abstract 000704) Perceived barriers to accreditation (number of responses)

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000705

Introduction: Predicting neurological outcome of post cardiac arrest patients is important but extremely difficult in quick decision. Prognostication was recommended to use multimodal methods. Several studies presented predicting score for return of spontaneous circulation (ROSC), survival admission and neurological outcome. Of those, scoring for predicting neurological outcome had simple variables though had complex calculation equation.
Objectives: The aim of this study is to develop a simple and broadly applicable score at admission to predict a poor neurological outcome at discharge in post cardiac arrest patients.
Methods: This was a retrospective study performed in a tertiary care hospital in South Korea from 2019 to 2021. Patients with admission for PCAC after ROSC were included. Poor neurological outcome was defined as a cerebral performance category of 3, 4, or 5.
Results: Total 259 patients were enrolled. Median age was 60.0 (IQR 25.00), male was 167 (67.5%). 214 (82.6%) was out of hospital cardiac arrest (OHCA). 177 (68.3%) was witnessed arrest. 61 (23.6%) showed first monitored shockable rhythm (Table 1). Targeted temperature management was performed for 253 (97.3%) patients, those target temperature was 33.0 °C (IQR 2.00). Median SOFA score was 10.0 (IQR 4.00). 46 (17.8%) was diagnosed with brain death. 135 (52.1%) were survived at discharge and good neurological state at was 48 (18.5%). Univariable analysis showed age, sex, cause of arrest, arrest duration, initial shockable rhythm and acute abnormal finding of brain CT at admission was correlated with poor neurological outcome at discharge. Binary logistic regression showed that age 65 or more, non-cardiac cause of arrest, arrest duration 20 min or more, initial nonshockable rhythm, acute abnormal lesion of brain CT were significant variables showing poor neurological outcome (adjusted R2 0.660). To build a simple scoring system, each variable was given 1 impact score except cardiac cause of arrest, which was given − 1 impact score. qCANS score can present − 1 to 4. Receiver operating characteristic (ROC) curve to predict performance showed area under curve (AUC) was 0.935 (95% CI 0.897–0.963) (Fig 1). The Hosmer–Lemeshow Goodness-of-Fit test statistic showed this model adequately fits the data (p = 0.116).

Table 1 (abstract 000705) Summary of variables of qCANS score according to neurological outcome at discharge

	Total (n = 259)	Good outcome (n = 104)	Poor outcome (n = 250)	P value
Age (years)	60 (25.00)	51 (22.00)	65 (24.00)	0.000
Initial shockable rhythm	61 (23.6)	38 (79.2)	23 (10.9)	0.000
CPR duration (min)	27.0 (25.00)	17.0 (13.00)	30.0 (27.00)	0.001
Presumed cardiac cause of arrest	164 (63.3)	8 (73.9)	156 (16.7)	0.000
Acute lesion of brain CT at admission	116 (46.8)	6 (14.3)	110 (53.4)	0.000

Data are presented as median (IQR) or n (%)

Conclusions: qCANS score is simple and easily applicable tool at admission to predict poor neurological outcome for post cardiac arrest patients.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000706

Introduction: The SARS-CoV-2 infection is a complex form of hypoxemic acute respiratory failure, leading to frequent progression to acute respiratory distress syndrome, multiorgan failure, and intensive care unit (ICU) admission. Due to invasive organ support, significantly prolonged ICU stay, and specific immunosuppressive therapies, these patients are prone to nosocomial superinfections. Furthermore, the manifestations of sepsis are recognizably poorly specific. Therefore, using serum biomarkers kinetics in conjunction with clinical manifestations could be the key to early identification and prompt therapy.
Objectives: Our aim was to assess the value of daily measurements of C-reactive protein (CRP) and Procalcitonin (PCT) in the early identification of ICU-acquired infections in COVID-19 patients.
Methods: We undertook a prospective observational cohort study (12 months). All adult patients admitted for $\geq$72 h to ICU care with COVID-19 pneumonia were divided into an infected group (n = 36) and a non-infected group (n = 82). Infected patients had a documented ICU-acquired infection if they presented: new clinical signs of sepsis, positive cultures, and started a targeted antibiotic therapy. The non-infected group did not present clinical signs of sepsis and were not receiving antibiotics for at least 5 days before day 0. Day 0 was considered the day of the diagnosis of infection (infected group) and day 10 of the ICU stay (non-infected group) considering that the median day of infection in the infected group was at D10 of the ICU stay. The kinetics of CRP and procalcitonin daily values were registered from day − 10 to day 10 of the ICU stay and evaluated using a general linear model, and univariate, repeated-measures analysis.
Results: 118 patients (mean age 63 years, 74% males) were eligible for the analysis. The groups did not differ in patients' age, gender, CRP, and PCT serum levels registered at ICU admission. However, the infected group encompassed patients with a higher severity score (SOFA score at ICU admission, p = 0.009), and with higher ventilation (p < 0.001), vasopressor (p < 0.001), renal replacement therapy (p = 0.004) requirements and 28-day mortality rate (p < 0.001). The infected group also presented higher maximum CRP and PCT serum levels registered during ICU length of stay (p < 0.001 in both analyses) and a significantly longer ICU length of stay (26 days (19; 37) vs non-infected group (11 days (10; 17), p < 0.001). CRP showed a significant increase in infected patients, whereas in noninfected it remained almost unchanged (P < 0.001), while PCT did not appear to retain diagnostic value to predict superinfection in COVID-19 patients (p = 0.593) (Figure 1).
Conclusions: COVID-19 patients who develop nosocomial superinfections exhibited different anticipatory biomarker profiles before diagnosing those infections. Daily CRP monitoring and the recognition of the CRP pattern could be helpful in the prediction of ICU-acquired infections.

Milrinone in addition to standard therapy in aneurysmal subarachnoid haemorrhage confers favourable neurological outcome: a meta-analysis

C. Camarda[1], L. Premraj[1], B. Jack[1], L. Unnah[1], S. Adriano[2], S. M. Cho[3], D. Battaglini[2]
[1]School of Medicine, Griffith University, Brisbane, Australia; [2]Anaesthesia and Intensive Care, IRCCS AOU San Martino, Genova, Italy; [3]Neurocritical Care, Johns Hopkins University, Baltimore, United States of America
Correspondence: C. Camarda
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000708

Introduction: Delayed cerebral ischemia (DCI) occurs in almost a third of patients with aneurysmal subarachnoid hemorrhage (aSAH) and is the leading cause of morbidity. Evidence for current DCI therapies is limited. A recent randomized controlled trial showed that milrinone, when used as an adjuvant, improved neurological outcome.
Objectives: We investigated the effect of milrinone as an adjuvant therapy on patients with aSAH. The primary aim was favourable neurological outcome (modified Rankin score = mRS $\leq$ 2) and DCI resolution. Secondary aims included mortality, intensive care unit (ICU), and hospital length of stay (LOS).
Methods: PubMed, EMBASE, Scopus, Google Scholar, and Web of Science were searched. Articles with more than 15 aSAH patients who received milrinone as an adjuvant therapy were included. The overall effect size was determined by a general linear mixed model with random effects. Models were moderated for milrinone administration method (intravenous (IV), intraarterial (IA) or intrathecal (IT), combined (IV + IA)), haemorrhage location (Internal Carotid (ICA), Middle Cerebral (MCA), Posterior Cerebral (PCA)) and study year.
Results: 19 studies (1648 patients, mean age of 55 years) that used milrinone as an adjuvant therapy were included. Among those with recorded World Federation of Neurological Surgeons Score, 46.7% had a score > 2. Overall, 67.9% (95% CI = 62.4–73.0, I2 = 48.3%) had favourable neurological outcome (mRS $\leq$ 2). DCI resolved in almost all patients (92.2%, 95% CI = 77.9–97.5, I2 = 89.2%). Route of administration (IV, IA, IT, IV + IA), haemorrhage location (ICA, MCA, PCA), and study year did not significantly affect neurological outcome or DCI resolution rate. Overall mortality was 7.5% (95% CI = 5.3–10.6, I2 = 51.3%), hospital LOS was 27.5 days (95% CI = 24.5–30.6, I2 = 0.0%) and ICU LOS was 20.8 days (95% CI = 18.3–23.3 I2 = 78.3%).
Conclusions: Our meta-analysis of over 1600 moderate to severe aSAH patients receiving milrinone as adjuvant therapy found a high prevalence of favourable neurological outcome with excellent inter-study agreement despite protocol variance. We also reported near-universal DCI resolution and < 8% mortality. Given the reported limited efficacy of standard therapy, milrinone shows promise as an adjuvant. Studies are needed to determine the effect of the route of administration and artery of haemorrhage more precisely. Given the above, confirmatory randomized trials are warranted.

Introduction: Coronavirus disease 2019 (COVID-19) can cause multiorgan dysfunction and systemic complications including acute stroke. The pandemic exacerbated global income inequality and disparity of healthcare resources between low-middle income countries (LMIC) and high-income countries (HIC), thus impacting clinical outcomes, ability to collect data, and to join international collaborations.
Objectives: We sought to investigate the disparity of ischemic and hemorrhagic stroke between LMIC and HIC in critically ill patients with COVID-19 and their risk factors and outcomes.
Methods: This is a retrospective analysis of a multicenter prospective observational study of a well-curated international database, the COVID-19 Critical Care Consortium, of COVID-19 adults admitted to intensive care units in 32 countries. Our primary outcome is stroke incidence per admission and 1000 admitted days in LMIC vs. HIC. Secondary outcomes included in-hospital mortality. Incidence rates and rate ratios were estimated using Poisson models clustered by site. Mortality rate ratios were weighted by inverse probability weights.
Results: Overall, 20,312 COVID-19 patients (median age = 61 (51–70)) yrs, 68.4% were males) were included, with an incidence of stroke per admission of 3.0%. Incidences of hemorrhagic type was 0.5% (n = 98) [HIC 0.5% (n = 75) vs. LMIC 0.8% (n = 23)] and ischemic type was 0.5% (n = 88) [HIC 0.4% (n = 60) vs. LMIC 1.0% (n = 28 After imputation, the IRR per admitted days by income region (LMIC vs. HIC) was IRR = 1.96 (95% CI = 1.54–2.51) (p < 0.001), whereas per admission IRR = 1.26 (95% CI 0.99–1.61) (p = 0.059). At multivariable analysis, LMIC group, age, previous neurological condition, chronic cardiac disease, diabetes, platelet count, mechanical ventilation, ECMO support, and pandemic phase (Jan 2021–Dec 2022 vs. Jan–Jun 2020) were independent risk factors of all types of strokes.
Patients from LMIC were more likely to die than those from HIC [RR = 2.54, 95% CI 2.32–2.79 per admitted days, p < 0.001; RR = 1.71, 95% CI 1.62–1.79 per admission, p < 0.001]. Patients with stroke were more likely to die than those without stroke [RR = 1.40, 95% CI 1.15–1.69, p < 0.001 per admitted days; RR = 1.73, 95% CI 1.57–1.90, p < 0.001 per admission]. Patients from LMIC were more likely to have a shorter hospital length of stay than those from HIC. Male gender, obesity, previous neurological condition, stroke during admission, ECMO, mechanical ventilation, and pandemic phases (Jul–Dec2020 vs. Jan 2021–Dec 2022) were independent risk factors for longer hospitalization.
Conclusions: The incidence of stroke per admitted days was higherfor those in LMIC vs HIC, but not for stroke per admission, whichmultidisciplinary taskforce is allowing us to rapidly provide more interventions to iteratively meet our objective. The formation of the taskforce is allowing multiple other interventions to run in parallel to improve delirium prevention and management; this includes extending visitor hours, supporting family involvement, reorientation boards and promoting sleep hygiene.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000715

Introduction: Frailty and physical decline occur in the elderly as they age, increasing their risk of health issues and disability. Recent studies have stressed the importance of evaluating frailty among critically ill population (1, 2). The Clinical Frailty Scale (CFS) is one of many assessment tools that has been well validated in critically ill patients (3). Sarcopenia is a domain of frailty that can be objectively quantified by muscle thickness measurement using muscle ultrasonography (MUS) (4).
Objectives:

- To analyse the relationship between Muscle thicknesses (MT) of rectus femoris plus vastus intermedius and CFS-based frailty assessments in a cohort of critically ill hospitalised elderly patients (> 65 years).
- To analyse MT measurements & CFS and its correlation with length of ICU stay, length of hospital stay, mechanical ventilation free days, vasopressor free days, requirement of Renal Replacement Therapy, Ventilator Associated Pneumonia, Blood Stream Infection, re-admission.

Methods: This was a prospective single centre observational study conducted in a 20 bedded intensive care unit in southern part of India. All patients aged more than 65 years were scored for CFS for the evaluation of frailty. Patients were excluded if they had undergone amputation, had limb asymmetry due to a prior hemiplegic stroke that resulted in unilateral muscle wasting, had neuromuscular muscle-wasting disorder as a known pre-existing condition, or had skin abrasions or wounds in the areas chosen for ultrasound examination. Through MUS axial cross-section, the rectus femoris and vastus intermedius muscle thicknesses (MT) were measured. Based on the CFS patients were classified into four groups as no frailty (CFS < 5), mildly frail (CFS = 5), moderately frail (CFS = 6), severely frail (CFS = 7&8).
Results: The study population consisted of 60 elderly patients, 39 men (65%), with median age of 76 (72–84) years, CFS of 5 (4–7), and MT of rectus femoris plus vastus intermedius 20.32 (16.32–23.18) mm. On multivariable regression analysis, CFS was associated significantly and independently with age (p = 0.017) and MT of rectus femoris and vastus intermedius (p = 0.047). None of the secondary outcomes such as mechanical ventilator free days, vasopressor free days, need for RRT were significantly different between the four groups based on CFS. We also found a significant difference in the prevalence of severe frailty between individuals aged 80 years and older and those younger than 80 years (11 vs 5, p = 0.004).
Conclusions: In a cohort of hospitalised elderly critically ill patients, MT of the vastus intermedius and rectus femoris was found to be associated to CFS, independent of other factors taken into consideration. Additional research is required to confirm this association and assess the therapeutic relevance of these findings.

Introduction: COVID-19 survivors may present with psychiatric and neurocognitive symptoms long after the acute phase [1, 2].
Objectives: To determine subjective psychiatric, neurocognitive, and fatigue symptoms two years after COVID-19.
Methods: We assessed three COVID-19 patient groups of different acute disease severity (ICU-treated, ward-treated, home-isolated) and non-COVID controls concerning neurocognitive symptoms (ABNAS; AB Neuropsychological Assessment Schedule), anxiety (GAD7; Generalised Anxiety Disorder 7), depression (PHQ9; Patient Health Questionnaire 9), post-traumatic stress (IES-6; Impact of Event Scale 6), and fatigue (MFI; Multidimensional Fatigue Inventory) with a mailed questionnaire approximately two years after acute COVID-19. We compared the results with those obtained six months after the acute disease [3, 4].
Results: Altogether, 58 ICU-treated, 35 ward-treated, 27 home-isolated COVID-19 survivors and 34 non-COVID controls responded to the questionnaire (Table 1). Cognitive impairment was reported by 26.8% of ICU-treated, 34.4% of ward-treated, 26.9% of home-isolated patients, and 2.9% of non-COVID controls (p = 0.011). COVID-19 patient groups had higher median scores in PHQ9, IES-6, and MFI compared to non-COVID controls (Table 1; no differences existed among the different COVID-19 severity groups. Self-reported anxiety

symptoms were rare, and no differences between groups existed (Table 1). The amount of neurocognitive, anxiety, and fatigue symptoms was similar to the six-month follow-up, but depressive and post-traumatic stress symptoms had decreased (Figure 1).

Table 1 (abstract 000717) Characteristics of study subjects in different groups, and outcomes of neurocognitive, depressive, anxiety, post-traumatic stress, and fatigue symptoms 24 months after acute COVID-19

	ICU, n = 58	WARD, n = 35	HOME, n = 27	CONTROLS, n = 35	p
Participated in 24 month-follow-up (%)	71.6	62.5	54	64.8	NS

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000718

Introduction: Accurate diagnosis of acute cor pulmonale (ACP) is key since it is prognostic in patients ventilated for an acute respiratory distress syndrome (ARDS). ACP is characterized by a paradoxical septal motion (PSM) which identification using two-dimensional echocardiography is highly subjective. Left ventricular (LV) radial strain has not yet been used to help the identification and assess the severity of PSM.
Objectives: We sought to describe LV radial strain changes related to PSM in patients at risk of sustaining ACP according to its severity.
Methods: This prospective bicentric study included patients ventilated for an ARDS related to COVID-19 who were assessed using transesophageal echocardiography between March 2020 and June 2021. Two-dimensional transgastric short-axis view at mid-papillary level was used to grade septal motion: normal (grade 0), transient end-systolic septal flattening (grade 1), prolonged end-systolic septal flattening or reversed septal curvature (grade 2). LV radial strain analysis was performed off-line on the same digital loops and six LV segments were distinguished: mid-infero-septal and mid antero-septal, their opposite segments (mid-infero-lateral and mid-antero-lateral, respectively), and the remaining two segments (mid-anterior

and mid-inferior). After having confirmed visually that LV radial strain curves were altered in certain segments when a PSM was present (Figure), we performed feature engineering. We calculated the "time-to-peak" defined as the time lag required to reach the maximal value of strain, which was normalized by the length of cardiac cycle and the "partial area under segmental strain curves" which was calculated as the area under each LV segmental strain curve between 33 and 66% of the cardiac cycle length (time period selected on graphical examination of the strain curves where most alterations of strain pattern occurred) to standardize the measurement.

Results: Overall, 318 echocardiography examinations performed in 184 patients were analyzed. Two-dimensional assessment identified a grade 1 and a grade 2 PSM at end-systole in 106 (33%) and 43 (14%) examinations, respectively. When compared with mid-anterior or mid-inferior segments, the time-to-peak of mid-septal and mid-lateral segments occurred significantly later in systole and this delay gradually increased with the grade of PSM (Figure). Similarly, the area under the strain curve of mid-septal and mid-lateral segments increased significantly with the grade of PSM, compared with mid-anterior or mid-inferior segments (Figure).

Conclusions: LV radial strain can objectively depict PSM and quantitatively assess its severity.

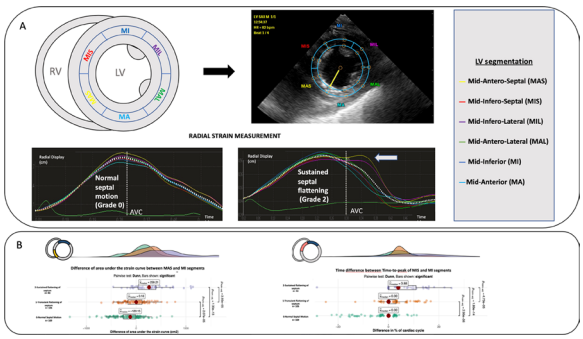

Figure (abstract 000718) **A.** Schematic representation of LV segmentation for strain analysis with illustrative examples of a normal septal pattern of contraction (grade 0) and of sustained septal flattening (grade 2). **B.** Boxplots with density plots of main result.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000719

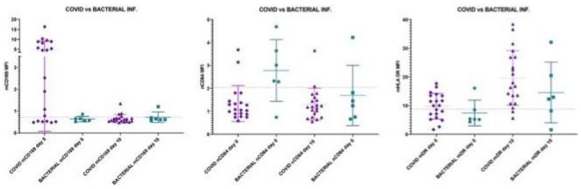
Introduction: Innate immune cells use a variety of pathogen-derived molecular pattern recognition receptors to survey their environment and activate myeloid cells as an early response to bacteria or viruses. Increased expression of CD64 on neutrophils has been associated with bacterial infections, while increased expression of CD169 on monocytes is associated with viral infections.

Objectives: To analyze the behavior of the nCD64 markers against bacteria, mCD169 against viruses, and HLA-DR in critically ill patients with COVID or bacterial sepsis.

Methods: Single-center prospective study conducted between December 2020 and May 2021. Adult patients admitted to the ICU due to severe pneumonia due to SARS-CoV-2 (COVID) or bacterial sepsis were included. The diagnosis of sepsis was made following the Sepsis 3 criteria. The diagnosis of COVID was made by evidence of bilateral pulmonary infiltrates in the chest X-ray or in the CT and confirmation by nasopharyngeal PCR test. All patients underwent a study of myeloid activation markers (nCD64 and mCD169) in the first 48 h of admission to the ICU and 10 days later. The expression of mCD169, nCD64 and HLA-DR was determined by flow cytometry. The result is expressed as the mean fluorescent intensity (MFI). ROC curve was made to establish the cut-off point (PC) of values for nCD64, mCD169 and HLA-DR with 95% confidence intervals with the corresponding sensitivity (S) and specificity (E) values. Demographic, clinical and intra-ICU mortality variables were collected. Quantitative data are expressed as mean ± standard deviation and qualitative data as percentage. Informed consent was requested from patients or relatives and the study was approved by the CEIC of our hospital (PR(AG)639/2020).

Results: Twenty nine patients were included in the study. The demographic and clinical characteristics of the patients are summarized in Table 1. The PCs were: for mCD169 0.97 (S 65% and E 88%), for nCD64 2.04 (S 88% and E 90%) and for HLA-DR 6.68 (S 66% and E 75%) (Fig. 1). On day 0, the expression of CD169 in patients with COVID was positive in 60% of the cases, decreasing in the study period, while only 17% of patients with sepsis were positive at baseline. CD64 expression was positive in 10% of COVID patients and 89% of sepsis patients, and became negative after 10 days. On day 0 the expression of HLA-DR in patients with COVID was 55% while at 10 days it increased to 90%. In patients with sepsis, the expression of HDL-DR at day 0 was 11% and at 10 days 77%. (Fig. 2).

Conclusions: The study of the expression of mCD169 and nCD64 in neutrophils is useful for evaluating the immune response of viral or bacterial origin.



Topic: Sepsis

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000720

Introduction: Although acute pancreatitis (AP) has been reported to occur in patients with accidental hypothermia (AH), the mechanism and risk factors remain unclear.

Objectives: We investigated the frequency and risk factors for the development of AP in patients with AH.

Methods: We conducted a multicentre prospective observational study in 36 tertiary emergency hospitals in Japan. Adult patients aged ≥ 18 years with a body temperature of ≤ 32 °C and admitted to emergency departments between December 2019 and March 2022 were included in this study. The patients were divided into two groups: those who developed AP within 1 week after admission (AP group) and those who did not (Control group). We explored risk factors for the development of AP by comparing the patients' characteristics, vital signs, blood gas analysis, and laboratory data.

Results: Of 499 patients with AH, 71 with missing serum amylase levels at admission were excluded, and 428 were analysed in this study. A total of 196 (45.8%) had elevated serum amylase levels on admission, and 17 (4.0%) developed AP within 1 week of admission. A negative correlation was observed between serum amylase level on admission and body temperature (Spearman's rank correlation coefficient − 0.100, p = 0.046). The AP group were younger than the Control group (AP: 69 years vs. Control: 82 years, p = 0.003) and had a higher proportion of alcohol consumption before emergency medical service transport. Body temperature at admission was not significantly different between the two groups (AP: 27.8 °C vs. Control: 28.6 °C, p = 0.146), and body temperature had no significant prognostic value for the development of AP (area under the receiver operating characteristic curve = 0.604, 95% confidence interval = 0.472–0.736). The 28-day mortality was higher in the AP group, but not statistically significant (AP: 35.3% vs. Control: 23.9%, p = 0.385). The AP group had a higher SOFA score (AP: 9.5 vs. Control: 6.0, p = 0.042), and by category, only the cardiovascular category showed a significant difference (AP: 4.0 vs. Control: 1.0, p = 0.004). The AP group showed lower base excess (AP: − 17.9 mmol/L vs. Control: − 6.6 mmol/L, p = 0.029), higher lactate (AP: 4.8 mmol/L vs. 2.9 mmol/L, p = 0.092), and higher serum creatinine (AP: 1.6 mg/dL vs. Control: 1.2 mg/dL, p = 0.041) in blood gas analysis results and laboratory data.
Conclusions: The frequency of AP within 1 week after admission was 4.0% in patients with AH below 32 °C, and risk factors for the development of AP were considered to be alcohol consumption, circulatory failure, and renal dysfunction.

Topic: Metabolism, endocrinology, liver failure and nutrition.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000721

Introduction: The number of ICU patients that survive critical illness has been rapidly increasing. Survivors have been facing a sequel of serious physical problems, as a consequence to their ICU stay. Decreased muscle strength and functionality are well described, yet the past few years a growing interest surrounds the clinical aspect of frailty. Although, as a syndrome is often seen in elderly population, in ICU populations seems to be encountered and in younger patients.
Objectives: The study aims to assess the incidence of frailty in ICU patients and its association with clinical outcomes. Secondary outcomes are muscle strength and level of mobility at ICU discharge.
Methods: All patients admitted in the ICU of General Hospital of Chalkida and Athens General Hospital "Evangelismos" were mechanically ventilated for > 48 h and were included in the study. Exclusion criteria were: history of neuromuscular disorders or neurological disease and end of life patients. Frailty was assessed by the Clinical Frailty Scale before ICU admission and after ICU discharge. Manual Muscle Strength Test (MMST) was used to evaluate muscle strength and MRC scale for the clinical diagnosis of ICUaw. Maximal Inspiratory and Expiratory Pressure for the respiratory muscles at weaning period.
Results: Ninenty-two critically ill patients (F:46/M:46, 63.8 ± 13.5 years) were included from 02/2022 till 12/2022.The presence of frailty at ICU discharge reached 69% and in patients < 65 years of age reached 71%. Muscle strength was significantly decreased in elderly patients (p < 0.05) and in patients who developed ICUaw. Frailty was significantly (p < 0.05) correlated with the days in mechanical ventilation, the duration of ICU stay and the MMST.
Conclusions: These descriptive data underline the increased incidence of frailty even in younger critical ill patients and its serious effects in their recovery. Further studies are needed to fully investigate the risk factors of these patients and the long term effects.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000722

Introduction: ICU-acquired diaphragm weakness affects more than half of mechanically ventilated ICU patients and may be caused by ventilator over or under assistance, resulting in atrophy and weakness of diaphragm muscle fibers (1). Muscle fibers are multinucleated cells that adapt to mechanical load by increasing or decreasing their nuclear content (2). In diaphragm muscle undergoing atrophy, protein synthesis rates may decrease (3). We recently observed a decrease in myonuclear content in atrophic fibers isolated from diaphragm biopsies of mechanically ventilated ICU patients (4). This raises the question whether transcriptional activity of the remaining nuclei in the atrophic muscle fiber remains static during atrophy. In this study we investigate whether transcriptional activity is diminished in atrophic diaphragm muscle fibers of mechanically ventilated ICU patients.
Methods: Diaphragm biopsies of mechanically ventilated ICU patients (median ventilation duration of 45 h) with established atrophy (cross-sectional myofiber size of < 2000 um2) were compared to biopsies of patients who underwent thoracic surgery for a small, primary, pulmonary nodule (Controls). Using immunofluorescent staining and confocal microscopy, we determined the transcriptional activity of single nuclei within manually isolated single muscle fibers by staining the enzyme responsible for transcription (RNA-polymerase-II) with an antibody specific for a post-translational phosphorylation at Serine 5. This phosphorylation occurs when the enzyme is activated and transcription of DNA into mRNA starts. Hence, fluorescence intensity is a measure of transcriptional activity. Optical slices of fibers were acquired using spinning-disk confocal microscopy and assembled into a 3D image. Nuclei were segmented using lamin A/C staining, and fluorescence intensity of phosphorylated RNA-polymerase-II within each nucleus was quantified in 3D. Furthermore, fluorescence intensity of all nuclei was summed before normalization for myofiber volume.
Results: 5 biopsies of ICU patients with established atrophy and 5 control biopsies were analyzed. From each biopsy, 10 fibers were isolated, stained, and imaged. Total fluorescence of phospho-RNA-Poll-II C-terminal domain (Ser5) staining within individual nuclei from ICU patients (2235) and control patients (2817) was measured. There were no significant differences in transcriptional activity per nucleus between the groups of 401 [222–638] in the ICU group vs 428 [246–615] in the control group arbitrary units (AU), p = 0.89 (median [IQR]). Furthermore, transcriptional activity normalized to fiber volume was not different across both groups. Finally, variation of transcriptional activity within each fiber was similar in both groups.

Conclusions: These findings indicate that transcriptional activity is not diminished within the atrophic diaphragm of mechanically ventilated ICU patients. This finding does not support the hypothesis that diminished transcriptional output contributes to early diaphragm atrophy in mechanically ventilated patients. Other mechanisms such as impairment of post-transcriptional events and increased proteolysis appear to play a more pronounced role.

High-risk pulmonary embolism patients treated with flowtriever mechanical thrombectomy: primary endpoint component analysis from the FLAME Study

A. Viana Tejedor[1]
[1]Cardiology, Hospital Clinico San Carlos, Madrid, Spain
Correspondence: J. Shaw
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000723

Introduction: Guidelines for hemodynamically unstable (high-risk or massive) pulmonary embolism (PE) recommend immediate reperfusion treatment due to the associated short-term mortality of over 25%. Systemic thrombolysis is the recommended front-line treatment despite limited evidence and increased risk of major bleeding and intracranial hemorrhage.
The FLAME Study (FlowTriever for Acute Massive PE) is the largest prospective interventional study in high-risk PE and was designed to evaluate outcomes in high-risk PE patients.
Objectives: Overall outcomes from the FLAME study have been previously reported; the objective of this expanded analysis was to evaluate the primary endpoint and its components, each of which was a secondary endpoint, in patients undergoing FlowTriever mechanical thrombectomy compared to an objective performance goal derived from a meta-analysis.
Methods: The FLAME study was a prospective, multicenter, nonrandomized, parallel group, observational study of high-risk PE (NCT04795167). Patients were treated with FlowTriever (FT) mechanical thrombectomy (FT Arm) or other contemporary therapies (Context Arm). PE treatment strategy was determined by the treating physician. The primary endpoint was an in-hospital composite of all-cause mortality, bailout to an alternate thrombus removal strategy, clinical deterioration, and major bleeding. Secondary endpoints included each component of the primary endpoint. These endpoints were compared in the FT Arm to an objective performance goal derived from a meta-analysis.
Results: A total of 53 patients were enrolled in the FT Arm and 61 in the Context Arm. The primary endpoint was reached in 9 (17.0%) FT Arm patients, significantly lower than the 32.0% objective performance goal ($P < 0.01$) (Table). Component analysis of the primary endpoint demonstrated significantly lower rates of all-cause mortality (1.9% vs. 28.5%, $P < 0.0001$) and bailout (3.8% vs. 30.3%, $P < 0.0001$) in the FT Arm versus the performance goal components. Clinical deterioration occurred in 15.1% of FT Arm patients and major bleeding in 11.3% of FT Arm patients, both not significantly different than their respective performance goal components. Even in these high-risk PE patients, 19.2% of FT Arm patients did not require an overnight ICU stay following treatment with FT.

The FT Arm Primary Endpoint Compared to the Performance Goal

	FT Arm	Performance Goal (meta-analysis)	P value
Composite Primary Endpoint	17.0%	32.0%	< 0.01
All-cause mortality	1.9%	28.5%	< 0.0001
Bailout	3.8%	30.3%	< 0.0001
Clinical deterioration	15.1%	15.6%	0.460
Major bleeding	11.3%	11.5%	0.484

Context Arm patients were treated with systemic thrombolysis (68.9%), anticoagulation alone (23.0%), catheter-directed thrombolysis (6.6%), and surgical thrombectomy (1.6%). In the Context Arm, the primary endpoint occurred in 39 (63.9%) of patients. Component analysis of the Context Arm primary endpoint showed that all-cause mortality occurred in 29.5% of patients, bailout occurred in 26.2% of patients, clinical deterioration occurred in 21.3% of patients, and major bleeding occurred in 24.6% of patients.
Conclusions: Treatment of high-risk PE with FT was associated with a low rate of adverse outcomes. The significantly lower frequency of the composite primary endpoint in the FlowTriever Arm compared to the objective performance goal was driven by low rates of all-cause mortality and bailouts, although the rates of clinical deterioration and major bleeding were more in line with the expected performance goal rates in these critically ill high-risk patients.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000724

Introduction: There is an urgency to make healthcare more sustainable, without affecting patient safety. To prevent pathogen transmission via the environment at the intensive care unit (ICU), patient rooms are cleaned after patient discharge and unused products are disposed. This generates 3–9 kg waste per patient per room. We hypothesized that the results of ICU admission cultures for highly resistant microorganisms (HRMO), already part of our surveillance program, could be used to decide on the indication of product disposal.
Objectives: We aimed to assess whether a new waste policy could reduce unnecessary waste at the ICU.
Methods: This retrospective study, at the Erasmus University Medical Center, included anonymous patient ICU admission and isolation data between 01–01-2019/30–09-2022. Patients are screened (throat and rectum) for HRMO on admission, e.g. carbapenem-resistant Gram-negatives; negative cultures are known within 72 h. We retrospectively categorized admissions into products to be disposed or not, whereby products could have been disposed after admissions with isolation precautions and after admissions < 72 h. Products could not have been disposed after admissions of > 72 h without isolation precautions during the full admission.
Results: We included 3923 ICU patients, with 4423 admissions. Isolation precautions were applied in 1012 (22.9%) admissions. Admission

duration was > 72 h for 2505 (56.6%) admissions, of which 1750 (69.9%) admissions did not require isolation precautions. Therefore, in 2673 (60.4%) of admissions products should have been disposed, while for 1750 (39.6%) this would not have been necessary.
Conclusions: The use of negative ICU screenings cultures to decide whether or not to dispose patient room products could reduce on average 40% of waste (e.g. 10,500 kg waste reduction) after patient discharge from the ICU. The new waste policy was implemented based on these results. This saved 4200 kg of waste per year, with a financial value of E163.333.

Introduction: The Covid-19 pandemic put health care services under pressure, either by the enormous flux of patients or their severity, frequently requiring admission in Intensive Care Units (ICU). Covid-19's proness to superinfections, in addition to the severity of disease and overwhelmed health care workers generated a predisposing environment for outbreaks of multidrug resistant organisms (MDRO). Acinetobacter spp are opportunistic non-fermenting gram-negative bacilli, frequently associated with nosocomial infections in the critically ill. We describe an outbreak of Acinetobacter spp that evolved through our 4 Covid-19 ICUs (46 beds) during the third pandemic wave.
Methods: Retrospective descriptive cohort analysis of patients infected or colonized by Acinetobacter spp during the outbreak duration, from November to February 2021. Distinction of infection vs colonization was based on clinical and analytical deterioration plus assistant physician input. Pneumonia diagnosis on ARDS patients required also new lung opacities or important reduction of PaO2/FiO2 ratio. Analysis of outbreak dynamics, predisposing factors and infection control measures used.
Results: Thirty-one patients were infected or colonized by Acinetobacter spp, from 218 patients admitted. Median age was 58 years old and 78% were men. Acinetobacter spp was identified in 111 samples from different sites, either by culture or molecular testing. A. baumanni was the most identified (N = 105; 94,6%). Resistance to carbapenem, quinolones and gentamycin was present in > 99% of isolates. Sixty-six percent of positive microbiological tests were associated with infection, being pneumonia the most common. Ninety-three percent of patients were in the ARDS stage of Covid-19 disease at time of Acinetobacter identification, 41,2% were under ECMO. All had been submitted to corticotherapy and broad-spectrum antibiotics. Colistin plus sulbactam was the most used therapy. Thirty-day mortality was 38,7%, with the decompensation leading to death associated with Acinetobacter infection in 91,7% of those. ECMO patients mortality was 46,2%. Cases were identified during a 3 months period of time, with overworked staff, patient transfer associated with ECMO and staffing logistics as the drivers for its dissemination. Excessive personal protective equipment (PPE) use had a negative impact in basic infection prevention measures compliance, such as hand hygiene, leading to cross contamination. Reeducation on PPE use, staff cohorting and optimized environment decontamination were the main interventions used for outbreak control.
Conclusions: Acinetobacter infections are particularly impactful in severely ill patients as critical Covid-19 patients, contributing to a high mortality rate.
Excessive PPE utilization decreases the adherence and effectivity of basic infection prevention measures, paving the way for outbreaks of MDRO.
This study shows that with implementation of adequate and coordinated actions, outbreaks of MDRO can be successfully controlled.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000726

Introduction: Pericardial fat (PF) is a fat layer surrounding the myocardium that is divided into epicardial adipose tissue (EAT) and cardiac adipose tissue (CAT) (1). PF and EAT may enhance the pro-inflammatory response and lead to more severe organ failure in Corona virus-19 (COVID-19) patients (2).
Objectives: The aim of this study was to examine the association between the volume of PF and EAT and multi-organ failure over time.
Methods: Consecutive mechanically ventilated COVID-19 patients at Maastricht University Medical Centre with an available chest CT were

included (March-June 2020) (3). PF and EAT volumes were quantified on non-contrast chest CT scans using a volumetric software. Patients were categorized into sex-specific PF and EAT tertiles. Variables to calculate the Sequential Organ Failure Assessment (SOFA) scores were collected daily to indicate multi-organ failure. Linear mixed-effects regression was used to investigate the association between tertiles for PF and EAT volumes separately and serial SOFA scores over time. All models were adjusted for age, sex, Acute Physiology And Chronic Health Evaluation II (APACHE-II) score, cardiovascular risk and chronic liver, lung, and renal disease.

Results: 63 patients were divided into PF and EAT sex-specific tertiles, with median PF volumes of 131.4 ml (IQR 27.6 ml), 199.8 ml (IQR 35.7 ml) and 318.8 ml (IQR 95.0 ml) and median EAT volumes of 69.6 ml (IQR 21.6 ml), 107.9 ml (IQR 10.5 ml) and 163.8 ml (IQR 56.5 ml). Patients in the highest PF tertile had a statistically significantly lower SOFA score over time (1.3 [−2.5; −0.1], p = 0.033) compared to the lowest PF tertile. EAT tertiles were not associated with SOFA scores over time.

Conclusions: A higher PF volume is associated with less multi-organ failure in mechanically ventilated COVID-19 patients, suggesting that PF might carry a protective function. EAT volumes were not associated with development of multi-organ failure. These results provide more information on the role of organ-specific adiposity and suggest that PF could be used as a marker for multi-organ failure in mechanically ventilated patients. However, more research is required to confirm these results and to establish the clinical implementation.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000728

Introduction: In Brazil, the high demand for ICU beds during COVID-19 pandemic caused great social impact (1,2). The lack of trained professionals, especially intensivists, motived the seek for alternatives to provide efficient care (3). The Tele-ICU COVID-19 Brazil program was developed to provide remote intensivists to lead daily multidisciplinary clinical rounds (DMRs) of systematic patient-centered discussions in public COVID-19 ICUs from Brazil, through a partnership between the Brazilian Ministry of Health and 5 world-class Brazilian hospitals.

Objectives: To evaluate the association between Tele-ICU COVID-19 Brazil program and clinical outcomes [ICU mortality and ICU length of stay (LOS)].

Methods: Prospective study with 16 ICUs participants of Tele-ICU COVID-19 Brazil program (March to November 2020). To explore the Tele-ICU impact, we calculated the proportion of DMRs performed by patient, as follows: DMR patient ratio equals to the number of rounds per patient divided by patient's ICU length of stay. Univariate analyses were performed to identify predictors of ICU mortality and length of stay and the variables tested with a p > 0.20 were included as fixed effects in the final analysis. We performed a multivariate analyses using multilevel mixed modelling (GLMM) with hospitals as random effect to evaluate independent predictors of ICU mortality and ICU LOS. When p < 0.05 the test was considered statistically significant. All analyses were performed using the R (R, version 4.1.0, Core Team, Vienna, Austria, 2021) software.

Results: In total**,** 1680 patients were included in this study. The median (IQR) age was 66 (55–76) years and 56.4% of patients were male. The median (IQR) SOFA was 4 (1–9) and the median (IQR) number of DMRs performed per patient was 3 (2–6). ICU and hospital mortality were, respectively, 49.0% and 51.1%. Median ICU and hospital LOS were, respectively, 8 (4–15) days and 11 (6–20) days. Independent predictors of ICU mortality in the final model were SOFA score, need of mechanical ventilation (MV) vasopressors, while the use of non-invasive ventilation (NIV) and DMR per patient ratio exhibited a protective effect (Table 1). Independent predictors of ICU LOS were SOFA score and the use of MV, while DMR per patient ratio showed a protective effect (Table 2). Duration of the Tele-ICU program in each hospital and the rate of DMR per hospital had no significant impact in clinical outcomes.

Conclusions: During Tele-ICU COVID-19 Brazil program, a higher proportion of daily multidisciplinary rounds was independently associated with lower ICU mortality and lower ICU LOS. Tele-ICU might have improved outcomes by increasing adherence to best practices and improving the continuity of care in the participants ICUs.

Table 2 (abstract 000728) Results of the General Linear Mixed Model (GLMM) with ICU length of stay as predictor and hospital as random effect

Fixed effects	OR	95% CI	P value
SOFA score	1.037	(1.02-1.05)	<0.001
Use of MV	1.228	(1.05-1.43)	0.010
DMR per patient ratio	0.166	(0.13-0.21)	<0.001

Table 1 (abstract 000728) Results of the General Linear Mixed Model (GLMM) with ICU death as predictor and hospital as random effect

Fixed effects	OR	95% CI	P value
SOFA score	1.238	(0.860-1.317)	<0.001
Use of MV	3.222	(2.056-5.043)	<0.001
Use of NIV	0.540	(0.331-0.881)	0.014
Use of vasopressor	1.870	(1.236-2.824)	0.003
DMR per patient ratio	0.520	(0.272-0.993)	0.048

Introduction: ARDS induced by SARS-CoV-2 has high mortality and few treatments are available. Stem-cell derived extracellular-vesicles (EVs) are emerging as a possible therapeutic strategy.
Objectives: Plasma of severe COVID-19 ARDS patients induces oxidative stress and damage on lung epithelial-endothelial barrier. EVs from bone marrow (MSC-EVs) and adipose (ASC-EVs) mesenchymal stem-cells mitigate these injuries.
Methods: BEAS-2B and HMEC cells were used as lung barrier model. We tested 5 plasmas of healthy volunteers and 10 plasmas of COVID-19 ARDS patients treated whit VV-ECMO. BEAS-2B and HMEC were seeded in chamber slides and multiwell plates and challenged with plasma of healthy volunteers or COVID-19 patients. MSC-EVs or ASC-EVs were added simultaneously with plasma or after 6 h. After 24 h, we evaluated oxidation parameters, antioxidant enzymes activity and expression of tight junction proteins ZO-1 and Occludin by immunofluorescence. Mann–Whitney test was performed for statistical analysis.
Results: COVID-19 plasma significantly increased oxidation parameters, the activity of antioxidant enzymes ($p < 0,001$) and attenuated ZO-1 and Occludin expression ($p < 0,0001$) compared to the healthy control in both BEAS-2B and HMEC (Fig. 1). MSC-EVs and ASC-EVs added together with COVID-19 plasma or after 6 h restored redox balance (Tab 1 Data are Median (IQR)) and expression of ZO-1 (MSC-EVs; ASC-EVs $p < 0,0001$) and Occludin (MSC-EVs; ASC-EVs $p < 0,001$) in BEAS-2B and HMEC.

BEAS-2B	Healthy	COVID	COVID + MSC-EV	COVID + ASC-EV	COVID + MSC-EV 6h	COVID + ASC-EV 6h

Conclusions: Plasma of severe COVID-19 ARDS patients induces damage and oxidative stress in a cellular model of lung epithelial-endothelial barrier. MSC-EVs and ASC-EVs mitigate this injury, suggesting a potential therapeutic effect.

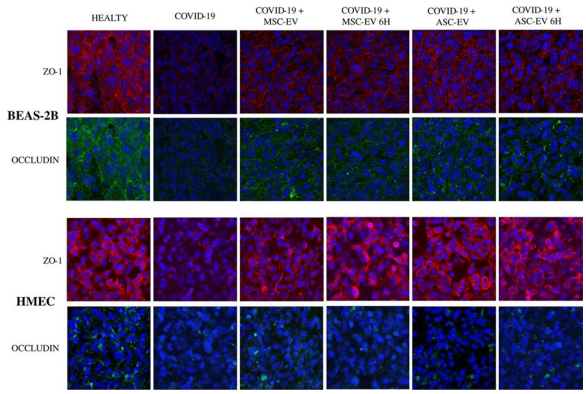

Fig. 1 (abstract 729) Representative images of ZO-1 and Occludin expression in BEAS-2B and HMEC cells. Plasma of severe COVID-19 induced loss of tight junction proteins expression. MSC-EVs and ASC-EVs mitigate this effect when they are added simultaneously with plasma or after 6 h. COVID-19 plasmas tested n = 10 for BEAS-2B n = 5 for HMEC

Introduction: The consequences of voicelessness in tracheostomised mechanically ventilated (TMV) patients secondary to cuff inflation are well established [1]. Cuff deflation and one-way valve (OWV) placement in-line with ventilation to restore trans-laryngeal airflow and voice is routine practice in our centre. However, introduction of new ventilators across our intensive care unit (ICU) gave rise to safety concerns regarding use of OWVs due to threshold alarms, apnoea ventilation override and potential for human error in managing these. Multidisciplinary team (MDT) review of current practice, available equipment and training resources was completed. Consensus was reached that the new ventilator was not safe, effective or accessible for use with OWVs. A scoping exercise identified Hamilton T1 ventilators as compatible for use with OWVs once specific software is enabled, overcoming safety concerns with the existing ventilator. However, their introduction necessitated new approaches for using OWVs and therefore potentially presented a barrier to access.
Objectives: To determine unmet need regarding the use of OWVs in TMV patients in our mixed cohort ICU and establish approaches to improve this.
Methods: For one month in 2021, Hamilton T1 ventilators were trialled. The number of cuff deflation and in-line OWV sessions completed across all 54 ICU beds was collected. Data also included who delivered these, any safety concerns and the overall number of sessions recommended by Physiotherapy (PT) and Speech & Language Therapy (SLT) to determine unmet need. A MDT steering group comprising of nursing, PT and SLT was formed to establish reasons for unmet need and how to approach this.
Results: 48 sessions of cuff deflation and OWV in-line with ventilation were indicated and 24 were delivered (50% unmet need). All sessions were completed by PT and SLT. The reason for un-delivered sessions was always cited as lack of appropriately trained staff. Steering group review of data and root cause analysis determined staff education and easily accessible training resources as proposed solutions. A standard operating procedure and accessible online guideline was written including a new instructional training video. This was ratified via internal clinical governance process.
Conclusions: Restoration of voice for TMV patients is a priority however ventilator compatibility and safety concerns can limit access. Therefore, having adequately trained staff is essential. A need for education and accessible training materials was established and a novel online training video and guideline has been developed to meet this need. Data is being collected on outcome measures since the launch of the training resources across the MDT.

Introduction: Although artificial intelligence (AI) is increasingly investigated in the ICU, use in clinical care is currently limited [1]. Besides technical and organizational factors, human readiness and acceptation play an important role in adoption of new applications [2]. To date, little is known about the attitudes of ICU physicians towards the use of AI in clinical practice.
Objectives: To assess the expectations and readiness of ICU physicians regarding the acceptation and use of AI in clinical practice.
Methods: Data was collected between April 2022 and October 2022 from physicians and residents working in an ICU in Flanders (Belgium). 9 out of 10 contacted hospitals participated. Participants completed an online survey assessing basic information such as age, gender, experience, etc. as was well as their opinion on statements probing current use of information and communication technology (ICT), AI research, AI use, and their future expectations by means of a 5-point Likert scale ranging from "Completely disagree" to "Completely agree". Statistical analysis was performed using R Studio. Continuous variables are presented as median with interquartile range (IQR, [Q25–Q75]). Categorical variables are presented as percentage of total evaluable instances. Statistical significane was defined as a p-value < 0.05.
Results: Characteristics of the 69 participants are listed in Table 1. Almost all participants thought the use of ICT benefits patient care (94.2%). The majority of the participants expect AI tools to also benefit patient care (75.4% - Fig. 1) and consider the implementation of AI tools in clinical practice inevitable in the future (85.5% - Fig. 2). Participants from academic hospitals were more likely to be interested in AI applications in clinical practice and research than participants from non-academic hospitals ($p = 0.04$). Despite the perceived benefit of using AI in clinical practice, a minority of physicians feels adequately familiar with concepts such as AI or big data (39.1%), or feel competent to use AI in daily clinical practice at this time (15.9% - Fig. 3). Age, gender, working environment and working experience were not associated with the self reported readiness to use AI. Rather than replacing physicians, participants believed that AI would become a tool used by clinicians (91.3% - Figure 4), but not to a point where clinicians who do not use AI tools were replaced by clinicians who do use them (17.4%).

Table 1 (abstract 000731) Descriptive statistics of the study participants ($N = 69$)

Age (years)	**40 [31–49]**	**Clinical experience (years)**	**11 [6–23]**
Gender (% Female)	42%	**ICU experience (years)**	6 [1–19]
Role		**ICU type**	
Consultant	66.7%	Mixed surgical and medical ICU	63.8%
Resident ICU	17.4%	Surgical ICU	29.0%
Resident other specialty	15.9%	Medical ICU	7.2%

Age (years)	**40 [31–49]**	**Clinical experience (years)**	**11 [6–23]**
Basic specialty		**Setting**	
Anesthesiology	63.8%	Non-academic hospital	62.3%
Internal medicine or subspecialty	26.1%	Academic hospital	37.7%
Emergency medicine	8.7%		
Pediatrics	1.4%		

Conclusions: ICU physicians and residents consider the use of AI in the ICU inevitable and think it will benefit patient care. Clinicians do not yet feel competent enough to start using AI routinely in clinical practice.

Introduction: Patients diagnosed with coronavirus disease-19 (COVID-19) may develop respiratory failure, requiring mechanical ventilation (1). Dynamic respiratory system compliance may be a valuable indicator of impaired lung mechanics caused by COVID-19.
Objectives: To describe the effect of dexamethasone and tocilizumab on regional lung mechanics over admission in mechanically ventilated COVID-19 patients.
Methods: In this prospective observational cohort study, invasive mechanically ventilated patients enrolled within the Maastricht Intensive Care Covid (MaastrICCht) cohort were included (2). Dynamic compliance, alveolar overdistension and collapse were serially determined using electric impedance tomography (EIT)(3, 4). Patients were categorized into three groups; no anti-inflammatory therapy, dexamethasone therapy, dexamethasone + tocilizumab therapy. The EIT variables were visualized using polynomial regression and evaluated throughout admission using linear mixed-effects models. Moreover, we compared respiratory variables between the three groups, including PaO2/FiO2-ratio, driving pressure, optimal positive end-expiratory pressure (PEEP) (the PEEP level with alveolar collapse closest and under 5%), clinically applied PEEP (PEEP set in the clinic when optimal PEEP was not implemented due to the clinical condition), dynamic compliance, alveolar overdistension, and alveolar collapse at the optimal PEEP.
Results: The no anti-inflammatory therapy group (n = 92) had 310 EIT measurements, the dexamethasone group (n = 60) 130 measurements, and the dexamethasone + tocilizumab group (n = 8) 13 measurements. Visual inspection of EIT variables showed a pattern of decreasing dynamic compliance. Overall, optimal set PEEP was lower in the dexamethasone group (-1.4 cmH2O, -2.6; -0.2). Clinically applied PEEP was lower in the dexamethasone and dexamethasone + tocilizumab group (-1.5 cmH2O, -2.6; -0.2; -2.2 cmH2O, -5.1; 0.6). Dynamic compliance, alveolar overdistension, and alveolar collapse at optimal set PEEP did not significantly differ between the three groups.
Conclusions: Optimal PEEP was similar in groups based on treatment, while optimal and clinically applied PEEP were lower in the dexamethasone and dexamethasone + tocilizumab groups. The results suggest that the potential beneficial effects of these therapies do not affect lung mechanics.

Effect of different early mobilization interventions within 72 h of admission or intubation of critically ill patients: a systematic review with network-meta-analysis

N. Daum[1]; N. Drewniok[1]; A. Buyukli[1]; B. Ulm[2]; J. Grunow[1]; S. J. Schaller[1]

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000734

Introduction: Previous studies demonstrated that an early start of mobilization has a positive effect on different intensive care unit (ICU) outcomes [1]. Since there is no uniform definition of early mobilization (EM) comparing studies is challenging [2].
Objectives: Aim of this systematic review was to investigate the effectiveness of different interventions defined as EM on outcomes.
Methods: Before screening, we registered our systematic review on PROSPERO (CRD42022363584). We conducted a systematic review and network-meta-analysis examining the effect of different EM interventions within 72 h of ICU admission or intubation compared to standard care. Randomized controlled trials were included from inception to October 8th, 2022. EM was defined as any patient intervention that initiates and/or supports passive or active range of motion exercises and aims to promote and/or maintain range of motion [3]. A network meta-analysis was performed using the `netmeta` package in R (version 4.1.2). Outcomes were pooled using a common-effects model.
Results: Of a total of 29,680 studies screened, 18 studies with a total of 1833 patients met the inclusion criteria and were included in the statistical analysis for ICU length of stay (LOS). We identified 7 different mobilization interventions defined as EM in the time frame of interest. 14 studies with a total of 1587 patients and 4 different mobilization interventions defined as EM could be included in the statistical analysis in relation to the hospital LOS. A network meta-analysis was only possible for ICU und hospital LOS because the number of studies was too small for other outcomes. In the network meta-analysis, EM alone, cycling, and EM with early nutrition showed the greatest weighting in relation to ICU LOS. In relation to hospital LOS, the greatest weighting was shown for EM alone and cycling (see Fig. 1, A and C). The combination of EM and early nutrition as well as EM alone had a significant effect on ICU LOS, while EM alone had a significant effect on hospital LOS (see Fig. 1, B and D). The overall heterogeneity of the studies was moderate with I2 = 50%.
Conclusions: This network meta-analysis confirmed the positive effect of EM alone as well as the combination of EM and early nutrition on ICU LOS. Furthermore, EM alone shortened hospital LOS.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000735

Introduction: In the last decade, it has been postulated that mechanical power (MP) can produce ventilator-induced lung injury (VILI) and has a direct association with increasing mortality, days of invasive mechanical ventilation (IMV), and ICU length of stay (LOS). Most studies only monitor MP once or twice a day. However, IMV is a continuous process, so they may not be a reflection of the real scenario.
Objectives: Analyze if the continuous measurement of MP through the clinical information system (CIS) has prognostic value regarding mortality, days of IMV, and ICU LOS in critically ill patients.
Methods: Retrospective observational study conducted in a 28-bed mixed ICU in Spain. All patients who received more than 24 h of IMV at the ICU from September 2015 to July 2022 were included. All data was collected through the process of extraction, transformation, and loading from the CIS. In particular, respiratory variables were stored in the CIS every two minutes throughout the entire duration of the IMV. Every hour with MP > 18J/min was recorded. Univariate analyses were performed using Chi-square or U-Mann–Whitney tests appropriately. Patients were divided into two groups based on their median days on IMV and ICU LOS. Subsequently, multivariate logistic regression analyses and Pearson correlation were performed. Statistical significance was defined at $p < 0.05$. The analyses were performed using the R software.
Results: 10.874 patients were admitted on the ICU. 2.623 were included, 1.826 (70%) male, median age of 64 (53–72) years, median SOFA of 5 (4–7), median APACHE of 21 (15–25). 1868 (64%) medical patients, 2506 (95%) urgent admissions and 277 (11%) SARS COV-2. The mortality rate was 30% (733), median days of IMV were 6 (3–15) and median ICU LOS was 11 (5–22) days. 552 (21%) tracheostomized and 213 (8%) re-intubated. The median MP was 16 (13–21) and the median hours with MP > 18 J/min were 35 (8–125).
In non-COVID patients (n = 2.282), MP was not independently associated with higher mortality (OR = 1 (95% CI 1–1, p = 0.19)) (AUC 0.73). However, it was associated with > 5 days on IMV (OR = 1.03 (95% CI 1.02–1.03, p < 0.001)) (AUC 0.91) and > 9 days of ICU LOS (OR = 1.02 (95% CI 1.02–1.02, p < 0.001)) (AUC 0.82). The Pearson correlation coefficient between hours with MP > 18 J/min and days of IMV was 0.79 and between hours with MP > 18 J/min and ICU LOS was 0.71.
Similar results were found in COVID patients. MP was not independently associated with higher mortality (OR = 1 (95% CI 1–1, p = 0.18)) (AUC 0.7). However, more hours with MP > 18 J/min were associated with over 18 days of IMV (OR = 1.01 (95% CI 1.01–1.01, p = < 0.001)) (AUC 0.81) and over 23 days of ICU LOS (OR = 1.01 (95% CI 1.01–1.01, p < 0.001)) (AUC 0.81). The Pearson correlation coefficient between hours with MP > 18 J/min and days of IMV was 0.72 and between hours with MP > 18J/min and ICU LOS was 0.68.
Conclusions: The number of hours with MP > 18J/min is not independently associated with higher mortality, but it is associated with an increased risk of spending more days on IVM and longer ICU LOS, both in COVID and non-COVID patients.
CIS provides an opportunity to obtain information from a scenario closer to reality in a more efficient manner.

Introduction: Corticoids were widely used to minimize the inflammatory response[1]. SARS -CoV2 affects the lungs causing inflammation and diffuse alveolar damage. The corticoids can suppress inflammation and inhibit immune response[2]. The primary objective is to evaluate 28-day mortality in patients in mechanical ventilation with SARS-CoV2. The secondary objectives are to correlate the risk of bloodstream infection and ventilator-associated pneumonia (VAP) and the time of mechanical ventilation, and the length stay in the intensive care unit (ICU) and the hospital.

Methods: A unicentric prospective randomized double-blinded study was designed to access the efficacy and the safety of methylprednisolone in patients in mechanical ventilation due to COVID-19.

Results: 148 patients with SARS were screened, 112 underwent to randomization. 58 to the methylprednisolone group and 54 patients to the placebo group. There was no significant difference in all-cause mortality at 28-days (46.7 in the methylprednisolone group vs 53.3% in the placebo group).

Methylprednisolone group had more extubation (67.2% vs 48.1%, p = 0.042) and lower number of tracheostomies (5 vs 14, p = 0.015). The median days in mechanical ventilation were lower in the methylprednisolone group (6 days vs 14 days, IC 95%, p = 0.012), as well as the mean days in ICU (12.5 days + 10.54 vs 18.76 + 15.1, p = 0.043). There was no significant difference in length hospital, bloodstream infection, or VAP.

Conclusions: In patients in mechanical ventilation due to SARS-CoV2, the use of methylprednisolone reduces the days in mechanical ventilation, ICU stay and favours early discharge.

Association of vasopressors dose trajectories with enteral nutrition tolerance in patients with sepsis shock

L. Wang[1], K. Yan[1], W. Qin[1]

[1]Department of Critical Care Medicine, West China Hospital, Sichuan University, Chengdu, China

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000738

Introduction: The optimal time to initiate enteral nutrition (EN) in patients with shock remains controversial. EN preserves intestinal barrier function in patients with septic shock, but introducing EN in the intestine where patients with sepsis shock are inherently at risk of inadequate perfusion may increase the risk of bowel-related complications or even non-occlusive bowel necrosis [1]. Current guideline recommendations and expert consensus suggest that initiating EN in patients with shock receiving low to moderate doses of vasopressors or at vasopressor dose equivalent scores > 12 [2, 3]. Vague definitions of vasopressor doses and the use of unvalidated scoring systems make guidelines and expert consensus less accurate guidance for clinical practice. Studies have reported that EN initiation in patients with shock was safe and feasible, and that the safety threshold of norepinephrine equivalent dose (NEQ) for initiating EN was < 0.3 μg/kg/min [4]. Most studies only reported the dose of norepinephrine or NEQ at a single time point. However, studies, describing the correlations between the long-term patterns of NEQ dose and EN tolerance in patients with shock, are limited.

Objectives: This study aimed to identify the NEQ trajectories and examine its correlations with FI in patients with sepsis shock.

Methods: This study prospectively enrolled the patients with sepsis shock requiring vasopressors from August 2020 to June 2022. The Growth Mixed Model was used to traverse longitudinal NEQ data at 6 h intervals and identify the latent trajectories of NEQ use in these patients. The primary endpoint was the occurrence of FI during the follow-up period (28 days after enrollment). FI was defined as the interruption of EN due to the presence of one of the following indications: vomiting/regurgitation, diarrhea, ileus, and suspected mesenteric ischemia/perforation. Kaplan–Meier survival curve analysis was performed to identify the cumulative risk for FI occurrence, and the log-rank test was used to test the differences among the groups.

Results: A total of 178 eligible patients with sepsis shock were included in this study. Consistent with the results of Growth Mixed Model, the model with three trajectory classes was the best. The trajectories of NEQ use in patients with sepsis shock are shown in Fig. 1 (a). Three trajectories of NEQ dose were identified and characterized by low-dose stable NEQ (L-NEQ, n = 83), moderate-dose stable NEQ (M-NEQ, n = 76), and rapidly rising NEQ (R-NEQ, n = 19) with NEQ doses of 0.2, 0.4 and 0.6 μg/kg/min at EN initiation, respectively. The occurrences of FI within 3 days after EN initiation were 10.84%, 21.05%, and 52.63% in the L-NEQ, M-NEQ, and R-NEQ groups, respectively ($P < 0.001$). The total incidences of FI were 37.34%, 69.74%, and 73.68% in the L-NEQ, M-NEQ, and R-NEQ groups, respectively ($P < 0.001$) (Fig. 1(b)). As compared to the L-NEQ group, the risk of FI occurrence increased in the M-NEQ and R-NEQ groups (all $P < 0.05$) (Fig. 1(c, d)).
Conclusions: The risk of FI was significantly associated with NEQ trajectories in patients with sepsis shock. It might be appropriate to initiate EN when the NEQ dose is stabilized below 0.2 μg/kg/min in patients with sepsis shock.

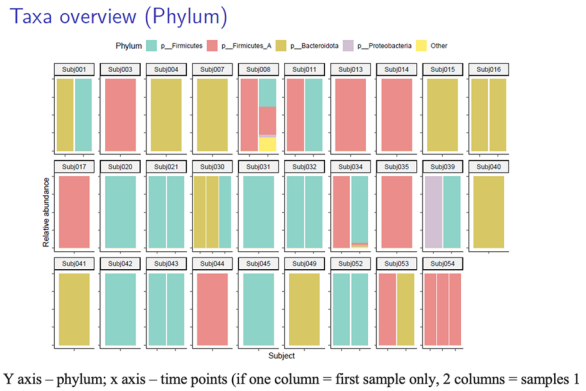
Introduction: Having a diverse gut microbiota plays an integral role in our health. Over 90% of commensal organisms are lost within hours of critical illness. Loss of diversity and expansion of pathogenic strains is known as dysbiosis; it is linked with increased morbidity and mortality. Unlike probiotic supplements, fermented foods increase microbiome diversity in outpatient settings. Their effect on the microbiome of the critically ill has not been evaluated. Kefir (a fermented milk beverage) can be safely administered even via a nasogastric tube.
Objectives: We investigated the composition of the gut microbiome of the critically ill and the effect of giving kefir as a first step to using fermented foods to mitigate dysbiosis in the critically ill. We also assessed for any preliminary associations between antibiotics with anaerobic coverage and microbiota composition.
Methods: An open-label phase I investigation of kefir administered in escalating doses to adult critically ill patients with an intact gastrointestinal tract, starting with 60 mL, then 120 mL 12 h later, and followed by 240 mL/day onwards. We attempted to collect two stool samples at least 72 h apart after initiating kefir.
Results: 52 patients (mean age 64 years (range 23–88), 62% male) were enrolled. 43 patients received antibiotics with anaerobic coverage within 72 h of admission. We collected one stool sample from 26 patients and two samples from 14 patients (54 samples total). Of those, 21 received anaerobic antibiotics and 5 did not (only one patient without anaerobic antibiotic coverage had 2 stool samples). Taxonomic profiling revealed a single dominant phylum at each time point, in contrast to the 5–8 dominant phyla that typically make up the human gut microbiome. 76% of the reads were classified as belonging to 29 species. All timepoint 1 samples exhibited very low species richness (range: 3–29), orders of magnitude lower than a healthy human gut microbiome. Alpha diversity analysis of timepoint 1 samples showed no significant relationships between diversity and anaerobic coverage (Shannon: $p = 0.71$; Inverse-Simpson: 0.44; species richness: 0.82). Differential abundance analysis did not find any taxa associated with anaerobic coverage (FDR-adjusted p-value < 0.20). Lack of observed effect of anaerobic coverage on diversity could be due to having only one patient with two samples for comparison. Alpha diversity association analyses between timepoints 1 and 2 were inconclusive (Shannon: $p = 0.21$, Inverse-Simpson: 0.45, Observed: 0.18). Two subjects demonstrated 18 × and 20 × increases in species richness, indicating that a subgroup of patients may recover their microbiome even while in the ICU.
Conclusions: Critical illness is associated with a dramatic decrease in gut microbiome diversity. Randomized comparative studies are warranted to test the effect of kefir on the microbiome of the critically ill.



Y axis – phylum; x axis – time points (if one column = first sample only, 2 columns = samples 1 and 2 analyzed).

The initial fluid volume required for resuscitation of septic shock patients depends on the source of infection

R. Shi[1], S. Cappio Borlino[2], F. Moretto[2], E. Rocca[2], M. Fasan[2], W. Mongkolpun[3], S. Carelli[2], C. Lai[2], JL. Teboul[2], X. Monnet[2]

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000742

Introduction: The Surviving Sepsis Campaign recommends an initial volume expansion of 30 mL/kg in all septic shock patients. However, the fluid volume required initially may differ with the sepsis source, which induces various degrees of absolute and relative hypovolaemia.
Objectives: We conducted a prospective observational study in septic shock patients in order to quantify the fluid volume received before the occurrence of preload unresponsiveness, i.e. a state in which fluid infusion does not increase cardiac output significantly.
Methods: In patients at initial phase of septic shock admitted in our intensive care unit, we repeatedly assessed preload responsiveness from inclusion, either through the response of cardiac output to a fluid bolus (143/222 measurements), or through a passive leg raising test (60/222 measurements), an end-expiratory occlusion test (13/222 measurements) or a tidal volume challenge (6/222 measurements). We quantified the volume of fluid received before the first occurrence of preload unresponsiveness.
Results: We enrolled 71 patients, whose demographical and clinical characteristics at baseline are presented in Table 1.

Table 1 (abstract 000742) Demographical and clinical characteristics at baseline

Variables	Study population (n = 71)
Age, years	64 (12)
Male sex, n. (%)	44 (62)
BMI, kg/m^2	27 (7)
SOFA score at ICU admission	8 (6–9)
Invasive mechanical ventilation at inclusion, n. (%)	28 (39)
Left ventricular ejection fraction at baseline, %	60 (50–65)
Noradrenaline support at inclusion, n. (%)	53 (75)
Noradrenaline dose at inclusion, mcg/kg/min	0.45 (0.27–1.13)
Volume of resuscitation fluid at inclusion, ml/kg	22 (12–36)

The source of infection was abdomen for 13 (18%) patients, lung for 29 (41%) patients, urinary tract for 15 (21%) patients, skin and soft tissues for 10 (14%) patients and miscellaneous for 4 (6%) patients. The time from shock diagnosis to inclusion was 425 (199–1000) minutes. Forty-four (62%) patients had been previously admitted to the emergency department and 25 (35%) had a history of significant fluid losses.
Only 49 (69%) patients were still preload-responsive at inclusion and, at this time, they had received 19 (12–33) ml/kg. They evolved into a non-responsive state after 29 (21–45) mL/kg of fluid infused from shock diagnosis. This volume was 37 (27–51) mL/kg for abdominal origin, 27 (19–41) mL/kg for pulmonary origin, 34 (23–61) mL/kg for urinary tract origin, 33 (19–36) mL/kg for cutaneous and soft tissues origin (Figure 1). Among the preload-responsive patients, 25 (51%) became preload unresponsive before receiving 30 mL/kg of fluid (median 20 [15–25] ml/kg) (Figure 2): 3 (50%) patients in the abdominal group, 13 (54%) patients in the pulmonary, 4 (50%) patients in the urinary, and 3 (43%) patients in the cutaneous.
Conclusions: The volume of resuscitation fluid required by septic shock patients at the initial phase seems to differ depending on the source of infection, abdominal sepsis requiring more fluid than others. Moreover a relevant number of patients with septic shock required a fluid resuscitation < 30 mL/kg from shock to preload unresponsiveness. The study is ongoing, but these primary results suggest a personalization of initial fluid therapy.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000743

Introduction: Acute pulmonary thromboembolism is a significant cause of morbidity and mortality, with an increasing incidence in recent years. We can use different therapeutic strategies according to the risk and the clinical situation of our patients, including mechanical thrombectomy.
Objectives: Evaluate the efficacy of rescue mechanical thrombectomy for the treatment of acute pulmonary thromboembolism.
Methods: We describe our experience with mechanical thrombectomy in high-risk PE from February 2021 to November 2022.
During this period of time, urgent thrombectomies were performed on 8 patients with high-risk PE, who had an average PESI score of 164, elevated troponin I concentrations with an average of 1.4ng/ml and an average d dimer of 2830 ng/ml.
77.7% of our patients were men, with a mean age of 53 years, 44.4% had HBP, 11.1% had an oncological disease, 33.3% were overweight, 22.2% were COPD, and 44.4% had a history of COVID infection in the last 3 months.
One of our patients had contraindication for fibrinolytic treatment.
Results: The main clots were treated with a fibrinolytic agent bolus and by rotating movements with the indigo ® system commonly used for pulmonary angiography.
We could observe clinical and mechanical improvement after thrombectomy in 87.5% of our patients. The mean pulmonary artery pressure decreased from 43 to 33 mmHg after mechanical treatment.
3 of our patients suffered cardiorespiratory arrest and 2 of them needed temporary ECMO support.
One of them died 24 h after the procedure due to refractory shock with multiple organ failure after CPR. Another patient died during the procedure due to rethrombosis and technical difficulties. The rest of our patients presented clinical and ultrasound improvement during their admission to the ICU, showing an improvement in the contractility of the right ventricle, with an average TAPSE before the thrombectomy of 13 mm and 17 mm after the procedure; on average they were on mechanical ventilation for 14 days.
There was no evidence of hemorrhagic complications related to the procedure, including hemorrhagic cerebrovascular events.
Conclusions: Mechanical thrombectomy in high-risk PE is a new therapeutic option that seems to have immediate positive hemodynamic effects. We need more studies to evaluate the efficacy of this therapy as a rescue for patients who have needed fibrinolysis before this procedure.

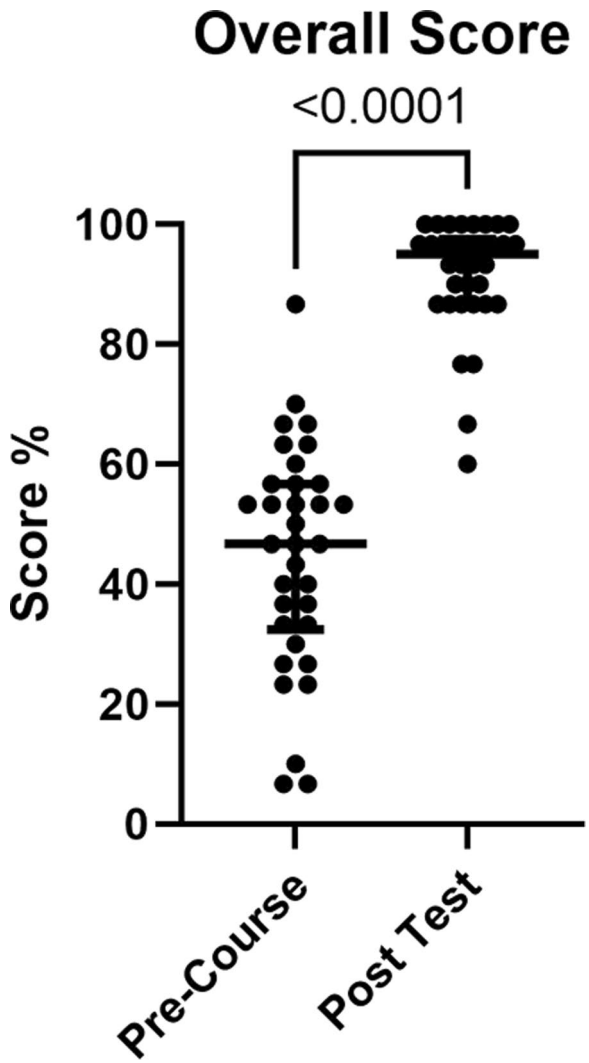
Correspondence: A. Y. K. C. Ng
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000744

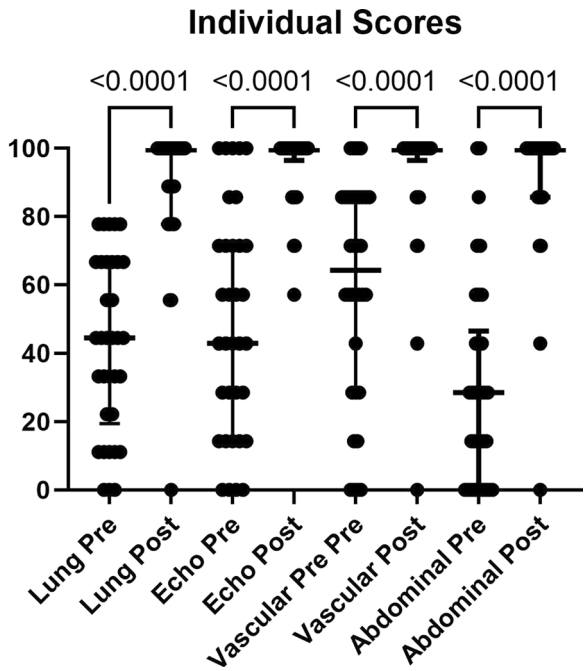
Introduction: The widespread availability of ultrasound machines in secondary care facilities has led to an increase in the use of point of care ultrasound in critical care. The development of unified accreditation frameworks such as FUSIC (The UK Intensive Care Society, ICS) and FAMUS (The UK Society for Acute Medicine) provide a useful training framework for practitioners to accredit in the use of ultrasound for limited applications, including the management of shock, diagnosis of acute lung injury, and for procedural applications. There is thus a growing and unmet need for multimodal ultrasound training courses that are affordable, effective, and deliverable at scale.
Objectives: To establish a course framework for the near-peer ultrasound teaching, and to assess both its efficacy in imparting basic sonographic skills to novice practitioners.
Methods: A standardised one-day course comprising lectures and practical stations was organised to deliver the basic elements of the following point of care modalities: echocardiography, lung ultrasound, vascular ultrasound, and abdominal ultrasound, based on the ICS accreditation framework. We designed a timed, structured assessment to obtain standardised views of normal structures in a healthy volunteer, marked on a 30-point scale, and including all four modalities. Consenting participants underwent this assessment before and after the course, and were marked by an examiner who did not prompt or help the candidates apart from introducing the key functions of the machine to them.
Results: 34 participants underwent our structured pre-course and post-course assessment. The median score of the pre-test assessment was 46.7%, which was evenly distributed amongst the four modalities. Candidates were most familiar with vascular ultrasound with a median score of 64.2%, while candidates were least familiar with abdominal

ultrasound with a median score of 28.6%. Candidate scores improved by 48.3%, achieving a median score of 95% after the course, which was statistically significant ($p < 0.0001$, Wilcoxon), and there was significant improvement in all four modalities.

Conclusions: Here we present evidence that a near-peer ultrasound course significantly and effectively improves novice practitioners' ability to identify key anatomical structures using point of care ultrasound. The cost to deliver the course was £50 per participant, making this a cost effective and economically scalable course. We aim to validate these findings in a wider cohort, and to examine longitudinal retention of these skills in trainees accrediting in point of care ultrasound.



Pre-Course and post-course test scores (percentage) are shown in this Fig. 34 individuals underwent structured assessment scored by non-prompting examiners before and after the course delivery. Individual scores are shown as dots, and the median score and interquartile range are shown as a horizontal line and error bars. There was a significant improvement in performance after sitting the course (Wilcoxon).



Pre-Course and post-course test scores (percentage) for each individual modality are shown. 34 individuals underwent structured assessment scored by non-prompting examiners before and after the course delivery. Individual scores are shown as dots, and the median score and interquartile range are shown as a horizontal line and error bars. There was a significant improvement in performance after sitting the course (Kruskal–Wallis).

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000745

Introduction: Orthotopic liver transplantation presents challenges from a preoperative to postoperative standpoint given their underlying comorbidities and large volume hemodynamic changes that occur in the perioperative period. One of the repercussions of such large hemodynamic changes include Takotsubo cardiomyopathy, a transient acute left ventricular dysfunction secondary to nonischemic cardiac stress. Though this condition may occur in the setting of various physiological and psychological stressors, this condition has

previously been thought to be transient with low mortality. However, the known cases in the setting of liver transplants often noted higher levels of morbidity and mortality.
Objectives: Here we do a thorough literary review thus far to discuss the appropriate workup and management of Takotsubo cardiomyopathy and analyze for common risk factors among patients who underwent a liver transplant.
Methods: A systemic literature review was conducted with searches made on databases such as PubMed, Google Scholar, and Embase.
Results: Takotsubo cardiomyopathy in setting of liver transplant patients have been associated with higher morbidity and mortality and often requiring more supportive measures. Despite this higher risk of complications, the current diagnostic approach is similar to that of patients who develop this condition from different etiologies. Even among liver transplant patients, those who developed Takotsubo cardiomyopathy had more complicated underlying cirrhotic disease or perioperative complications.
Conclusions: Many known cases of Takotsubo cardiomyopathy in setting of liver transplantation have been published in case reports and series. Despite this, the leading cause of death in liver transplants, especially in cases of advanced cirrhosis, is cardiovascular complications. Further studies on Takotsubo cardiomyopathy should aim to evaluate predictors of morbidity and mortality and discuss the benefits and risks of mechanical circulatory support as well as continue to highlight this rare diagnosis in this high-risk population.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000746

Introduction: Human resource constraints for ICU care during COVID-19 pandemics caused significant burden for patients in Brazil and worldwide (1,2). Lack of experts caused the need for alternative strategies like telemedicine (3). The Tele-ICU COVID-19 Brazil program was created to offer remote assistance to guide daily multidisciplinary rounds (Tele-rounds) discussions in public COVID-19 ICUs in Brazil. The program consisted in daily Tele-rounds of systematic patient-centered discussions with the remote intensivist and the local ICU multidisciplinary team to establish joint therapeutic goals for the next 24 h of care and to improve adherence to evidence-based best practices.
Objectives: To evaluate the association between the participation in the Tele-rounds during Tele-ICU COVID-19 Brazil program, and the use of respiratory support, and protective mechanical ventilation in the participating ICUs.
Methods: Prospective study with 16 ICUs participants of Tele-ICU COVID-19 Brazil program (March to November 2020). To explore the Tele-ICU impact, we calculated *Tele-round ratio*, as follows: the number of rounds per patient divided by patient's ICU length of stay. Tele-round groups were defined as high, intermediate, or low (intensities) when *Tele-round ratios* were higher than 66%, between 33 and 66% or lower than 33%, respectively. Protective mechanical ventilation was defined as the report of Tidal volume < 6 ml/kg and Driving pressure < 15 mmHg during invasive mechanical ventilation (MV). Data were collected by the remote intensivist during Tele-round. We compared the use of invasive and non-invasive ventilation during ICU stay and the use of protective MV between the groups. Two-tailed non-parametric tests were used, and $p < 0.05$ was considered statistically significant.
Results: 1680 patients were included in this study, out of those 769 were submitted to invasive MV. 56.4% were male, the mean age was 66 (55–76) years and SOFA score was 4 (1–9). Hospital mortality was 51.1%. Groups comparisons showed about 150% higher use of non-invasive ventilation high Tele-round group, than and low Tele-round groups ($P < 0.001$) and about 30% less need of invasive mechanical ventilation ($P < 0.008$). Parameters of protective MV were not different between the groups - Table 1.
Conclusions: During Tele-ICU COVID-19 Brazil program, there was a significant association between the proportion of Tele-rounds with more frequently non-invasive ventilation use and less frequent need of invasive MV.

Table 1 (abstract 000746) Comparisons between the defined groups

	Low Tele-round group	Intermediate Tele-round group	High Tele-round group	p*
N= 1680	518	747	415	
SOFA score during the first 24h of ICU admission, n=841/1680, (median [IQR])	2 (0-7)	2 (0-5)	2 (0-4)	0.348#
SOFA score during the first 72h of ICU admission, n=1368/1680, (median [IQR])	5 (1-9)	4 (2-8)	3 (0-7)	0.008#
Support during ICU stay, n(%)				
Mechanical ventilation	259 (63.6)	361 (58.6)	149 (45.0)	<0.001$
Noninvasive ventilation	30 (7.4)	81 (13.1)	57 (17.2)	<0.001$
Patients who received invasive MV, n/total n (%)				
Protective MV	187/259 (72.2)	268/361 (74.2)	100/149 (67.1)	0.264$

Values represent median (IQR) or n/n total (%). SOFA score: sequential organ failure assessment score, ranges from 0 to 24, with higher scores indicating more severe organ dysfunction; MV: mechanical ventilation. * P values were calculated using # Mann-Whitney U test, $ X^2 test.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000747

Introduction: Electrical impedance tomography (EIT) is a clinically established real-time imaging technique for bedside monitoring of regional ventilation (V) of the lung (1). In addition, EIT allows measurement of regional pulmonary perfusion (Q) (1). Therefore, the determination of regional V/Q ratios using EIT is possible (2). However, validation against a reference procedure is necessary for routine clinical application.

Objectives: To validate EIT-based regional V/Q imaging using single-photon emission computed tomography (SPECT) in a porcine model.

Methods: After approval by the local animal ethics committee (5.8.18–15,771/2017, Uppsala, Sweden), V and Q defects were generated by segmental bronchial and pulmonary arterial balloon blockade, respectively, in 7 anesthetized, ventilated pigs. Regional V and Q measurements were obtained by EIT (Pulmoviata 500) after electrolyte bolus injection (10 ml NaCl 1molar) (3) and SPECT (V: 81mKr gas; Q: 99mTc-MA albumin) (4). We analyzed the similarity of V and Q images (pixel-wise linear image correlation, r) and the regional (3 × 3 regions) agreement (Bland–Altman analysis: correlation coefficient r, limits of agreement LoA) of the quantitative V,Q and V/Q signals between SPECT and EIT, and between SPECT and calibrated EIT (cEIT) after compensation of local EIT imaging errors using pixel-wise backward regression.

Results: Fig. 1 shows example images with detectable V and Q defects, and their effects on the regional V/Q ratio. Image agreement between EIT and SPECT was strong (r = 0.77) for V and moderate r = 0.62) for Q and was significantly improved by calibration of EIT (V: strong, r = 0.89; Q: very strong, r = 0.93). EIT calibration also significantly improved the agreement of regional quantitative analyses of V, Q, and V/Q signals (data as r/LoA. EIT vs SPECT: V: 0.83/9.1%, Q: 0.76/15.4%, V/Q: 0.50/0.87 logV/Q; cEIT vs SPECT: V 0.92/6.0%, Q: 0.95/6.1%, V/Q: 0.85/0.50 logV/Q).

Conclusions: The regional V and Q imaging by means of EIT exhibits small regional aberrations. These are amplified during the pixel-wise division of the individual V and Q signals, which causes a bias of the regional V/Q image. Calibration of the EIT-based V and Q images significantly improves the agreement of the quantitative regional V/Q analysis. While the qualitative detection of V and Q defects, as well as their effects on the regional V/Q, is possible by EIT, the quantitative regional V/Q analysis requires calibration of EIT.

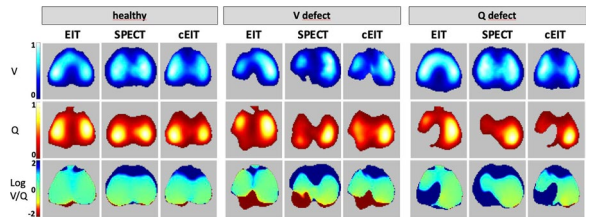

Fig. 1 (abstract 000747) Visualization of regional ventilation and perfusion defects using electrical impedance tomography (EIT), single-photon emission computed tomography (SPECT), and calibrated ETI (cEIT). Top row: relative regional ventilation (V); middle row: relative regional perfusion (Q); bottom row: weighted regional V/Q ratio, logarithmic color scale: Zero corresponds to a V/Q of 1:1, 2 corresponds to V/Q = 100:1 (dead space), -2 corresponds to V/Q = 1:100 (shunt)

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000748

Introduction: COVID-19-associated pulmonary aspergillosis (CAPA) is a new disease where Aspergillus infects COVID-19 patients in critical

states with ARDS and mechanical ventilation. CAPA raises mortality rates, posing a severe threat to affected individuals. Our study examines CAPA incidence, contributing factors, and potential impact on prognosis in patients admitted to all Spanish hospitals during the first three pandemic waves. We aimed to identify risk factors that predict mortality, disease severity, and ICU admission.

Methods: We analyzed data from the Spanish National Health System's Hospital Discharge Records Database (NHSHDRD) of all COVID-19 patients admitted in 2020. We collected data on patients with pulmonary aspergillosis as a secondary infection using ICD-10-CM. Multivariate logistic regression analysis was conducted to design predictive models for CAPA development in COVID-19 hospitalized patients and to identify the main factors related to severity and mortality in this patient subgroup.

Results: Out of 252,114 patients, 0.27% developed Aspergillus superinfection, with the majority being male (73.8%) and over 60 years old (78.2%). Mortality was notably higher in patients admitted to the ICU (61.8%) than those who were not (34.5%) ($p < 0.0001$), with an overall mortality rate of 53.3%.

Multivariate logistic regression analysis identified these risk factors for CAPA development: ICU admission (OR 3.857; 95% CI 2.87–5.18), leukemia (OR 5.86; 95% CI 3.86–8.921), lymphoma (OR 2.781; 95% CI 1.495–5.176), multiple myeloma (OR 4.465; 95% CI 2.212–9.02), COPD (OR 2.28; 95% CI 1.846–2.819), transplantation (OR 2.294; 95% CI 1.29–4.07), sepsis (OR 2.144; 95% CI 1.771–2.596), asthma (OR 1.88; 95% CI 1.407–2.534), ARDS (OR 1.894; 95% CI 1.582–2.268), mechanical ventilation (OR 5.91; 95% CI 4.385–7.973), age (OR 1.177; 95% CI 1.10–1.25), and sex (OR 1.374; 95% CI 1.147–1.646); all significant at $p < 0.0001$. Logistic model predicts CAPA development with an AUROC of 0.903.

Additionally, logistic regression analysis identified several predictors of hospital mortality: Aspergillus infection (OR 1.913; 95% CI 1.592–2.299), age (OR 2.506; 95% CI 2.477–2.535), sex (OR 1.4; 95% CI 1.365–1.435), admission to the ICU (OR 2.2; 95% CI 2.085–2.331), mechanical ventilation (OR 2.62; 95% CI 2.46–2.79), ARDS (OR 2.436; 95% CI 2.32–2.56), sepsis (OR 4.748; 95% CI 4.469–5.045), leukemia (OR 1.454; 95% CI 1.298–1.628), lymphoma (OR 1.692; 95% CI 1.484–1.928), multiple myeloma (OR 1.958; 95% CI 1.633–2.347), and transplantation (OR 2.273; 95% CI 1.99–2.596), all significant at $p < 0.0001$ Logistic model predicts CAPA mortality with an AUROC of 0.835.

	Aspergillus (N = 675)	No Aspergillus (N = 251,439)	P-value
ICU Admission	466 (69%)	22,491 (8.9%)	$p < 0.0001$
Mechanical Ventilation	449 (66.5%)	15,211 (6%)	$p < 0.0001$
COPD	117 (17.3%)	19,090 (7.6%)	$p < 0.0001$
ARDS	261 (38.7%)	11,682 (4.6%)	$p < 0.0001$
Sepsis	174 (25.8%)	6,227 (2.5%)	$p < 0.0001$
Leukemia	26 (3.9%)	1,786 (0.7%)	$p < 0.0001$
Lymphoma	11 (1.6%)	1,490 (0.6%)	$p < 0.0001$
Multiple Mieloma	9 (1.3%)	687 (0.3%)	$p < 0.0001$
Asma	52 (7.7%)	13,274 (4.3%)	$p = 0.005$

Conclusions: Based on the Spanish NHSHDRD data, the incidence of CAPA among hospitalized patients was low. Our study highlights the significantly elevated risks of mortality, ICU admission, and mechanical ventilation in this patient cohort. We identified several independent risk factors for the development of CAPA and hospital mortality, including age, gender, mechanical ventilation, sepsis, ARDS, leukemia, lymphoma, multiple myeloma, and transplantation. Our findings provide a valuable predictive tool for predicting the emergence of CAPA and unfavorable clinical outcomes in this particular group of patients.

Introduction: After critically ill patient was extubated, there was a rate of reintubation of 20% within 48 h due to hypoxemia being the primary cause. The use of high-flow nasal cannula (HFNC) is a widely used alternative to prevent intubation, and may result in delayed reintubation. The ROX index (ratio of SpO2/FiO2 to breathing frequency) has been validated to predict HFNC success in subjects with hypoxemic respiratory failure. However, this index has not been testing in postextubation patients, may be useful to reduce the chance of unnecessary reintubation or delayed reintubation.

Objectives: Validate test performance of ROX Index and the cut-off value to predict successful extubation in high-risk extubation failure patients treated with HFNC.

Methods: Prospective observational cohort study was conducted from Jan 1, 2022-Jan 1, 2023, with high-risk postextubation patients in medical ICU. The performance of ROX index in predicting successful extubation was evaluated.

Results: 68 subjects were included: 57 in success extubation group and 11 in reintubation group, age 74.5 ± 11.8 years. ROX index at 2 h > 9.9, at 6 h > 10.3 and at 12 h > 10.5 predict successful extubation, with sensitivity 89.7%, 93.1%, and 100%, specificity 54.6%, 72.7%, and 72.7%, area under the ROC values of 0.79, 0.90 and 0.87, respectively.

Conclusions: ROX index has a good diagnosis accuracy. The cut-point values of ROX index in this study presented a good performance to predicts success extubation in the high-risk postextubation failure patients.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000751

Introduction: Determining if a neuro-critically ill patient is suffering cerebral tissue hypoxia-mediated secondary brain injury is imperative to guiding their clinical care. However, cerebral tissue hypoxia may arise due to a multitude of pathophysiologic factors that manifest as impairments in convective and/or diffusive cerebral oxygen delivery but are as of yet detectable at the bedside.
Objectives: We aimed to determine the utility of blood-based biomarkers of brain injury as a method to detect impairments in the diffusion of oxygen from the cerebral vasculature into the brain (i.e. O2 diffusion).
Methods: Radial artery and internal jugular vein blood gas and brain injury biomarker analyses were performed in 12 healthy controls and 14 comatose patients with a hypoxic-ischemic brain injury (HIBI) following cardiac arrest. We measured cerebral blood flow (controls & HIBI patients) and brain tissue oxygen tension (PbtO2; HIBI only) prior to, and during, a ~ 10 mmHg reduction in arterial carbon dioxide tension (i.e., hypocapnia). The functionality of O2 diffusion was defined as the slope of the relationship between the hypocapnia induced change in cerebral oxygen extraction fraction (O2EF) and cerebral blood flow (ΔO2EF% · ΔmL-1 · min-1). The mean ± standard deviation for O2 diffusion in the controls was used to calculate O2 diffusion Z-scores for controls and patients. A Z-score > 1.65, indicating an O2 diffusion that would be worse than 95% of a control population, was considered impaired O2 diffusion.
Results: O2 diffusion was impaired in HIBI patients with cerebral tissue hypoxia (PbtO2 < 20 mmHg; -0.19 [− 0.26 – − 0.11] % · mL-1 · min-1; P = 0.01), but not patients without cerebral tissue hypoxia (PbtO2 > 20 mmHg; − 0.57 [− 1.40 – − 0.36] % · mL-1 · min-1; P = 0.99) when compared to controls (− 0.60 [− 0.75 – − 0.39] % · mL-1 · min-1). The serum concentration of Neurofilament-light predicted impairments in O2 diffusion (Z-score > 1.65) in HIBI patients with a sensitivity of 75% and specificity of 100% (receiver operator curve characteristic analysis area under the curve = 0.92; P = 0.001).
Conclusions: Blood-based biomarkers of brain injury hold promise as a tool for the bedside diagnosis of impairments in the diffusion of oxygen from the cerebral vasculature into the brain. This may help inform patient care and help guide the implementation of treatments that aim to avoid cerebral tissue hypoxia.

Characteristics and outcomes of patients with Guillain–Barre Syndrome admitted to the ICU: a retrospective observational study

S. AlQahtani[1], H. Arishi[1], A. Peeran[2], HM. Al-Dorzi[1], F. Alenezi[1], J. Jose[3], M. Sadat[1], F. Bin Humaid[1], Y. Arabi[1]
[1]Intensive Care Department, King Saud bin Abdulaziz University for Health Sciences (KSAU-HS), Riyadh, Saudi Arabia; [2]Neurology Department, King Saud bin Abdulaziz University for Health Sciences (KSAU-HS), Riyadh, Saudi Arabia; [3]Department of Bioinformatics and Biostatistics, King Abdullah International Medical Research Center (KAIMRC), Riyadh, Saudi Arabia.
Correspondence: S. AlQahtani
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000753

Introduction: It is estimated that 30% of patients with Guillain–Barre Syndrome (GBS) require intensive care unit (ICU) admission and mechanical ventilation (MV) secondary to acute respiratory failure. The higher tendency toward more complication and longer hospital stay have been reported with fair functional recovery.
Objectives: To evaluate the clinical characteristics and outcomes of patients with GBS admitted to ICU.
Methods: A retrospective observational study of all adult patients with GBS who required ICU admission in a tertiary care hospital in Riyadh, Saudi Arabia from Jan 1999 to Dec 2020. Patients were divided into two groups according to MV requirements. We reported the functional status at maximum follow-up using GBS disability score (Hughes' scale).
Results: During the study period, 43 patients with GBS were admitted to the ICU. Their median age was 44 years (Q1, Q3: 37, 63), 23 patients (53.5%) were males and 26 (60%) had a history of chronic diseases. Sessional variations were observed with 24 (55.8%) admission during the colder season (Oct-Feb) with no significant difference in outcomes. The most common cause for ICU admission was acute respiratory failure (bulbar dysfunction in 12 patients [27.9%], respiratory distress with hypoxia in 12 [27.9%], and inability to clear airways in 6 [14%]). Most patients (n = 27, 62.8%) received MV for a median duration of 13 days (Q1, Q3: 11, 17). These patients had a significantly lower baseline muscle strength (median medical research council sum score of 18 [Q1, Q3: 2, 36] vs. 36 [Q1, Q3: 28.5, 42] in the non-MV group; P = 0.0043). The MV group had longer median stay in ICU (26 days [Q1, Q3: 22, 42] vs. 6 days [Q1, Q3: 3, 6], P = 0.0001] and hospital (120 days [Q1, Q3: 70, 174] vs. 39 days [Q1, Q3: 11, 91.5], P = 0.0007]. MV patients had more complications during ICU and hospital stay (deep vein thrombosis in 2 [4.7%] patients, pulmonary embolism in 2 [4.7%], gastrointestinal bleeding in 2 [4.7%], bacteremia in 5 [11.6%], bedsore in 1 [2.3%], and side effects related to intravenous immunoglobulin in 4 [9.4%] vs. none in the non-MV group for all these complications. Most patients (n = 22, 81.5%) in the MV group had tracheostomy. For all patients, the best Hughes' scale score was zero with full recovery in 11 patients (25.5%), 1–3 in 18 (41.8%), 4–5 in 12 (27.9%), and 6 in 2 (4.6%) who died in the hospital. The median Hughes' scale score was higher in the MV group (3 [Q1, Q3: 3, 5] vs. 0.5 [Q1, Q3: 0, 3], P = 0.0005).
Conclusions: In patients with GBS who were admitted to ICU, higher rates of complications, longer stay, and worse functional recovery were observed among those who received MV. Further research is needed to address this population.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000754

Introduction: Magnesium perfusion is recommended in obstetric emergencies, such as eclampsia and HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet count). Although magnesium high doses are generally safe [1], unrecognized accumulation, due to acute kidney injury (AKI), may cause significant morbidity and even death.
Methods: We present a case report of a patient with HELLP syndrome complicated by AKI. Informed consent was obtained.
Results: A 32-year-old pregnant woman was admitted to the hospital in the 32nd gestational week due to a high fetal cardiac rate and uterine growth restriction. In the next few days, she developed severe HELLP syndrome and preeclampsia. AKI was also noted. An urgent cesarean section was performed. She was started on magnesium sulfate (4 g bolus followed by perfusion 2gr/h). Sixteen hours later, she developed progressive weakness, slurred speech, and tongue paresis, along with visual disturbances and bradycardia. Magnesium toxicity was suspected and perfusion stopped. (Table 1) Complete neurologic recovery was noted. Nifedipine was started for blood pressure control.
HELLP syndrome develops in 0.5–0.9% of all pregnancies. It is complicated with AKI in 36–50%. Admission to Intensive Care is strongly recommended due to the maternal and fetal high risk of death (11.5% and 26–48.2%, respectively) [2].
Clinical signs of magnesium toxicity, including loss of deep tendon reflexes and progressive weakness, including the diaphragm and respiratory muscles, along with hypotension and complete heart block should foster immediate discontinuation of magnesium.
Conclusions: AKI is a common complication of HELLP syndrome, and poses a high risk for toxicity when high magnesium doses are administered. Clinical awareness is crucial to ensure patient safety.

Table 1 (abstract 000755) Blood analytical results, along the first days of internship compared to the day of birth (D0) and last previous results (D -22)

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000756

Introduction: Acute cholangitis is an acute inflammatory disease of the bile duct that occurs when biliary obstruction results in cholestasis and biliary infection. Several studies have investigated predictors of acute cholangitis severity, suggesting procalcitonin, presepsin, and the delta neutrophil index (DNI) as prognostic markers. However, their high cost or dependence on specific analyzers prevents their wide availability. The neutrophil–lymphocyte ratio (NLR) is reportedly predictive of adverse outcomes in acute pancreatobiliary diseases. The NLR is predictive of disease severity, septic shock, organ failure, or ICU admission in acute pancreatitis and cholecystitis. We evaluated the utility of the NLR for predicting the severity of acute cholangitis.
Objectives: We investigated the predictive value of the neutrophil-lymphocyte ratio (NLR) in acute cholangitis.
Methods: We retrospectively evaluated 178 patients with acute cholangitis who underwent biliary drainage. The severity of acute cholangitis was graded according to the Tokyo 2018 guideline. Patients were dichotomized according to the acute cholangitis severity in two groups, and blood culture positivity. The baseline NLR and white blood cell (WBC) count were compared between groups.

Results: The severity of acute cholangitis was graded as mild, moderate, or severe in 59 (33.1%), 89 (50%), and 30 (16.9%) patients, respectively. Positive blood culture (n = 62) was observed more frequently in severe acute cholangitis The NLR was significantly higher in patients with severe cholangitis and positive blood culture. The area under the curve (AUC) for the NLR and WBC, for severe acute cholangitis was 0.85 and 0.69 respectively. The AUC for the NLR and WBC for positive blood culture was 0.74 and 0.62, respectively; the NLR had greater power to predict disease severity and positive blood culture. The sequential NLR values from admission to 3 days after admission were significantly higher in patients with severe cholangitis.

.

Table (abstract 000756) Demographic and clinical characteristics of 178 patients diagnosed with acute cholangitis

	Mild-to-Moderate Acute Cholangitis (*n* = 150)	**Severe Acute Cholangitis (*n* = 28)**	***p*-Value**
Age, mean ± SD, years	74.8 ± 12.7	79.5 ± 10.95	0.038
Etiology of acute cholangitis			
Choledocholithiasis	132 (74.1%)	18 (10.1%)	0.789
Benign biliary stricture	8 (4.5%)	1 (0.6%)	0.401
Malignant biliary stricture	17 (9.5%)	2 (1.2%)	0.908
Biliary drainage method			< 0.001
ERCP	136 (76.4%)	16 (9%)	
PTBD	14 (7.9%)	12 (6.7%)	
Laboratory data			< 0.001
WBC count (/μL)	9.5	16.2	
NLR	8.15	24.84	

Conclusions: The ratio of neutrophils and lymphocytes is a reliable predictor in predicting adverse outcomes in patients with acute cholangitis. The high predictive value of PCT, as well as the high availability and low cost of clinical blood testing, make NLR a more promising test in clinical practice.

Can surgical prophylaxis influence the outcome of bilateral lung transplant recipients?

S. Congedi[1], M. Nardelli[1], C. Legnaro[1], B. Martina[1], G. Bertoldo[1], I. Paiusco[1], I. Fior[1], G. Gianino[1], N. Cacco[1], E. Pistollato[1], C. Simoni[1], C. Schiavolin[1], P. Navalesi[1], A. Boscolo Bozza[1]
[1]DIMED, University of Padua, Padova, Italy

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000758

Introduction: Postoperative infections (PI) are one of the most common causes of death after bilateral lung transplant (LT). Overall prevalence of Gram-negative (GN) pathogens is increasing annually (4.33/1000 recipient-days); the prevalence of multidrug-resistant (MDR) GN is around 30% after LT. PI in LT recipients due to GN MDR, are associated with an in-hospital mortality six times greater than recipients experiencing GN bacterial infections with no antimicrobial resistances. Long-term exposure to immunosuppression to prevent graft rejection has been recognized as the most relevant risk factor for increasing vulnerability to infections. However, the benefit of 'personalized' surgical prophylaxis in LT recipients pre-colonized by Gram-negative (GN) bacteria is still unclear.
Objectives: With this retrospective observational study, enrolling LT recipients pre-colonized by GN bacteria, we aimed to assess: *i)* the overall prevalence of MDR GN bacteria, over the whole bacterial isolates, within the first 30 days following bilateral LT; *ii)* the prevalence of infections and colonizations due to MDR GN bacteria; and *ii)* the impact on short- and mid-term outcomes of the exposure to 'standard' or 'targeted' surgical prophylaxis (according to in vitro susceptibility).
Methods: All consecutive bilateral LT recipients admitted to the Intensive Care Unit of the University Hospital of Padua (February 2016–2023) were retrospectively screened. Only patients with pre-existing GN bacterial isolations were enrolled and analyzed according to the antimicrobial surgical prophylaxis ('standard' vs. 'targeted' to preoperative colonizations).
Results: One hundred eighty-one LT recipients were screened, 46 were enrolled. Twenty-two (48%) participants received 'targeted' prophylaxis, while 24 (52%) were exposed to 'standard' prophylaxis. The overall prevalence of postoperative MDR GN bacteria isolation was 65% (30 patients), without differences between surgical prophylaxis (p-value 0.364). The most frequent MDR GN bacteria isolates were *Pseudomonas aeruginosa* and *Klebsiella pneumoniae* from respiratory samples. The prevalence of 30-day infection due to MDR GN bacteria was 50%. Of these recipients, 4 belonged to the 'standard' and 11 to the 'targeted' prophylaxis (p-value 0.027).
Conclusions: The administration of a 'targeted' prophylaxis in LT pre-colonized recipients does not prevent the occurrence of postoperative MDR GN bacteria and infections.

Procalcitonin to predict severity of acute cholangitis

J. Fuss[1], A. Voloboyeva[2], V. Polovyj[3]
[1]Department of surgery, Regional hospital of Pustomyty, Lviv, Ukraine, [2]Icu, Communal Municipal Clinical Hospital 8, L'viv, Ukraine, [3]General surgery, Bukovinian State Medical University, Chernivtsi, Ukraine
Correspondence: J. Fuss
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000759

Introduction: Acute cholangitis (AC) is a medical emergency and systemic condition due to biliary infection and obstruction with an associated high mortality rate [1,2].
Previously, the levels of leukocytosis and C-reactive protein (CRP) were assessed for predicting the severity of AC, but neither was found to be useful [1–5]. On the other hand, procalcitonin (PCT) was shown to increase in the first hours after systemic inflammation and peaked earlier than CRP did in the plasma [6].
Objectives: The aim of this study is to evaluate the potential use of PCT level in defining the severity of AC apart from the standard acute-phase reactants.
Methods: A total of 134 patients who were diagnosed with AC between Juny 2019 and March 2022 were included in the study. We examined the relationship between WBC count, erythrocyte sedimentation rates (ESR), PCT level, CRP level, USI findings, and the disease stage.
Results: 134 patients diagnosed with acute cholangitis were included in the study. 57 of them (42.5%) were male. The mean age of the patients was 58.93 ± 1.96 (min: 19; max: 94). When we classified the patients for the severity grades of acute cholangitis, 52 (38.8%) were allotted to grade 1, 37 (27.6%) to grade 2, and 45 (33.6%) to grade 3.
The laboratory values for PCT, white blood cell (WBC), C-reactive protein (CRP), the international normalised ratio (INR), and platelet, which were measured to determine the severity grade of acute cholangitis, are listed in Table 1.
Univariate analysis of demographical, physiological, and process parameters revealed values of age ($p < 0.001$), PCT ($p < 0.001$), CRP ($p < 0.001$), INR ($p = 0.001$), and platelet ($p = 0.012$) as the factors which affected clinical severity (Table 2).

Table 1 (abstract 000759) Laboratory median values of patients

Laboratory value	Median	Q1–Q3
PCT (ng/ml) 0.333 0.078–1.67	0.333	0.078–1.67
WBC (× 109 /L)	11.0	7.7–14.3
CRP (mg/L)	2.39	0.84–8.91
INR	1.07	1.02–1.14
Platelets (× 109 /L)	223	169–272

Table 2 (abstract 000759) Univariate analysis of factors affecting the severity of acute cholangitis and relationship between procalcitonin values and acute cholangitis severity levels

	Grade 1 median (Q1–Q3)	Grade 2 median (Q1–Q3)	Grade 3 median (Q1–Q3)	p
Gender				0.436
Male	16	12	29	
Female	36	25	16	
Age	49.50 (36–61.75)	72.00 (48–79)	72.50 (62.75–81)	< 0.001
PCT	0.104 (0.03–0.65)	0.353 (0.09–1.61)	1.466 (0.17–9.00)	< 0.001
WBC	10,550 (8342–13,100)	12,900 (8010–18720)	11,280 (6777–18,225)	0.338
CRP	1.06 (0.31–2.43)	1.87 (0.97–4.29)	9.07 (2.90–17.82)	< 0.001
INR	1.04 (1.00–1.09)	1.09 (1.04–1.16)	1.11 (1.05–1.21)	0.001

Conclusions: The higher the severity level of the patients, the higher the PCT levels in patients. We found a difference between the patients' PCT values and their severity grades of acute cholangitis. PCT can be used as an effective laboratory method in the severity assessment of acute cholangitis, yet we need additional studies, which would include a higher number of the patient population.

Evaluation of clinical management in suspected meningitis cases: a dual-center audit

A. J. Rezaee[1], B. Hardy[1], R. Desvignes[1], L. Hodgson[1]
[1]Department of Intensive Care Medicine, University Hospitals Sussex, Worthing, United Kingdom
Correspondence: A.J. Rezaee
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000760

Introduction: Meningitis is an infectious disease affecting the central nervous system, with potentially life-threatening consequences (1). Current evidence suggests that early diagnosis and initiation of appropriate antibiotics are crucial to improve patient outcomes (2). Dexamethasone has also demonstrated a benefit for patients infected with *Streptococcus pneumoniae* in particular (3). This study aims to assess the quality of clinical management in suspected meningitis cases across various intensive care units (ICUs) by evaluating the documentation of symptoms and signs, diagnostic workup, treatment, and patient outcomes.
Methods: We conducted a dual-center, retrospective audit of patients with suspected meningitis admitted to ICUs over a 5-year period (2017–2022) of patients with a diagnosis code including "meningitis" or "meningococcal sepsis". Important data points were collected: documented symptoms (headache, altered mental status, neck stiffness), signs (fever, rash, abnormal neurology), presence or absence of seizures, signs of shock (HR > 90, SBP < 100, Lac > 2.0), blood cultures sent and results, lumbar puncture (LP) sent and results, referral for intensive care review, administration and timing of antibiotics (Ceftriaxone), antivirals, steroids, survival, and length of stay (LOS).
Results: A total of 16 suspected meningitis cases (9 males: 7 females and an average age of 55.6 years) were identified across participating ICUs. Symptoms of meningitis including headache, altered mental status, and neck stiffness were documented in 15 (94%) of the cases. Signs including fever, rash, and abnormal neurology were documented in all (100%) of the cases. Intensive care review was conducted in 15 (94%) cases within 24 h of presentation. 14 (88%) patients were intubated either in the emergency department or on admission to ICU. Seizures were recorded in 8 (50%) of patients, and signs of shock were present in 9 (56%) patients. Lumbar punctures were performed in 14 (88%) patients, yielding positive results in 9 (56%) cases, of which 7 (44%) isolated *Streptococcus pneumoniae* and 2 (13%) isolated *Neisseria meningitidis*. Blood cultures were sent in all patients (100%), with 12 (75%) returning positive results. 11 (69%) of blood cultures grew *Streptococcus pneumoniae* and 1 (6%) grew *Neisseria meningitidis*. Ceftriaxone was administered in 15 (94%) patients. Additionally, 10 (63%) patients received antivirals and 11 (69%) patients received steroids. The survival rate was 75%, and the median LOS was 14.4 days.
Conclusions: The study revealed variability in the documentation of symptoms and signs, as well as the administration of specific treatments in suspected meningitis cases. Although most cases were managed according to established guidelines, there is room for improvement in some areas, such as the timely administration of antibiotics, antivirals, and steroids. These findings highlight the need for continued education and reinforcement of best practices in meningitis management.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000762

Introduction: Multidrug-resistant bacteria (MDR) are a major public health problem. Surveillance of microbiological isolates, both colonizations and infections, in Services such as Inte40635_2023_546nsive Care Units (ICU) are crucial for controlling the spread of these bacteria, as well as for choosing empirical antibiotic treatment.
Objectives: To analyze the microbiological isolates of MDR taken in our ICU during the years 2021–2022 and their temporal distribution.
Methods: A retrospective descriptive observational study of MDR isolates from January 1, 2021 to January 29, 2022 from patients admitted to our ICU. It is a multipurpose 12-bed ICU expanded to 24 beds during the pandemic period. Oropharingeal and rectal exudate samples are collected and the isolates are therefore due to infection as well as MDR colonization.
Results: During the study period we had a total of 892 MDR isolates, 648 (72.64%) in 2021 and 244 (27.35%) in 2022.
Regarding the annual isolates ordered by frequency: in 2021: an outbreak of *Acinetobacter baumanii* (AB) only sensitive to tigecycline appears at the beginning of the year with a total of 374 positive samples (41.92%), between the months of January to May, after which we did not obtain any positive isolates for this MDR again. The second bacterium was *multiresistant Pseudomonas* (MR-P) with 134 isolates (20.67%) followed by *Klebsiella pneumoniae ESBL* (KP-ESBL) with 67 isolates (10.33%). *Enterobacteriaceae with carbapenemase*(EBC) we obtained 41 (6.32%), *methicillin-resistant Staphylococcus auseus* (MRSA)31 (4.78%), and *vancomycin-resistant Enterococcus* (VRE) 1 (0.15%). In 2022 we obtained by frequency: MRSA with 113 isolates (46.31%) followed by MR-P with 57 (23.36%), KP-ESBL 49 (20.08%), EBC 25 (8.19%) and VRE 0.
Regarding the temporal distribution of the isolates: a very clear AB outbreak appears at the beginning of 2021. MR-P has a more constant distribution during 2021 and more intermittent in 2022. KP-ESBL has grouped its isolates into two–three months in both years. MRSA in 2021 presents almost all its cases at the beginning of the year while in 2022 it is more constant throughout the year. EBC has a clear peak in the months of July–August in both years.
Conclusions: The most frequent MDR in our ICU were: AB (41.92%), MR-P (21.41%), MRSA (16.14%) and KPB (13%). Despite the fact that AB isolates account for 41.92% of the total, after the eradication of the outbreak this MDR was not isolated again.
BMR isolates (except AB, which was an outbreak) change over the years. Bacteria such as MR-P and MRSA have a more continuous distribution while others such as KP-ESBL and EBC have grouped most of their isolates for 2–3 months of the year.

VRE are the least isolated MDR in our ICU, accounting for 0.11% of the total.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000763

Introduction: Septic cardiomyopathy (SCM) is a frequently encountered entity in the course of a septic shock episode. Current guidelines recommend against the use of levosimendan for themanagement of septic patients with SCM. Moreover, there are no evidenced based recommendations for the management of cardiogenic shock due to SCM.
Objectives: To evaluate the efficacy of levosimendan administration in the management of septic patients with SCM and cardiogenic shock.
Methods: Observational study of patients admitted in the Intensive Care Unit (ICU) of the University Hospital of Larissa, presenting cardiogenic shock due to severe SCM. Patients were included if they presented severely reduced left ventricular ejection fraction (LVEF < 30%) and signs of circulatory failure (lactate > 2 mmol/lt, ScvO2 < 70%).
Results: Twenty three patients were included in the study. The median age was 61 (30, 84) years and 14 (61%) were male. The median time for SCM establishment (from the last known cardiac function level) was 7.5 (2, 56). All patients presented sepsis induced cardiogenic shock as depicted by a depressed EF [median EF 15% (5, 30)], ScvO2 [median 62% (38, 74)], and increased Pa-vO2 [median 10.8 (1, 15) mmHg] and lactate [median 4.4 (2, 18) mmol/lt]. The median troponin levels were 0.38 (0.01, 10) ng/ml. All the patients received noradrenaline and vasopressin.
Fourteen patients (61%) were treated with levosimendan, and the rest received dobutamine (n = 2) or only noradrenaline. Patients in the levosimendan group were more severely ill compared to the other treatment group [APACHE II: 27 (14, 37) vs 14 (13, 28), respectively, p = 0.012] and there was a trend for more decompensated LV function depicted by the LVEF [15 (10, 20) vs 20 (15, 25), respectively, p = 0.061] and the Pa-vCO2 [12 (10, 15) vs 9 (5, 14), p = 0.069], one of the indices indicating more severe circulatory failure. Concerning the response to the treatment administered, patients in the levosimendan group presented significantly higher increase in LVEF after five days [250% (− 25, 350) vs 0 (− 25, 100), p = 0.02], and significant decreases in lactate clearance during the first 12 [− 34.5% (− 50, 3) vs 2.2% (− 100, 31), p = 0.014] and 24 h [− 48% (− 10, − 78) vs 28% (− 48, 71), p = 0.05] (Table 2). Concerning the ScvO2 values there was a significant decrease in the levosimendan group across the first 72 h [p = 0.002 (ANOVA)], while in the other treatment group the change did not reach statistical significance (p = 0.063).
In nine patients in the levosimendan group (64.3%), SCM was resolved vs 2 (22.2%) in the other treatment group (p = 0.054). ICU survival was higher in the first group (50% vs 22.2%) although it did not reach statistical significance (p = 0.172).
In Cox Regression analysis, the confounders affecting survival were the ejection fraction that the patients presented during the episode of septic cardiomyopathy [HR 0.887 (95% CI 0.790 to 0.996), p = 0.042]. On the contrary, the APACHE II score was not identified as a predictor.
Conclusions: Levosimendan can reverse the adverse signs of circulatory failure in patients with circulatory failure due to cardiogenic shock in the course of a septic episode, while it results in higher likelihood of improvement in the left ventricular function.

Introduction: Enhanced oxidative stress and inflammation are the main pathophysiologic explanations for the relationship between hyperoxemia and ventilator-associated pneumonia (VAP), suggested by a retrospective clinical study [1].
Objectives: The primary objective of this study was to assess the impact of hyperoxemia at ICU admission on VAP occurrence.
Methods: This prospective observational cohort study was conducted in a 50-bed mixed ICU during a four-year period. All adult patients requiring > 48 h of invasive mechanical ventilation were included. Inclusions were discontinued for almost a year due to COVID-19 pandemic. Hyperoxemia at ICU admission was defined as a percentage of time ≥ third quartile spent with peripheral capillary oxygen saturation (SpO2) ≥ 98% during the first 24 h. SpO2 was continuously collected with non-invasive infrared sensor during the whole period of mechanical ventilation. VAP was defined using clinical, radiologic and quantitative microbiological data. The cumulative incidence of VAP according to the presence of hyperoxemia was estimated using the Kaplan–Meier method. The association of hyperoxemia with the probability of VAP event was assessed using Cox's proportional hazard model.
Results: Among the 534 patients included in the analysis, 289 (54,1%) had hyperoxemia at ICU admission. One hundred and twelve (21%) developed at least one VAP episode including 68 (23,5%) in the « hyperoxemia group» versus 44 (18%) in the group without hyperoxemia. Hyperoxemia was significantly associated with VAP occurrence (adjusted HR 1.53 [95%IC 1.03–2,26]) (Figure). VAP episodes were mainly related to Gram-negative bacilli, 27% were polymicrobial and 19.6% related to multidrug resistant bacteria.
Conclusions: Hyperoxemia is significantly associated with increased risk for VAP.

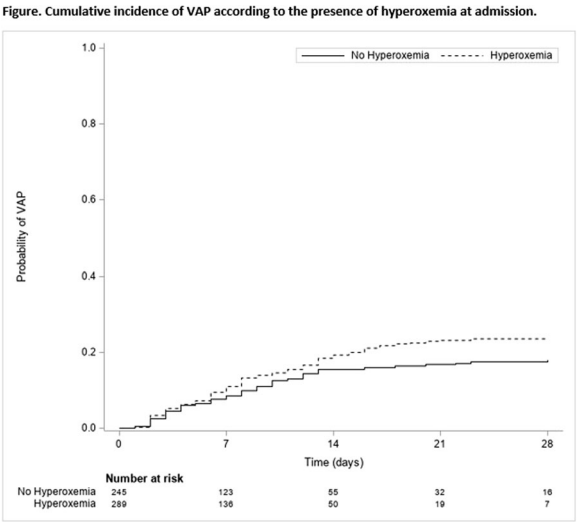

Figure (abstract 000764) Cumulative incidence of VAP according to the presence of hyperoxemia at admission
Abbreviation: VAP = ventilator-associated pneumonia

Predicting the need for intubation using ROX index in patients with COVID-19 pneumonia requiring long-term High-flow nasal cannula oxygenation

R. Son[1], K. Shigemitsu[1], A. Tsuruoka[1], H. Rinka[1]
[1]Department of Emergency and Critical Care Medical Center, Osaka City General Hospital, Osaka, Japan
Correspondence: R. Son
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000767

Introduction: High-flow nasal cannula oxygenation (HFNC) is a useful non-invasive respiratory support that may reduce the need for invasive mechanical ventilation (IMV) [1]. However, COVID-19 pneumonia may delay intubation because of the long duration of the illness and unawareness of severe hypoxemia [2, 3]. Although some recommend early intubation, the course of hypoxia-induced lung injury in COVID-19 varies [4]. Some patients recover after the inflammatory stage, while others require IMV after acute exacerbation [5]. The need for intubation has been predicted using the ROX index, a fraction of oxygen saturation, FiO2, and respiratory rate, during early HFNC in patients with COVID-19 pneumonia [6, 7, 8]. However, there are no reports of ROX index use in patients requiring long-term HFNC.
Objectives: To evaluate the efficacy of ROX index for predicting intubation need in patients with COVID-19 pneumonia-induced respiratory failure requiring long-term HFNC.
Methods: This single-centre retrospective study included patients with COVID-19 pneumonia requiring HFNC, who were admitted to our hospital from September 2020 to April 2022. Patients who received at least 48 h of HFNC were selected. The patients were divided into two groups: those weaned from HFNC (success group) and those that required intubation (failure group). ROX index was evaluated 2, 6, 12, 24, 36, 48, 60, and 72 h after HFNC initiation. The prediction accuracy of the ROX index for intubation was evaluated using the ROC curve and quantified using AUROC.
Results: The study included 120 patients. Among them, 75 patients received HFNC for ≥ 48 h (61 [81%] and 14 [19%] in the success and failure groups, respectively). The median duration of HFNC was 119 and 57 h in the success (time-to-weaning) and failure (time-to-intubation) groups, respectively (p = 0.01). No significant difference in gender (male: 77 vs 86%, p = 0.72), BMI (median: 26 vs 25 kg/m2, p = 0.74), smokers (43 vs 64%, p = 0.23). The respiratory status before HFNC initiation tended to be slightly worse in the failure group than in the success group: RR (24 vs 26 / min, p = 0.81), SpO2 (92 vs 90%, p = 0.02), and O2 (8 vs 9 L/min, p = 0.04). ROX indexes were similar in both groups from 2 to 24 h after HFNC initiation; however, they were significantly lower in the failure group than in the success group from 36 to 72 h. The ROX index since 36 h after HFNC initiation was a useful predictor of HFNC failure (AUROC: 0.82–0.89) (Table 1). ROX index ≤ 7.1 accurately predicted intubation 48 h after HFNC initiation.
Conclusions: Some patients with COVID-19 pneumonia required intubation on deterioration of respiratory condition soon after HFNC initiation. Patients whose condition was stable at first but worsened after 36 h also required intubation. Long-term monitoring of ROX index in patients with COVID-19 pneumonia requiring HFNC could help predict the need for and avoid delays in intubation.

Hours since HFNC (h)	Success (n=61) Median [IQR]	Failure (n=14) Median [IQR]	AUROC [95%CI]	p-value
2	7.7 [6.1, 8.7]	6.9 [6.4, 7.9]	0.57 [0.41 - 0.73]	0.869
6	7.6 [6.6, 9.2]	7.3 [6.7, 8.5]	0.52 [0.37 - 0.68]	0.862
12	7.6 [7.0, 9.6]	7.4 [5.8, 8.4]	0.62 [0.45 - 0.78]	0.131
24	7.8 [6.5, 9.6]	6.6 [5.9, 7.8]	0.66 [0.49 - 0.82]	0.089
36	8.3 [6.8, 10.1]	6.1 [5.8, 7.0]	0.82 [0.70 - 0.93]	<0.001

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000768

Introduction: Septic shock remains a leading cause of mortality in intensive care units (ICU), with mortality rates ranging between 30–40%.

Despite advances in understanding and management, some patients progress to refractory septic shock with a mortality rate exceeding 90%. Hemoadsorption therapies have emerged as an additional tool to restore immune homeostasis and target cytokine neutralization.
Objectives: To evaluate the effectiveness of hemoadsorptive therapy in treating refractory septic shock in a non-concurrent cohort of patients, building on current knowledge and experience in the clinical setting.
Methods: A non-concurrent review of patients admitted to the ICU with refractory septic shock who received hemoadsorptive therapy over five years was conducted. Clinical variables, including age, gender, APACHE II and SOFA scores, vasopressor requirements, and laboratory parameters, as well as in-hospital mortality and mortality at 30 and 90 days, were analyzed. Descriptive statistics were calculated, and pre- and post-therapy variables were compared using the Mann–Whitney test.
Results: The median age of the cohort was 65.5 years, with a male-to-female ratio of 0.43. Hemoadsorptive therapy was associated with a reduction in vasopressor requirements, with a median initial noradrenaline requirement of 0.7 mcg/kg/min (IQR 0.45–0.8875) decreasing to 0.12 mcg/kg/min (IQR 0–0.225) post-therapy. Median APACHE II scores pre- and post-therapy were 30.5 and 20.5, respectively, while SOFA scores were 13.5 and 11.5, without statistical significance. Median lactate levels decreased by 62%, from 7.86 mmol/l pre-therapy to 2.97 mmol/l post-therapy. Inflammatory parameters, such as C-reactive protein, decreased from 206 mg/dL to 180 mg/dL, and procalcitonin decreased from 58 to 8.91. In-hospital mortality was 0.57, increasing to an index of 0.64 at 90 days of follow-up.
Conclusions: Hemoadsorptive therapy demonstrated encouraging efficacy in the management of refractory septic shock in our non-concurrent cohort of 14 patients. A significant decrease in vasopressor requirements, lactate levels, and inflammatory parameters was observed, although changes in APACHE II and SOFA scores were not statistically significant. These promising results warrant further investigation through larger cohort studies to evaluate the impact of hemoadsorptive therapy on long-term mortality and to explore its potential role as a standard treatment option for refractory septic shock.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000769

Introduction: Ventilator associated lower respiratory tract infections (VA-LRTI) are among the most common infectious complications occurring in the intensive care unit (ICU) (1). They include both ventilator-associated tracheobronchitis (VAT) and ventilator-associated pneumonia (VAP). Immunocompromised patients account for a growing proportion of critically ill patients. Using the TAVEM database, we have recently shown that immunocompromised patients had a lower incidence of VA-LTRI when compared to non-immunocompromised patients (2), but the influence of immunosuppression (IS) type on VA-LRTI has not yet been investigated.
Objectives: To determine whether immunosuppression of hematologic cause is a risk factor for developing a VA-LRTI in comparison to other types of immunosuppression.
Methods: We conducted a multicenter, retrospective cohort study to investigate whether the type of IS (hematologic malignancy or other type) had an impact on incidence, microbiology and outcome of VA-LRTI. We merged two multicenter databases, TAVEM (3) and COVAPID (4). Immunocompromised adults requiring mechanical ventilation for more than 48 h were included and classified in two groups: hematologic malignancies and others.
Clinical outcomes and occurrence of a VA-LRTI, VAP and VAT were collected. Patients were followed up until day 28 or ICU discharge if it occurred before. The association of the type of immunosuppression with 28-day cumulative incidence of VA-LRTI, VAP and VAT was assessed by fitting cause-specific Cox models with death and extubation alive as competing risks. Analysis were adjusted for center and pre-specified baseline confounders.
Results: 854 immunocompromised patients were included, among whom 162 had an hematologic malignancy. Mean age was 65 (56 to 74), with 57.6% of male patients. Mean SAPS II at baseline was 53.0 (41.0 to 66.0). Leading causes of ICU admission were pneumonia, respiratory failure, ARDS, sepsis and shock. Hematologic malignancies were associated with a lower 28-day cumulative incidence of VA-LRTI (13.6% versus 20.1% for other patients, cause-specific hazard ratio [cHR] 0.59, 95%CI 0.36 to 0.97, p = 0.035) (Figure 1).
VAT incidence did not vary between groups (Figure 2), but VAP tended to be less frequent in hematologic patients (9.3% versus 13.9% for other patients, cause-specific hazard ratio [cHR] 0.55, 95%CI 0.29 to 1.04,

p = 0.064) (Figure 3). Both extubation alive and ICU discharge alive were less frequent in hematological patients in both adjusted and non-adjusted analysis.

Conclusions: Hematologic patients had a lower 28-day cumulative incidence than other immunocompromised patients of VA-LRTI, mainly due to a lower VAP incidence. Hematologic patients had worse clinical outcomes.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000770

Introduction: Healthcare-associated infections (HCAIs) are the most common adverse event in hospitalized patients worldwide. Although the burden of HCAIs in high-income countries is widely known, limited data is available to assess the characteristics and outcomes of HCAIs in low and middle-income countries (LMICs). This study was part of the IMPACTO-MR, a Brazilian nationwide platform to assess infections and multidrug resistance in intensive care units.

Objectives: We aimed to assess the impact of HCAI on hospital length of stay (LOS) and mortality in critically ill patients from Brazil.

Methods: This observational prospective cohort study was nested in the IMPACTO-MR platform. We included all adult patients admitted to the 51 participating ICUs from September 2019, to December 2021. We collected baseline and demographic data at ICU admission, daily data on HCAIs (ventilator associated pneumonia – VAP, catheter-associated bloodstream infection – CABSI, catheter-related urinary tract infection – CAUTI), LOS and vital status at hospital discharge. HCAIs were defined based on Brazilian Health Regulatory Agency (ANVISA) criteria. A multi-state model adjusted for age, SAPS 3 and admission type and considering the exposure to HCAIs risk as a time dependent variable was built to evaluate hospital LOS. A Cox Model adjusted for age, SAPS 3 and admission type was used to evaluate mortality.

Results: We included a total of 67,473 patients in this analysis. The infection densities were: 2.13 CABSI/1000/device-days, 1.5 CAUTI/1000/device-days, and 7.7 VAP/1000/device-days. Patients' characteristics are shown in the table below. Patients with HCAI were younger, had a higher proportion of males and clinical admission reason, higher SAPS 3 scores, and more COVID-19 diagnosis at ICU admission. The mean Hospital LOS was 17.4 days vs 41.7 days and Hospital Mortality was 24.8% vs. 57.6% in the no-HCAI vs HCAI groups, respectively. Our multi-state model showed an increase in Hospital LOS of 4.1 days (95% CI 3.2; 5.0, $p < 0.001$). HCAIs also increased the mortality risk, when compared to patients without HCAIs (HR 1.29, 95% CI 1.22; 1.36, $p < 0.001$).

	HCAI	
	No (n = 64,200)	**Yes (n = 3273)**
Age, y	61.1 ± 17.7	59.5 ± 16.7
Men, n (%)	33,841 (52.7%)	1971 (60.2%)
Admission type at first ICU admission, n (%)		
Clinical	38,288 (66.2%)	2638 (80.7%)
Elective Surgery	14,054 (24.3%)	232 (7.1%)
Emergency Surgery	5534 (9.6%)	398 (12.2%)
Charlson Comorbidity Index	1.4 ± 1.9	1.3 ± 1.9
Modified Frailty Index	1.4 ± 1.3	1.4 ± 1.3
SAPS 3	46.1 ± 16.6	57.8 ± 15.6
COVID-19 at ICU admission, n (%)	5967 (9.3%)	967 (29.5%)
HCAIs, n*	0	4068
CABSI, n (%)	0 (0%)	1133 (27.8%)
CAUTI, n (%)	0 (0%)	688 (16.9%)
VAP, n (%)	0 (0%)	2247 (55.3%)
Hospital LOS, d	17.4 ± 29.9	41.7 ± 32.7
Hospital Mortality	15,195 (24.8%)	1790 (57.6%)

* Each patient might have more than 1 distinct infection
SAPS 3: Simplified Acute Physiology Score 3

Conclusions: Our results show that HCAIs increase both hospital LOS and mortality. To our knowledge, this is the biggest study on this subject in LMICs, adding important and robust information to the literature on the burden of HCAIs. Also, the use of a multistate model evaluating LOS, showed that although HCAIs are associated with longer LOS, its magnitude is lower than previously published.

Introduction: Hypoxic ischemic brain injury (HIBI) following cardiac arrest is associated with poor outcomes. Elevations in arterial carbon dioxide tension (PaCO2), termed hypercapnia, may hold promise for mitigating secondary injury following HIBI by increasing cerebral blood flow (CBF) and oxygen delivery.
Objectives: We aimed to determine the effect of mild hypercapnia on CBF, brain oxygenation, cerebral arterio-venous differences (a-vDIFF) of blood-based brain biomarkers and cerebrovascular CO2 reactivity in humans with HIBI versus healthy controls.
Methods: Twenty HIBI patients and 14 healthy controls had radial artery and jugular venous bulb catheters placed to measure blood gases and collect blood specimens for the analysis of blood-based brain biomarkers. The a-vDIFF was determined from the arterial and jugular bulb blood samples, where a negative value indicates cerebral release. Jugular venous bulb oxygen saturation (SjvO2) was measured as an index of brain oxygenation (oximetry), while blood velocity through the middle cerebral artery (MCAv) was measured as an index of CBF (using transcranial Doppler ultrasound). Physiologic data and blood specimens were collected prior to and during mild hypercapnia (+ 10 mmHg PaCO2) in the HIBI patients (1 & 2 h of hypercapnia) and healthy controls (5 min of hypercapnia).
Results: In the HIBI patients, hypercapnia led to a modest (~ 5%) increase in MCAv from 38 [33–48] to 40 [35–52] cm/s ($P = 0.03$; 2 h timepoint); however, SjvO2 remained unchanged (76 [65 – 79] vs. 76 [65–83] %; $P = 0.73$). In the healthy controls, hypercapnia increased MCAv (78 [68–97] vs. 105 [87–128] cm/s; $P < 0.0001$) and SjvO2 (69 [65–72] vs. 80 [78–83] %; $P < 0.0001$). Comparing HIBI patients to controls, cerebrovascular reactivity to CO2 was markedly (~ 95%) lower in the HIBI patients (0.14 [− 0.01–0.70] vs. 2.97 [2.41–3.82] cm/s/mmHg; $P < 0.0001$). In the HIBI patients, the arterial concentrations and a-vDIFF of blood-based brain injury biomarkers glial fibrillary acidic protein (GFAP), neurofilament light (Nf-L), and Tau remained unchanged. In the healthy controls, arterial concentrations of blood-based brain injury biomarkers Nf-L and Tau remained unchanged, however GFAP increased (66 [56–84] vs. 83 [64–97] pg/mL; $P = 0.0003$). The a-vDIFF of blood-based brain injury biomarkers in the healthy controls remained unchanged with hypercapnia.
Conclusions: Mild hypercapnia in patients with HIBI led to a modest increase in MCAv but lower cerebrovascular CO2 reactivity than healthy controls. This impairment in cerebrovascular CO2 reactivity was associated with no improvement in SjvO2 during mild hypercapnia. Arterial concentrations and a-vDIFF of blood-based biomarkers of brain injury remained unchanged during hypercapnia.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000776

Introduction: The COVID-19 pandemic has had a significant impact on the care of neurocritical patients. Patients with neurocritical pathology are at high risk for morbidity and mortality, and the pandemic has further exacerbated the challenges of treating these patients.
Objectives: To analyze the impact of the COVID-19 pandemic on the admission and evolution of neurocritical patients.
Methods: Observational study of patients admitted emergently to a trauma and neurocritical care unit between January 2019 and December 2022. The cohort was compared by differentiating the different periods into pre and post-pandemic years. Admission, demographic, severity, evolution and outcomes of patients with subarachnoid hemorrhage (SAH), major trauma (MT); spontaneous intracerebral hemorrhage (SIH), acute ischemic stroke (AIS) were analyzed. Categorical variables are expressed as counts and percentages and were compared using the $\chi 2$ test and Fisher test; continuous variables are expressed as means and standard deviation and were compared ANOVA test, with Bonferroni test post hoc.
Results: There were a total of 2582 trauma and neurocritical admissions, of which 1505 were emergent: SAH (n = 219), MT (n = 590), SIH (n = 285), AIS (n = 411). During the same period, a total of 648 patients were admitted with critical illness due to COVID-19: 2019 (n = 0), 2020 (n = 292), 2021 (n = 324), 2022 (n = 32). 62.5% were men and the mean age was 59.3 ± 17.3 years old, with no statistical difference between the different periods. The temporal evolution of admissions is shown in Figure 1. There were no differences in ICU mortality in the whole cohort; however, during the pandemic ICU length of stay (LOS) progressively decreased (2019: 10.4 ± 12.2; 2020: 8.8 ± 13.8; 2021: 8.6 ± 12.1; 2022: 7.2 ± 10.7, days; p = 0.004). MT had a higher number of admissions in 2022 (post-pandemic) and a higher severity estimated by ISS (injury severity score) on admission during the pandemic period (2020, 2021), p = 0.046. AIS had a significant increase in the number of admissions in the post-pandemic period, with an increase in mortality during the pandemic period and a decrease in the post-pandemic period (2019: 17.4%; 2020: 21.7%; 2021: 20.6%; 2022: 7.6%; p = 0.009). The remaining results are summarized in Table 1.
Conclusions: The COVID 19 pandemic has been a major challenge for neurocritical care units. In our cohort, the number of emergent admissions has been maintained throughout the pandemic, with an increase in MT and IAS in the post-pandemic period. During the pandemic the LOS in ICU was lower and the mortality at ICU discharge did not present statistically significant differences.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000778

Introduction: Amidst the increasing awareness of the importance of EEG in hospitalised patients with alteredsensorium, most are done in the ICU. There are certain specified indications for doing EEG inICU and most organisations recommend doing a continuous EEG over 30 to 48 h (rarelylonger). However, in resource constrained settings, doing cEEG is labor intensive and resourceconsuming. We wanted to audit 100 patients who underwent rEEG in the year 2021–22 in atertiary care mixed ICU of Kolkata, India. This audit highlights the use and misuse of rEEG, towhat extent it could pick up seizures, and how pharmacological agents may affect EEG findings.
Methods: 21–23 lead EEG was done in patients with altered sensorium which was unexplained byavailable clinical factors as well as physicians gestalt. Each rEEG was done over 20 min andrepeated once more within 48 h if advised, but not on the same day.The rEEGs were interpreted by trained neurologists and reported. The age, comorbidities, neurological diagnosis, infections, antibiotics and anti epileptics were recorded along with theEEG findings.
Results: A statistical analysis was done of the collected data using Pearson Chi square test to find outany significant association between the EEG findings and other factors, viz. leukocytosis orleukopenia

hyponatremia or hypernatremia, calcium level, blood culture positivity, urine culturepositivity, sputum culture positivity, antibiotics, neuroimaging and renal failure.Analysis showed the majority of patients were subjected to rEEG because of altered mentalstatus 81% and 9% were done for jerky movements, blank stare or myoclonus. Of these 5% were done after cardiac arrest. Four predominant EEG findings were1. Encephalopathy 2. Seizure spikes 3. Triphasic waves, 4.Diffuse slowing.Imaging studies revealed 7 strokes, 2 TBI and 1 SOL.Leukocytosis was seen in 10 patients, leukopenia in 1, hyponatremia in 4, hypercalcemia in 1patient. Most common antibiotic was meropenem in 14 patients. Majority were male patients. 21% of patients were having seizure spikes in EEG. All of them were treated with AED. 7patients were treated with 2 or more AEDs. Most common EEG findings in these patients wereencephalopathy in 54%. Another 19% had diffuse slowing whereas 6% had triphasic waves. Chi square test could not show any correlation between seizures and renal failure or antibiotics (Mero/PolyB) or infections.

Conclusions: The increasing role of EEG in identifying patients with non-convulsive seizures is beingrecognised in various studies. A recent publication (4) has also questioned the need for cEEG in all ICU patients as compared to rEEG. Continuous EEG picked up more spikes on EEG whichqualified as seizure (more than 5 s) but did not change outcome or mortality whencompared to rEEG in the other group. The incidence of seizures picked up by rEEG in this study was comparable to our audit although two rEEGs were done in all patientson two consecutive days in this study. Our study found most patients were done for acute change in mental status. In resource limited settings, a rEEG done for 20 min also picked up 21% seizures of which 12% were nonconvulsive seizures. Unlike usual belief no correlation was found with sepsis, renal failure or electrolyte imbalance although the numbers were very few. It is also a common practice to assume carbapenems cause seizures and stop it in anypatient with mental status change. However, neither meropenem or Polymyxin or any other combination of these two drugs could show any correlation with incidence of seizures. The study was not followed for outcome or mortality hence the effect of rEEG on mortality was not assessed.

Needs and priorities in eHealth follow-up care from the perspectives of patients' relatives in the intensive care unit

E. Berger[1], P. Van Der Meer[1], M. Van Der Veer[1], M. Van Mol[1]
[1]Department of Intensive Care, Erasmus University Medical Center, Rotterdam, Netherlands

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000779

Introduction: For patients' relatives, intensive care unit (ICU) admission is known to be a stressful event [1]. As a result, they are at risk of developing post intensive care syndrome family (PICS-F) [2]. In addition to inpatient follow-up contact, eHealth innovations might be an easy, user-friendly and inexpensive method to self-monitor symptoms of PICS-F [3]. It is unknown which eHealth interventions in ICU follow-up care meet the best the needs of ICU patients' relatives to reduce PICS-F [4].

Objectives: To explore the needs and priorities in eHealth follow-up care from the perspectives of ICU patients' relatives.

Methods: A qualitative multicentre study in four ICUs including one academic medical centre and three general hospitals. One focus group interview was conducted in each participating hospital, and for each interview five to ten relatives were included. A priori, a semi-structured topic list was drafted and followed during the meetings. All interviews were audio-recorded and transcribed verbatim. Data were analysed by two researchers with a thematic approach.

Results: All participants involved in the first two focus groups were partners of former ICU patients (n = 10). Median [interquartile range] length of ICU stay of the patients was 24 [17–30] days. The focus group discussion yielded several key themes related to the experiences of patients' relatives. The first theme comprised physical and psychological symptoms experienced by participants including pain, exhaustion, anxiety, stress, insomnia, powerlessness and worrying about their relatives. The second theme that emerged from the discussions was the social dilemma. Participants expressed that the period after ICU discharge was experienced as arduous and restrictive due to concerns and fears of leaving their partner alone. This resulted in decreased social contacts and feelings of guilt, whether or not to do something for oneself. The third theme focused on facilitating recovery after ICU discharge. Participants shared several strategies that helped them cope with their experience, including talking about their ICU experience with their relatives, utilizing an ICU diary and photographs, visiting a general practitioner, going to an acupuncturist, and attending an ICU follow-up clinic. The importance of providing personalized information through a web portal, analogous to a diary, was also emphasized. Finally, participants expressed that sharing their experiences with peers during the focus group interview was helpful and provided a sense of support. The incorporation of peer support into an eHealth application, such as using stories or videos of peers, was suggested as a potential strategy to enhance support for individuals and their relatives following ICU discharge.

Conclusions: Preliminary data suggest that ICU patients' relatives have a need for information and support through an eHealth intervention to mitigate PICS-F and a social dilemma after discharge. A digital diary and peer support were suggeted to help to strengthen their coping mechanisms.

Introduction: Septic shock, characterized by a complex dysregulation of the immune system, is among the leading causes of death in the ICU. Despite advances in understanding the underlying pathomechanisms, there is still no specific treatment available. Therapeutic plasma exchange (TPE) represents an emerging adjunctive treatment option to restore an imbalanced immune homeostasis. A recent randomized-controlled trial revealed a rapid improvement in hemodynamics, probably due to the elimination of harmful mediators and replacement of protective plasma proteins.
Objectives: The goal of this study is to further describe the underlying immunomodulatory mechanisms and to predict treatment response based on potential biomarkers.
Methods: After obtaining written informed consent, 53 patients with early septic shock (< 24 h duration) who received norepinephrine (NE) at a rate of ≥ 0.4 µg/kg/min were randomized to receive either standard of care (SOC) or SOC + a single TPE. TPE was immediately initiated after randomization. Blood samples were drawn at randomization and 6 h after randomization. Levels of inflammatory mediators (IL-6, IL-8, TNF-α, IL-2Rα), acute phase proteins (CRP and pentraxin3 (PTX3)) and damage-associated molecular patterns (DAMPs) (cell-free DNA (cfDNA), HMGB1) were analyzed via multiplex analysis or ELISA.
Results: TPE caused a significant reduction in acute-phase protein levels (CRP $p = 0.0008$, PTX3 $p = 0.0008$) while no difference was observed in the SOC group. Serum levels of inflammatory cytokines TNF-α-, IL-6- und IL-8 were significantly reduced in both groups, though no significant difference was observed between groups except for IL-2Rα ($p = 0.02$). cfDNA und HMGB1 levels were significantly reduced in the TPE group compared to the SOC group ($p = 0.004$, $p = 0.03$). Treatment responders, defined as a decrease in NE dose of ≥ 50% 6 h post randomization, showed significantly decreased IL-8 and increased cfDNA levels compared to non-responders.
Conclusions: TPE is associated with the removal of inflammatory mediators such as acute-phase proteins and DAMPs that may explain the rapid hemodynamic improvement recently detected in septic shock patients. A dual biomarker approach (increased cfDNA levels in combination with decreased IL-8 levels) may predict treatment response.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000782

Introduction: Interleukin-6 (IL-6) is a molecule that has proinflammatory effects in sepsis, and which has been consistently associated with patient outcomes. Patients with extremely high levels of IL-6 have not been previously characterized.
Objectives: To describe the clinical and prognostic profile of a subgroup of patients with septic shock and extremely high hypercytokinemia.
Methods: Single-center, observational, retrospective. Inclusion criteria: septic shock, multiorgan dysfunction and extremely high levels of IL-6 who were activated by Sepsis Code in the period from September 2018 to December 2022. Sepsis-3 criteria were used for the diagnosis of sepsis. IL-6 (analysis performed through electrochemiluminescence immunoassay; Elecsys® IL-6, from ROCHE) in a peripheral blood sample was prospectively detected in the first 12 h of shock evolution. There is no agreed definition of extreme hypercytokinemia, so we have arbitrarily defined it as those IL-6 levels greater than 5,000 pg/mL. Demographic variables, severity (APACHE II), organic dysfunction (SOFA), mortality (ICU and hospital) have been collected. The data have been expressed as "n" (%) if they are categorical and as median (interquartile range) or mean (standard deviation) if they are quantitative and were compared using the Student's T test. Multivariate logistic regression was performed for hospital mortality. The study was approved by the Clinical Research Ethics Committee of our center (PR(AG)336/2016).
Results: During the described period, 74 patients met the inclusion criteria: 56.8% women, 64 (17) year-old, SOFA 11 (7), cardiovascular SOFA 4 (1), APACHE II 24 (12), baseline lactate 5.5 (4.2). Table 1 summarizes the characteristics of the included patients. The median IL-6 was 115,705 (251,261) pg/ml and was higher in patients who did not survive (480,406 vs 118,352 pg/ml, $p = 0.002$). IL-6 levels greater than 318,738 pg/ml are associated with mortality greater than 60% and a change in the trend is observed when IL-6 exceeds 186,167 pg/ml (Figure 1). In the multivariate analysis, the SOFA scale and IL-6 level were associated with mortality while lactate levels were not. Hospital mortality was 56%, and ICU mortality was 34.7%.
Conclusions: In patients with septic shock and multiorgan dysfunction, extremely high levels of IL-6 are associated with very high mortality. Extreme hypercytokinemia could be considered as a clinical diagnostic tool to select patients with septic shock and multi-organ dysfunction who may be eligible for precision medicine through the application of cytokine hemoadsorption.

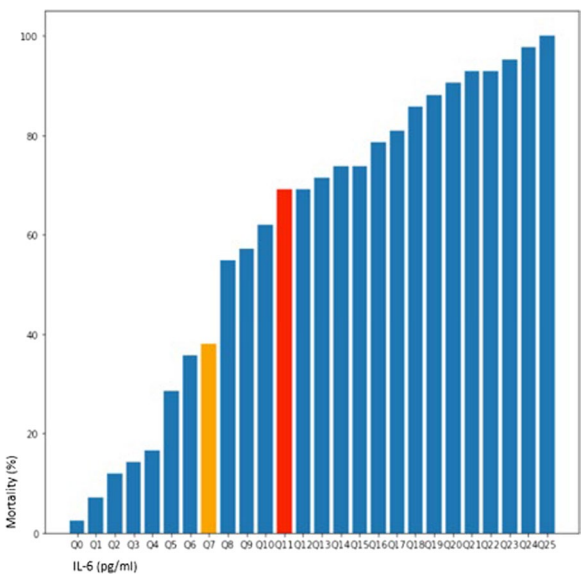

Figure 1 (abstract 000782) Representation by quantiles in relation to accumulated mortality. Mortality exceeds 60% when the IL-6 value exceeds 318,738 pg/ml (red quantile) and a change in trend is observed when IL-6 exceeds 186,167 pg/ml (yellow quantile)

Table 1 (abstract 000782) Characteristics of the study population. The data have been expressed as "n" (%) if they are categorical and as median (interquartile range) or mean (standard deviation) if they are quantitative. The biochemical and analytical variables refer to the initial value after activation of the Sepsis Code. *CKD: chronic kidney disease.*

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000783

Introduction: Patients with COVID-19 are at risk for delirium due to several factors (1). Additionally it is well known that delirium may be related to the development of symptoms of Post-Traumatic Stress Disorder (PTSD) (2). In this article, we describe our experience in COVID-19 patients that developed ICU-delirium together with its impact in mental health after one year of ICU discharge.
Objectives: To analyze the impact of ICU-delirium as a complication of the COVID-19 critical infection in mental health after one year of ICU discharge.
Methods: This cross-sectional study among critical ill COVID-19 survivors aged 18 years who presented delirium during intensive care unit admission. Mental health was assessed one year after ICU discharge. Medical records were reviewed and a validated instrument was used: the Post-Traumatic Stress Disorder Checklist-5 (PCL-5), based on the Diagnostic and Statistical Manual of Mental Disorders (DSM-5) for screening PTSD which was administered through phone-based questionnaire. The PCL-5 can determine a provisional diagnosis of PTSD using a cut-point score of 31–33. Categorical variables are expressed as counts and percentages and were compared using the χ2 test and Fisher test; continuous variables are expressed as medians and interquartile range (IQR) and were compared using Mann–Whitney U test. A two-sided level of significance of 5% was used. Data analysis was performed using STATA version 13 ® (StataCorp LCC).
Results: A total of 270 patients agreed to answer the phone survey. The 46% of them developed ICU-delirium. One-year mortality didn't differ between patients with or without delirium (7,46% Vs 4,81%, p = 0,2), but those who developed ICU-delirium have an increased in hospital length of stay (24 Vs 8 days; p = 0) and ICU length of stay (22 Vs 38 days; p = 0). There were not significant differences in the demographics baseline. Treatment with psychotropic drugs (antidepressants, benzodiazepines, neuroleptics and opioids) was collected before ICU-admission and after 1 year from ICU discharge. A comparison between patients who didn't developed ICU-delirium and patients who developed it showed that the latter group of patients was taking higher doses of benzodiazepines after 1 year from ICU discharge (1,39% Vs 1,61%; p = 0,01). With respect to PTSD, our study indicates that it was more frequent in patients who developed ICU-delirium (14,4% Vs 5,52%; p = 0,01). The items with higher scores were:

1. Repeated, disturbing and unwanted memories of the stressful experience.
2. Repeated, disturbing dreams of the stressful experience.
3. Suddenly feeling as if the stressful experience was actually happening.
4. Having strong physical reactions when something reminded you of the experience.
5. Trouble remembering important parts of the experience.
6. Having difficulties for concentrating.

Conclusions: Patients who developed ICU-delirium were treated with higher doses of benzodiazepines than before admission after one year of ICU discharge. There were not differences in mortality but the group with ICU-delirium had an increase in hospital and ICU length of stay. PTSD as a marker of mental health was more frequent in patients who developed ICU-delirium.

Table 1 (abstract 000783) Baseline characteristics, mortality and lenght of stay

Correspondence: U. Ojha
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000784

Introduction: The role of inotropic agents within patients with acute heart failure (AHF) and advanced heart failure (AdHF) remains unclear. Both the phosphodiesterase inhibitor-5 (Sildenafil) and the calcium sensitiser (Levosimendan) may enhance cardiac function within certain patients, when utilised as monotherapies. The combination of these therapies has not been studied previously.
Objectives: To report our clinical experiences regarding the indications, efficacy, and safety profiles of dual treatment with Levosimendan and Sildenafil in critically ill adult patients.
Methods: An observational retrospective analysis was performed for all patients admitted to Intensive Care Unit (ICU) between July 2010 and October 2021 who received both Levosimendan and Sildenafil within seven days of each other. Clinical and mortality data was obtained from the hospital electronic record.
Results: 112 patients received dual treatment with Levosimendan and Sildenafil. The group included 74 (66.1%) males and 38 (33.9%) females, with a mean age of 55.0 ± 16.5 years. Mean body mass index was 27.6 ± 5.5 kg/m2. The mean Simplified Acute Physiology (SAPS) II score was 38.4 ± 11. 5. Indications for combined use of Levosimendan and Sildenafil were primarily right ventricular failure (33.9%) and biventricular failure (48.2%). Other indications also included pulmonary hypertension (8.0%), left ventricular failure (7.1%), weaning from intra-aortic balloon pump (0.8%) and weaning from veno-arterial extracorporeal membrane oxygenation (0.8%). The median length of stay on ICU was 27 ([interquartile range (IQR) 16–47] days. The Median vasoactive-inotropic score (VIS) decreased from 13.5 ((IQR 3.5–23.0) pre dual therapy to 10 (IQR 1 – 20) after 72 h ($p = 0.0005$). Median oxygenation index increased from 38.1 (IQR 26.3–46.3) pre combined treatment to 40 (30.5 – 50) after 72 h ($p = 0.019$). 76 patients (69.1%) were discharged from ICU, 3 patients (2.73%) were readmitted to ICU within 48 h and overall hospital survival rate was 55.1%.
Conclusions: The study documents the novel observation of the combination use of sildenafil and Levosimendan. Further work is needed to understand and characterise this novel observation in more detail.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000785

Introduction: The 2019 ESC guideline for the diagnosis and management of acute pulmonary embolism (PE) recommends thrombolytic therapy only in high-risk PE cases because of the bleeding risk [1]. According to the literature, the risk of major haemorrhage is 10% and fatal or intracranial bleeding is 1,7% among patients receiving thrombolysis with rtPA, the most often used drug [2]. The recommended dose is 100 mg over 2 h.
Objectives: Based on our previous observations, this work aimed to increase the safety and efficiency during thrombolysis by using the viscoelastic tests of the ClotPro system.
Methods: Adult patients at Central ICU of the Semmelweis University diagnosed with PE between December 2021 and April 2023 were enrolled in this randomised interventional study.
In the control group viscoelastic measurements were performed without any modification in the thrombolysis.
In the ClotPro guided group EX, IN, FIB, TPA, AP, ECA and RVV tests were performed every hour during thrombolysis. The dose of rtPA was modified based on the FIB and ECA tests' lysis time and maximum clot firmness. Fibrinogen was administered to maintain the FIB MCF over 9 mm. Echocardiography was performed every two hours for right ventricular dysfunction (RVD) signs. If the RVD were reversed, the thrombolysis was terminated.
Results: A total of 21 patients (pts) were eligible. 6 pts were excluded due to active bleeding (2 pts) or intermediate-low risk (4 pts). 6 pts were randomised in the control group (female/male: 3/3; mean age: 67.46 ± 8.95 years); 9 pts in the ClotPro guided group (female/male: 3/6; mean age: 57.89 ± 14.9). Based on the echocardiography, the length of the thrombolysis was different in the ClotPro guided group (mean length: 8.55 ± 1.86 h). The dosage rate and the cumulative dose of rtPA were modified (mean dose: 37.44 ± 11.92 mg). 5 pts needed fibrinogen substitution (1–6 g).
In the control group patients received 100 mg/2h of rtPA. Alteration of the therapy was required because of severe bleeding on two occasions. In one case pericardial hematoma and gastrointestinal bleeding occurred when the thrombolysis was done after non-traumatic CPR. In the other case blood aspiration occurred due to rhinorrhagia. Only 3 pts (50%) in the control group showed early right ventricular function improvement. In two cases the RVD persisted despite the lysis and in one case the right ventricular function wasn't measurable due to the pericardial hematoma. Prolonged (> 12 h), severe functional fibrinogen deficit (FIB MCF 0 mm) was observed on four occasions after thrombolysis.
In the ClotPro guided group RVD was dissolved in all cases. There was one adverse bleeding event, cerebral haemorrhage (the patient denied that he suffered trauma, later it came to our knowledge that he had collapsed before hospital admission).
Conclusions: The new ClotPro guided prolonged thrombolysis's revascularisation effect seems to be efficient and safe. Further randomised controlled studies are needed to validate this observation.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000788

Introduction: In-hospital cardiac arrest is assoaciated with a high mortality rate. Despite this, it has received little attention compared with stroke or myocardial infarction.
Objectives: To analyze the epidemiological features as also the factors related to mortality in patients admitted t in the ICU after recovery from cardiac arrest (CA).
Methods: Retrospective descriptive analysis on a prospective cohort performed in a 15-bed ICU from 2019 to 2022. Demographic outcomes, comorbidities, severity scores (APACHE II and SAPS II), treatment received, mechanical ventilation (MV), risk factors, ICU acquired infections, antibiotherapy, ICU and hospital length of stay (LOS) and mortality were collected.
Statistical analysis: categorical variables (frequencies and percentages) and quantitative variables (mean and standard deviation or median and interquartile range). Comparisons: X2 test (percentages), Student's t test (means) and Mann–Whitney U test (medians). Multivariate logistic regression. Statistical significance at $p < 0.05$.
Results: 1470 patients were included. CA group (N = 50) vs. non-CA group (n = 1420) were compared: Age (68.4 ± 14.7 vs 63.1 ± 15.3, p = 0.015). SAPS II (58.5 [49.25; 69.75] vs 28 [19; 42], p = < 0.001), APACHE II (23 [18; 27.5] vs 10.5 [6; 16], p = < 0.001); GCS (15 [8; 15] vs 15 [13; 15], p < 0.001). COVID infection (0 (0) vs 166 (11.6), p = 0.004). Risk factors: Central venous catheter (CVC) (98% vs 60%, p < 0.001); MV (98% vs 39.7%, p < 0.001), Urinary catheter (UC) (100% vs 70.4%, p < 0.001). Comorbidities: neoplasia (4% vs 16.5%, p = 0.016); Chronic obstructive pulmonary disease (COPD) (18% vs 8.3%, p = 0.032). Duration of MV (days) (5 [1; 11] vs 0 [0; 2], p < 0.001); Duration of CVC (days) (9 [4; 15] vs 1 [0; 6], p = 0.001. Mortality (60% vs 28.4%, p < 0.001).
Survivors and dead were compared: Dead (n = 30) vs. survivors (n = 20): SAPS II (66 [54; 75] vs 54 [38; 58], p = 0.006); APACHE II (25 [20; 32] vs 19 [15; 24], p = 0.007). Duration of MV (days) (3 [1;5] vs 1 [1; 3], p. = 040); ICU-LOS (3 [1;5] vs 4 [3; 8], p = 0.087), Hospital-LOS (4 [2;12] vs 14 [8; 21], p = 0.004); non-invasive ventilation (NIV) (0 [0; 0] vs 0 [0; 0]; p = 0.004; First period of CVC (days) (2 [1; 4] vs 4 [3; 6], p = 0.021). Location of cardiac arrest (p = 0.291): out-of-hospital (23.3% vs 15%), wards (36.6% vs 25%), emergency department (23.3% vs 55%). Initial rhythm (p = 0.767): asystole (66.6% vs 65%), Ventricular fibrillation (V-Fib)/ Ventricular tachycardia (V-tach) (13.3% vs 25%), Pulseless electrical activity (PEA) (16.6% vs 10%). Multivariate logistic regression: APACHE II (OR 1.12 [1.03–1.26, p = 0.018).
Conclusions: Mortality in patients successfully resuscitated from cardiac arrest who were admitted to the intensive care unit is quite hight. No differences were found in terms of locations of CA or initial rhythm. Prognosis score APACHE II was associated as an independent risk factor for mortality.

Use of angiotensin II for refractory vasodilatory shock in intracerebral hemorrhage

N. Zorko Garbajs[1], N. Milivojević[1]
[1]Department of Vascular Neurology and Intensive Therapy, University Medical Center Ljubljana, Ljubljana, Slovenia

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000791

Introduction: Neurogenic shock occurs in patients with acute neurologic injuries, namely acute brain, spinal cord, and rarely peripheral nerve injuries. Caused by three mechanisms, vasodilatory (distributive), cardiogenic, and adrenal insufficiency, its treatment is accordingly complex. Mostly contributed to cardiogenic shock, hypotension occurs in 3% of subarachnoid hemorrhage patients. Isolated vasodilatory shock, unresponsive to treatment, was described in 1995 by Gipe and McFarland but rarely since. In our neurointensive care unit, although infrequently, we encounter refractory neurogenic vasodilatory shock without other underlying causes, unresponsive to standard treatment with IV fluids, adrenergic vasopressors, and high-dose corticosteroids. Angiotensin II, a peptide endocrine hormone, important in volume and blood pressure control, has been approved in its synthetic, intravenous form for distributive, vasodilatory shock in adult patients. It is a G-protein stimulator at vascular AT1-receptor, whose signaling leads to contraction of vascular smooth muscle and consequential vasoconstriction.
Objectives: In this contribution, we wanted to explore the rationale behind and identify possible intracerebral hemorrhage patients with neurogenic vasodilatory shock, who can benefit from an early application of angiotensin II.
Methods: We searched for all literature describing the use of angiotensin II in neurogenic vasodilatory shock. The search was carried out according to Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) criteria. It was conducted using MEDLINE (Pub Med), Embase, and Web of Science from inception through March 31st 2023. It included all studies, case reports, case series and expert opinions on use of angiotensin 2 in adult patients with neurogenic vasodilatory shock.
Results: We found no studies, articles or case reports describing the use of angiotensin II in vasodilatory neurogenic shock. In our experience, angiotensin II is useful in said patients after excluding alternate causes of shock, as the application of initial dose of angiotensin II (20 ng/kg/min) after adequate volume resuscitation, high dose noradrenaline (> 1,0 ug/kg/min), argipressin (0,03 IU/min) and high-dose corticosteroids, rapidly resolved profound hypotension and enabled weaning of all vasopressors within 12 h. Literature search suggests the initial surge of catecholamines in intracerebral hemorrhage, however, why this is ineffective in certain remains to be discovered. Theoretically, the laterality of injury to the insular cortex may play a role. In cases where "warm and dry" shock continues despite high concentrations of conventional vasopressors, the application of angiotensin II, whose effect is elicited through its own receptor, seems reasonable.
Conclusions: There is a need to study isolated vasodilatory shock in intracerebral hemorrhage patients, as the application of intravenous angiotensin II is promising in faster hemodynamic stabilization of such patients.

Introduction: Advanced age is a well-known risk factor for poor prognosis in COVID-19[1]. During the Sars-Cov-2 pandemic, there was a difficulty in selecting candidate patients who would benefit from intensive care because the less of intensive care unit (ICU) bed during pandemic demand. This particularity becomes very relevant when it comes to a very elderly population, ≥ 80 years old, due to the reduced life expectancy, multimorbidity, functional impairment and the fragility that can be present in this age group[2].
Objectives: The aims of this study was to compare mortality between octogenarian patients (age ≥ 80 years old) who were admitted to the ICU using invasive mechanical ventilation (MV) versus those who stayed on the ward receiving less invasive oxygen therapies during Sars-Cov-2 pandemic.
Methods: In this single-center study we enrolled critically ill octogenary patients with severe pneumonia by SARS-CoV-2 who were admitted to the ICU in invasive MV (group 1) versus those received less invasive oxygen therapies (group 2) between April, 2020 and September, 2020. Primary outcome was mortality between the two groups. Secondary outcomes were defined as length of ICU and hospitalar stay.
A frailty screening (Katz, Pfeffer and Modified Frailty Index) was carried out in patients ≥ 80 years old with severe pneumonia by COVID-19, so that less frailty patients were considered candidates for invasive MV and were admitted to the ICU.
Results: Were included 90 patients, 39 in group 1. The means age of the group 1 was 83.18 ± 2.79 versus 85.45 ± 6.19, p = 0.036. Hypertension, Diabetes Melittus and OCPD were equal in both groups. There was no difference between groups in the Charlson index, however the Katz index was higher in the group 1 (5.79 × 4.33, p = 0.0001) and the Pfeffer index was lower in the group 1. The hospital mortality rate was statistically significant very high in group 1, 92.3% (36 patients) and 33.3% in group 2, p < 0,0001. There was no difference between groups regarding time of hospital stay (group 1: 11.51 ± 7.018 versus 14.95 ± 13.01, p = 0.122).
Conclusions: Despite patients with greater functionality and less previous frailty, mortality was higher in this group that received invasive MV at ICU, possibly because of the severity of the disease of these patients and your complications like pneumonia associated to MV.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000794

Introduction: Monitoring respiratory drive and effort can be useful in critically ill patients under spontaneous assisted breathing to prevent respiratory muscle atrophy and patient self induced lung injury. Acute respiratory distress syndrome (ARDS) commonly causes increased respiratory drive and effort. In COVID-19 related ARDS (CARDS), respiratory drive and effort may be even higher, leading to relapse of acute respiratory failure and worse outcomes (1). Therefore, further research comparing CARDS and ARDS patients is needed to highlight differences in respiratory drive and effort and their impact on clinical outcomes.
Objectives: The first aim was to investigate the changes in respiratory drive and effort using neurally-adjusted ventilatory assist (NAVA) catheters in CARDS patients compared to ARDS patients. The second aim was to evaluate the incidence of the composite outcome of a transition from light to deep sedation (Richmond Agitation-Sedation Scale, RASS from 0/-2 to -4/-5) or from assisted to controlled ventilation within 48 h from spontaneous assisted breathing.
Methods: This multicenter study was conducted in four ICUs in Italy and prospectively recruited patients with CARDS, comparing them to a historical cohort of patients with ARDS. All patients who transitioned from controlled ventilation to assisted ventilation and had a RASS level of 0/-2 were included. The CARDS cohort was divided into 'mild' and 'severe' COVID-19 groups according to P/F ratio at ICU admission (2). Respiratory mechanics variables were recorded for 90 consecutive breaths and 2 end-expiratory occlusions were performed to measure Pmusc/Eadi index (PEI). The study protocol included the assessment of respiratory drive using P0.1vent, and respiratory effort using NAVA catheter (ΔEdi, PmusEdi) (3). Inspiratory pressures in pressure support mode were kept at 10 cmH2O for all patients.
Results: We enrolled 55 patients (10 severe-COVID19, 7 mild-COVID19, and 38 non-COVID19 patients) and analyzed a total of 4301 breaths. Baseline characteristics were reported in Table 1. P0.1vent was significantly different between the three groups (Figure 1). Respiratory effort (ΔEdi, PmusEdi) was markedly different between severe-COVID19 and the other two groups (Figure 1). Within the cohort of severe-COVID19 patients, 70% underwent a transition from assisted to controlled ventilation or from a RASS score of 0/-2 to -4/-5. None of the patients in the mild-COVID19 cohort required such a transition, while 2.6% of the non-COVID-19 cohort experienced this shift.
Conclusions: In severe-COVID19 patients, respiratory drive and effort are markedly altered. Our findings highlight significant differences in clinical outcomes, ventilation duration, ICU mortality, and ICU length of stay among patients with severe CARDS. These results suggest that greater caution should be exercised in implementing spontaneous mechanical ventilation strategies in CARDS patients.

Causes for non-completion of organ donation in patients with brain death at the Municipal Hospital Djalma Marques, in São Luís-MA

H. Sousa Bastos[1], P. Costa Bortolon Melo[2], GA. Lisboa Oliveira[2], V. Freire Pereira[2], V. Freitas Neto[2], AM. Clayton[2], MN. Caroline[2], SS. Luciana[2], P. De Carvalho Bacelar[2]

Introduction: Family refusal to donate organs is a serious problem against the improvement of transplant rates in the country. The causes are diverse and are intrinsically linked to the socio-cultural context.
Objectives: The objective is to investigate the profile of potential organ donors and identify the main causes of non-donation of organs in a public hospital in the capital of Maranhão.
Methods: It consists of a retrospective observational study, involving 40 patients admitted to an adult intensive care unit at a tertiary public hospital in São Luís-MA, between January 2022 and July 2022, with confirmed brain death. Data collection was performed by analysis of medical records and data were stored in a Microsoft Excel spreadsheet, with analysis performed in the computer program IBM SPSS Statistics v.20.0. Armonk, NY: IBM Corp.
Results: Of the 40 patients analyzed, 20 reached the end of the brain death diagnostic process. Of these, most are male (55%) and aged between 18 and 45 years (65%). Family refusal occurred in 55% of cases (11). Among the reasons for refusal in the interview, the desire not to donate the potential donor in life presented 45.5%, followed by 27.3% for the desire to have a healthy body and 27.2% did not want to wait for the logistics of the process. Among the reasons for not having been interviewed, it was observed that 35% occurred due to cardiorespiratory arrest before the conclusion of the protocol, followed by refractory sepsis with 30%, contraindicative organ failure with 25% and positive contraindicative serologies in 10%.
Conclusions: There are several causes of family refusal, requiring education strategies to encourage the population to discuss in society about organ donation and the social impact that this attitude carries, in addition to optimizing the maintenance of the potential donor to reduce the number of interviews not carried out. Bring a protocolised process for approaching the families in PD-generating hospitals, with education of doctors, other healthcare professionals and the society is a possible key to overcoming the fear related to the donation of organs and tissues.

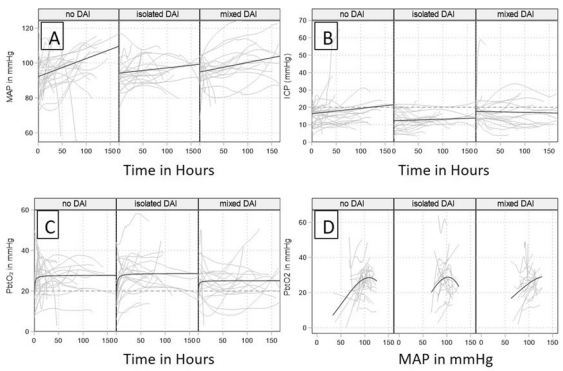
Characterization of the neurophysiologic differences between phenotypes of traumatic brain injury: an historical cohort study

E. Chow[1], E. Yang[1], E. Ursu[1], R. Hoiland[1], M. Sekhon[2], D. Griesdale[1]
[1]Department of Anaesthesiology, Pharmacology and Therapeutics, The University of British Columbia, Vancouver, Canada; [2]Medicine, The University of British Columbia, Vancouver, Canada
Correspondence: D. Griesdale
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000797

Introduction: Traumatic brain injury is characterized by different pathoanatomic patterns of injury, which include diffuse axonal injury and other phenotypes (contusions, extra-axial collections, and subarachnoid and intraventricular hemorrhage). Although radiographically delineated, the physiologic responses to injury have not previously been characterized. The purpose of this project was to compared

patients with either isolated DAI, mixed DAI (DAI and other pattern of injury) and non-DAI with respect to intracranial pressure (ICP), mean arterial pressure (MAP), and brain tissue oxygenation PbtO2). In addition, we sought to characterize the response of PbtO2 to MAP in the three groups.
Methods: This was a single-centre historical cohort study of patients admitted to the ICU at Vancouver General Hospital with a diagnosis of TBI and who underwent invasive multimodal neuromonitoring between September 2014 to November 2022. Admission computed tomography (CT) scans of the head were used to determine following pathoanatomic patterns: isolated DAI (petechial or intraventricular hemorrhage), non-DAI (epidural or subdural hematoma, contusion, and traumatic subarachnoid hemorrhage), or mixed DAI (DAI and one of a non-DAI phenotype). ICP, MAP and PbtO2 were collected using ICM + Brain Monitoring Software (Cambridge UK). We fitted a linear mixed model (specifying "patient" as a random effect) to estimate the average profiles of PbtO2, ICP and MAP over time. We used a restricted cubic-splines model to plot the non-linear relationship bewteen PbtO2 and MAP.
Results: There were a total of 72 patients included in the cohort with the following phenotypes of injury: 22 (31%) with isolated-DAI, 21 (29%) with mixed-DAI, and 29 (40%) with no-DAI. The mean (standard deviation [SD] of the cohort was 36 (15) years, and 56 (78%) were male. The most frequent etiologies of the TBI were motor vehical colisions in 28 (40%) and falls in 18 (26%). The median (interquartile interval [IQI] admission Glasgow Coma Scale Motor was 3 [1–4]. The median duation of invasive monitoring was 4 [2.0–5.5] days. Overall, 16 of 72 (22%) of patients died in hospital, which was highest amongst those who sustained a mixed-DAI phenotype of injury (7 of 21 [33%]). The trajectories of MAP, ICP and PbtO2 over time are shown in the figure. During the monitoring period, the mean ICP was lower for patients with an isolated-DAI (13 [5]) compared to those with either mixed-DAI (17 [11]) or no-DAI (17 [9]) (P = 0.048). There was no difference in either MAP or PbtO2 comparing the three phenotypes. MAP increased over time in all phenotypes. Overall, 16 of 72 (22%) of patients died in hospital, which was highest amongst those who sustained a mixed-DAI phenotype of injury (7 of 21 [33%]). Finally, there was a non-linear increase in PbtO2 as MAP increases in all three phenotypes.
Conclusions: Irrespective of phenotype of injury, all patients had similar trajectories of MAP and PbtO2 over time. ICP was lower in those patients with an isolated-DAI. Our next steps will include 1) examining indices of autoregulation, and 2) comparing therapeutic interventions (e.g., use of hypertonic saline) amongst the three phenotypes of injury.



Panels A – C are mean arterial pressure (MAP), intracranial pressure (ICP and brain tissue oxygen (PbtO2) are plotted over time. Individual patient Locally Weighted Scatterplot Smoothing (LOWES) plots are shown in light grey. The predicted probabilities are shown in the dark grey line. Panel D shows the non-linear relationship between PbtO2 and MAP.

Tracheostomy in critically ill patients. Factors related to mortality
M. Salgado[1], A. Alonso[1], M. Cózar[1], A Alvarez[1], A. Ubeda[1]
[1]Intensive Care Unit, Hospital Punta de Europa, Algeciras, Spain
Correspondence: A. Ubeda
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000799

Introduction: Tracheostomy is a frequent alternative in patients who require prolonged mechanical ventilation in the ICU. Early tracheostomy has been demonstrated to reduce the duration of mechanical ventilation and length of stay. However, its association with mortality remains ambiguous.
Objectives: To analyze the characteristics of tracheostomized patients during their admission in a intensive care unit (ICU) in Punta Europa Hospital, as also analyze the factors related to mortality in our ICU.
Methods: Retrospective descriptive analysis was performed using a prospective cohort obtained from a 15-beds ICU collected between 2019 and 2022. 2 groups were compared: tracheostomized patients vs. no tracheostomized patients. Demographic variables, comorbidities, prognosis scores (APACHE II and SAPS II), risk factors, microorganism isolated, ICU and hospital length of stay (LOS), antimicrobial therapy used and mortality were collected. Statistical analysis: continuous variables (mean and standard deviation or median and interquartile range), categorical variables (percentages and frequencies). Comparison: Chi-square test (percentages) and T-student test (mean) or Wilcoxon-test (median). Multiple logistic regression. Statistical significance was set at p-value < 0.05.
Results: 1470 patients were included. Non-tracheostomized (n = 1388) vs. tracheostomized (n = 82). Age (63.33 [± 15.51] vs. 62.39 [± 12.81], p < 0.001). Covid-19 (1% vs 34%, p < 0.001).Origin (p < 0.001): community (58.3% vs. 23.3%), ward (38.6% vs. 62.2%), other ICU (3% vs. 14.6%). SAPS II (28 [19;43] vs. 33 [27.2;48.7], p < 0.001), APACHE II (11 [6;17] vs. 14 [9.25;19], p < 0.001), GCS on admission (15 [13;15] vs. 15 [7;15], p < 0.001). Comorbidities: neoplasia (15.5% vs. 25.6%, p = 0.024). Risk factors: Previous ATB (28% vs. 58.5%, p < 0.001), urgent surgery (14.3% vs. 43.9%, p < 0.001), central venous catheter (CVC) (59.2% vs. 96.3%, p < 0.001), mechanical ventilation (MV) (38.8% vs. 91.4%, p < 0.001), urinary catheter (UC) (69.8% vs. 98.7%, p < 0.001). ICU LOS (days) (3 [2;6] vs. 29 [12.2;40.7], p < 0.001) and hospital LOS (days) (9 [5;18] vs. 50 [27.5;60,7], p < 0.001). Days of MV (0 [0;2] vs. 22 [10;33], p < 0.001). Mortality (27.7% vs. 58%, p < 0.001).
Survivors (n = 34) and dead (n = 48) were compared: Age (57.3 [± 14.2] vs. 66 [± 10.4], p < 0.001).GCS on admission (9 [3;15] vs. 15 [9;15], p = 0.021). Comorbidities: neoplasia (41% vs. 14.5%, p = 0.009). First ICU-adquired infection (p < 0.032): secondary bacteriemia (0% vs, 24.4%), Catheter-related bloodstream infection (CRBSI) (17.8% vs. 20%), Ventilator-associated pneumonia (VAP) (32.1% vs. 13.3%), Catheter-associated urinary tract infections (CAUTI) (7.1% vs. 6.6%). Hospital LOS (days) (59.5 [51.2;82.7] vs. 37.5 [19;51.2], < 0.001). Multivariate analysis (mortality): Age (OR 1,08 [IC 95% 1.04–1.14], p < 0.001), neoplasia (OR 0.12 [IC 95% 0.03–0.41], p < 0.001).
Conclusions: Mortality in tracheostomized patients in ICU is high. Age was a mortality independent predictor, while neoplasia as comorbidity was a protective factor.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000801

Introduction: Patients who are transferred from the intensive care unit (ICU) to the general ward are at high risk of complications and readmission to the ICU. There is a need to identify effective strategies to reduce readmission rates and improve patient outcomes.
Objectives: To investigate the impact of a 48-h monitoring protocol on the readmission rates of patients transferred from the ICU to the general ward.
Methods: We conducted a retrospective cohort study of adult patients who were transferred from the ICU to the general ward in a single large academic medical center between January 2020 and September 2021. Data of patients who were monitored for 48 h after transfer to the general ward were collected prospectively. We compared the readmission rates of patients who received 48-h monitoring with those who did not.
Results: A total of 286 patients were included in the study, of whom 102 received 48-h monitoring and 184 did not. The readmission rate in the 48-h monitoring group was 1%, compared to 6% in the group that did not receive 48-h monitoring ($p = 0.028$). After adjusting for confounding factors, the odds of readmission were 35% lower in the 48-h monitoring group (OR 0.65, 95% CI 0.48–0.87). There were no statistically significant differences in medical history, demographics or clinical characteristics.
Conclusions: Our study suggests that a 48-h surveillance protocol may be effective in reducing the readmission rates of patients transferred from the ICU to the general ward. Further prospective studies are needed to confirm these findings and evaluate the cost-effectiveness of this approach.

Non-theatre emergency airway management in the paediatric population: a prospective observational study of technique and adverse events across eight acute hospitals in the South East of England

J. Gibson[1], T. Leckie[2], B. Hardy[2], S. Tun[3], L. Hodgson[2]

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000802

Introduction: Airway management in the paediatric population is known to be challenging [1] with a high rate of adverse events [2]. Whilst gaps exist in optimal management even in tertiary centres [3], adverse events are more common outside of the tertiary setting [2]. Ways to mitigate adverse events are better evidenced in the adult population, however large bodies of work have provided recommendations for paediatric intubation [1] including the use of capnography and videolaryngoscopy.
Objectives: This study aimed to establish the incidence of adverse events during tracheal intubation of the paediatric patient in the non-theatre setting, and how clinical practice compared with existing recommendations.
Methods: Data relating to any emergency tracheal intubation outside of the theatre environment in children (< 18 years) was recorded on a secure electronic case report form across eight acute NHS hospital sites in the South East of England. Data was collected continuously over six weeks. The project was reviewed by the lead site research department and classified as a service evaluation project, with subsequent local review and adoption at each site. One participating centre included a tertiary children's hospital, whilst the remaining seven were district general hospitals. Data gathered included the age, airway technique and adverse events. Cases managed by dedicated neonatal teams were excluded.
Results: A total of 46 tracheal intubations were recorded, 26 of which were in children aged under 2 years, with six cases in children aged 2 to 5 years and 14 cases in children aged 6 to 17 years. Capnography use was universal across all events. Videolaryngoscopy was used first line for tracheal intubation in 42% of those under 2 years old, 66% in 2 to 5 year olds and in 50% of those aged 6 years and over. Within these age categories, videolaryngoscopy was available for 88%, 100% and 86% of events. Overall, first-pass success of tracheal intubation was 76%, falling to 62% in those under 2 years. In this youngest age group, adverse events included $SpO2 < 80\%$ in 31%, ≥ 3 attempts at intubation in 19% and oesophageal intubation in 8% of cases. One of these was not immediately detected.
Conclusions: Emergency tracheal intubation outside of the theatre environment was common. Those aged under 2 years disproportionately represented the workload. This subset encountered adverse events most frequently, in-keeping with existing literature [2]. The complete use of capnography meets current recommendations during tracheal intubation of the child. However, despite high availability, subsequent use of videolaryngoscopy is markedly less. This may be a factor as to why adverse events were high in those aged under 2 years. Further work should explore reasons for lower rates of videolaryngoscopy within this patient population, with consideration of whether the improved safety profile of videolaryngoscopy observed in adults is also present in the paediatric population.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000803

Introduction: Acute brain injury can lead to increased intracranial pressure (ICP), which can cause secondary ischemic insult. Conventional (or first-tier) treatments of increased ICP include proper sedation and pain control, hyperosmolar agents, such as mannitol or hypertonic saline, hyperventilation and CSF drainage. If unresponsive to these methods, second-tier treatments such as decompressive craniectomy, barbiturate infusion and/or mild hypothermia are considered. Barbiturate infusion is effective in reducing ICP but its notorious side effects make it less favorable. Mild hypothermia (body temperature of 32–35 degree C) is relatively safe treatment but its efficacy as a monotherapy in acute brain injury is not clear. Combining barbiturate and mild hypothermia may be synergic in reducing ICP.
Methods: This was a retrospective review of patients admitted at Seoul National University Hospital from 2012 to 2021 with acute brain injury. Patients who had raised ICP despite the conventional treatments underwent unilateral decompressive craniectomy. If ICP was elevated (> 10 mmHg) even after decompressive craniectomy, either thiopental infusion or thiopental infusion and mild hypothermia were started. Primary endpoints included mortality, modified Rankin scores (mRS) at 3 and 6 months. Secondary endpoints included improvement in ICP, complications, length of intensive care unit (ICU) stay, length of hospital stay.
Results: A total of 51 patients with acute brain injury were enrolled (23 in thiopental only group, 28 in thiopental and mild hypothermia group). The mortality was 6% in thiopental only group, 11% in the other group. There was no statistically significant differences in 3- and 6-month mRS.
The initial ICP prior to thiopental /hypothermia was similar between the two groups (11.0 ± 11.6 vs 16.6 ± 9.6, p-value 0.066) and there was no statistically significant differences in mean ICP during the first 48 h of treatment. After discontinuation of thiopental infusion, ICP remained similar between the groups for the next 48 h.
Body temperature was significantly low in thiopental and mild hypothermia group (36.9 ± 1.2 vs 35.0 ± 1.4, $p < 0.001$) with higher incidence of fever after discontinuation of thiopental infusion (BT > 37.8○C) in thiopental only group (39.1% vs 3.6%, p-value 0.003).
The duration of thiopental infusion was longer in thiopental only group (7130.4 ± 4164.6 min vs. 4073.3 ± 1918.0 min, p-value 0.003) but there was no statistically significant differences in vasoactive-inotropic score (VIS), incidence of pneumonia, incidence of deep vein thrombosis or pulmonary thromboembolism, length of ICU stay and length of hospital stay.
Conclusions: Combining mild hypothermia to thiopental infusion in patients with increased ICP, despite medical and surgical treatment, had no additional effects on neurological outcomes.

Introduction: Although a higher PEEP is recommended in patients with ARDS to prevent collapse and atelectrauma, an excessively high PEEP may cause overdistention of nondependent lung and barotrauma.
Methods: Retrospective cohort study on data derived two ICUs in Japan. In this study, we retrospectively collected cases of mechanically ventilated COVID-19 ARDS (CARDS) patients with transpulmonary pressure-guided PEEP setting and investigated whether lung mechanics measured early after intubation, including transpulmonary pressure (PL) derived esophageal pressure (Pes) and elastance-derived plateau PL, are associated with barotrauma.
Results: Fifty-six patients were investigated. The PEEP setting guided by the end-expiratory PL was 14 cmH2O (12–15), the end-inspiratory PLderived Pes was 13 cmH2O (11–14) and ΔPL was 11 cmH2O (10–12). Barotrauma occurred in 8 patients (14%), and among respiratory mechanics, PaO2/FiO2 ratio, setting PEEP, plateau pressure, driving pressure, end-inspiratory PL derived Pes and ΔPL were not associated with barotrauma, but higher elastance-derived plateau PL was associated with the development of barotrauma (21 cmH2O vs. 24 cmH2O, $p = 0.041$).
Conclusions: The end-inspiratory PL derived Pes were not associated with barotrauma, and monitoring elastance-derived plateau PL may be necessary to prevent barotrauma.

Introduction: Cell-free DNA (cfDNA)/Neutrophil Extracellular Traps (NETs) are associated with sepsis. We investigated the selective removal of cfDNA/NETs from the circulation in a porcine intensive care model of sepsis using NucleoCapture® apheresis in a blinded randomised controlled trial. The NucleoCapture® column contains sorbent beads coated with linker histone H1.3 which selectively bind to cfDNA/NETs.
Methods: We induced sepsis in 18 pigs with a 3-h intravenous infusion of E. coli. Nine pigs were randomly allocated to treatment with NucleoCapture® selective apheresis for 5 h. Nine pigs were subjected to apheresis with a sham column. The column was used in conjunction

with the Terumo Optia system using regional citrate anticoagulation. The operators were blinded to the column type. We measured cfDNA/NETs using the NuQ H3.1 and H3R8cit nucleosome assays (Volition).

Results: A single pass of septic plasma through the NucleoCapture® column resulted in near complete removal (96–99.1%) of cfDNA/NETs.

There was no evidence of non-specific direct adsorption of proteins such as albumin and cytokines.

The baseline levels of circulating cfDNA/NETs measured in the NucleoCapture® and sham treated pigs prior to the experiment were 11.6 (±4.1) ng/ml and 10.2 (±3.5) ng/ml (mean ± SD), respectively. Infusion of E. coli. resulted in an increase in cfDNA/NETs levels to 68.6 (±24.5) ng/ml and 71 (±53.1) ng/ml, respectively.

The level of cfDNA/NETs in the sham treated pigs rose continuously during the experiment reaching 361.2 (±190.2) ng/ml (Figure 1). In contrast, NucleoCapture® treatment prevented a continuous rise in cfDNA/NETs with levels plateauing at 149.9 (±152.98) ng/ml ($p < 0.05$). The low cfDNA/NETs levels in the NucleoCapture® treated pigs were consistent with the attenuation of septic shock as evidenced by reduced total norepinephrine required (1,172 (±1,832) µg vs 6,360 (±5,017) µg, $p < 0.05$, Figure 2), reduced lactate (4.6 vs 6.9 mmol/l, $p < 0.05$, Figure 3) and improved survival (9/9 vs 7/9). There was also a twofold increase in urine output in the NucleoCapture® group.

No technical difficulties with the use of the NucleoCapture® column or any problems with anticoagulation were found.

Conclusions: In this blinded randomised controlled study, selective cfDNA/NETs apheresis with NucleoCapture® safely and effectively removed cfDNA/NETs from the circulation of septic pigs, resulting in improved organ function and survival. We aim to progress the investigation of NucleoCapture® to clinical trials in sepsis and other indications.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000807

Introduction: Avoiding and treating hemodynamic instability and raised intracranial pressure (ICP) in patients with subarachnoid haemorrhage (SAH) is of utmost importance. Brain Trauma Foundation recommend monitoring of ICP and cerebral perfusion pressure (CPP) to optimize cerebral blood flow after head trauma. However there are no guidelines on such treatment algorithms in patients with SAH.
Objectives: The aim of this study was to evaluate the effects of a protocolized CPP guided treatment on mortality and functional outcome in patients admitted to the intensive care unit (ICU) with SAH.
Methods: This was a single center retrospective study performed in an Intensive Care Unit in Poland. Fifty four ICU patients with SAH admitted between March 2019 and December 2021 were included in the study. Patients with cardiac arrhytmias, patients breathing spontaneously, patients with previuos neurologic deficits were excluded from the analysis.
In the study group fluid therapy, vasoactive and inotropic drugs, as well as diuretics and osmotherapy was managed according to the treatment protocol guided to maintain CPP above 70 mmHg based on transpulmonary thermodilution hemodynamic monitoring and ICP measurement. In the control group standard monitoring was used to optimize hemodynamic status of the patients.
The primary endpoints of this study were mortality and functional outcome assessed in Rankin and Glasgow Outcome Scale scales after 30 days. The incidence of delayed cerebral ischemia (DCI) constituted secondary outcome.
Results: Values of MAP, as well as cumulative dose of crystalloids and fluid balance were similar in both groups. The incidence of DCI was significantly lower in the study group (14% vs. 64%, $p < 0.01$), and the functional outcome determined by the Glasgow Outcome Scale on 30th day post ictus was also significantly better in the study group (29.0% vs. 5.5%, $p = 0.03$).
Conclusions: The study showed that patients treated with CPP guided therapy had lower incidence of DCI and had a better functional outcome after 30 days.

Gut microbiota alterations and fecal ph as potential prognostic markers in critically ill patients

H. Wozniak[1], V. Lazarevic[2], TS. Beckmann[1], L. Fröhlich[1], C. Le Terrier[1], T. Rochat Negro[1], T. Soccorsi[1], N. Suh[1], C. Chaabane[2], N. Gaïa[2], J. Pugin[1], J. Schrenzel[2], CP. Heidegger[1]

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000808

Introduction: Critical illnesses leading to intensive care unit (ICU) hospitalization have been associated with alteration of the gut microbiota, resulting in dysbiosis characterized by lower diversity and richness compared to healthy subjects. Such dysbiosis has been previously associated with poor outcomes in critically ill patients. A prior study suggested that stool pH, which can be easily measured at the bedside, may serve as a simplified biomarker for gut microbiota composition.
Objectives: Our study aimed to investigate early changes in gut microbiota in ICU-admitted patients and their association with overall mortality, hypothesizing that the early development of intestinal dysbiosis is associated with mortality. We also explored if fecal pH could be a simplified biomarker for gut microbiota alteration.
Methods: Fecal samples were collected for gut microbiota and pH assessments on Day 1 (D1) and Day 3 (D3). Fecal pH measurement was conducted by inserting a pH meter directly into the fecal sample. Microbiota analysis was performed using full-length 16S rRNA gene sequencing. The Shannon index and observed (species or genus) richness were used to assess within-sample alpha diversity. Differences between bacterial communities were assessed by Bray–Curtis similarity (overall community, beta-diversity) and DESeq2 (individual taxa). Wilcoxon rank-sum test was used to compare differences between survivors and non-survivors in (i) gut microbiota changes (Bray–Curtis similarity) and (ii) alpha-diversity indices. To test intra-individual differences in alpha-diversity between sampling points we used Wilcoxon signed-rank test. To test the significance of microbiota differences between sampling points or between patient survival outcomes, we used PERMANOVA (for overall microbiota) and DESeq2 (for individual taxa). The association between microbiota and fecal pH was tested using DISTLM. Spearman correlation analysis was conducted to investigate the correlation between gut microbiota changes (Bray–Curtis) and fecal pH changes.
Results: A total of 101 patients were enrolled, and 24 patients died within 60 days. Non-survivors had higher APACHE II scores on ICU admission compared to survivors (27.6 (SD 7) vs. 23.2 (SD 5) $p < 0.01$). The richness and diversity of gut microbiota decreased between D1 and D3 ($p < 0.01$). Overall bacterial communities' profiles at D3 significantly correlated with mortality ($p = 0.014$ for species, $p = 0.036$ for genera). Regarding pH, the delta pH (D3-D1) was of $+0.3$ (SD 0.6) in non-survivors and of -0.01 (SD 0.9) in survivors. Genus-level bacterial community profiles were associated with pH ($p = 0.013$ at D1, $p = 0.034$ at D3), but there was no significant correlation between gut microbiota changes and fecal pH changes. However, a fecal pH change of ≥ 0.1 was associated with mortality, after adjusting for the APACHE II score at ICU admission (OR 5, 95% CI 1.6–15.3, $p < 0.01$).
Conclusions: Early microbial composition or changes may potentially serve as an early marker for poor prognosis. Fecal pH changes were not associated with changes in bacterial profiles, but were associated with mortality. Further research is warranted to investigate the potential of fecal pH and gut microbiota dysbiosis as prognostic markers in critically ill patients, with larger studies and investigations needed to elucidate the underlying mechanisms and implications for patient outcomes.

Introduction: Venovenous extracorporeal membraneoxygenation (VV ECMO) has been used as a rescue therapy in severe acute respiratory distress syndrome (ARDS). We compared the clinical course and outcome of patients who received VV ECMO for corona virus disease 2019 (COVID-19) and other etiologies.
Methods: This single center retrospective evaluation enrolled adult patients with severe ARDS receiving VV ECMO during COVID-19 pandemic from March 2020 to February 2023.
Results: There were 22 patients with COVID-19 and 24 patients without COVID-19 who received VV ECMO due to severe ARDS during the study period. They were 60 ± 9 years and eighteen were women. Charlson Comorbidity index was 3 (2–4.25), and SOFA score on the first day of ECMO was 9 (7–12). Days between the first day of mechanical ventilator and ECMO was 2 (0–7), and the duration of ECMO was 13.5 (7.75 – 43.50) days. In patients with COVID-19, SOFA score was lower (10.8 ± 3.8 vs. 8.0 ± 3.6, p = 0.035) and the duration of ECMO was longer (10.5 [3.25–29.25] vs. 24.5 [10–63.25], p = 0.042) than in patients without COVID-19. The weaning rate of ECMO was 24/46 (52.2%) in all; 12/24 (50%) for non-COVID-19 patients and 12/22 (54.5%) for COVID-19 patients (p = 0.78). In multiple cox regression analysis adjusted with age, sex, sequential organ failure assessment score, and Charlson comorbidity index, COVID-19 was a significant parameter related with lower weaning rate of VV ECMO (Hazard ratio 0.284, 95% confidence interval 0.102–0.790, p = 0.016).
Conclusions: In the adjusted Cox regression model, COVID-19 decreased the possibility of weaning from VV ECMO in patients with severe ARDS. Considering the longer treatment period of COVID-19 than other etiologies of ARDS, evidence based patient selection should be followed in this COVID-19 pandemic.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000814

Introduction: The weight of obesity prevalence is growing in the intensive care unit (ICU). Although obesity is a known risk factor for chronic kidney disease (CKD), its association with acute kidney injury (AKI) and their combined impact on patient outcomes warrant further investigation.
Objectives: To explore the association between obesity, AKI incidence, and clinical outcomes in patients with sepsis.
Methods: This nationwide prospective cohort study analyzed patients with sepsis admitted to 20 tertiary hospital ICUs between September 2019 and December 2021. Patients were categories by body mass index (BMI), and the primary outcome of AKI incidence during ICU stay was analyzed by logistic regression analysis adjusted for key characteristics and prognostic factors. The secondary outcomes were clinical recovery and mortality.
Results: Of the 4,041 patients included in the study, 1,367 (33.8%) developed AKI. Obesity was associated with a higher incidence of AKI (adjusted odds ratio [aOR], 1.40; 95% confidence interval [CI], 1.15–1.70), as was every 5 kg/m2 increase in BMI (aOR, 1.31; 95% CI, 1.19–1.43) (Table **1**).

Outcome	Underweight (n = 813)	Normal weight (n = 1668)	Overweight (n = 628)	Obesity (n = 932)	P-value	Ajdusted OR (95% CI) per 5 kg/m2 positive
AKI	201 (24.7)	546 (32.7)	242 (38.5)	378 (40.6)	< 0.001	1.31 (1.19–1.43)
Clinical recovery within 30 days	366 (45.0)	818 (49.0)	313 (49.8)	480 (51.5)	0.054	1.07 (0.98–1.16)

While obesity was associated with lower in-hospital mortality in patients without AKI (aOR, 0.81; 95% CI, 0.71–0.93), no difference was observed in those with AKI (aOR, 1.10; 95% CI, 0.94–1.27) (Table 2).

Outcome		Underweight	Normal weight	Overweight	Obesity	Per 5 kg/m2 positive
ICU mortality		212 (26.1%)	385 (23.1%)	141 (22.5%)	242 (26.0%)	
Adjusted OR (95% CI)	Without AKI	1.66 (1.21–2.27)	1 (ref)	0.78 (0.51–1.19)	0.95 (0.65–1.38)	0.81 (0.69–0.96)
	With AKI	1.16 (0.80–1.70)	1 (ref)	0.99 (0.69–1.43)	1.19 (0.87–1.64)	1.09 (0.94–1.26)
In-hospital mortality		301 (37.0%)	555 (33.3%)	202 (32.2%)	309 (33.2%)	
Adjusted OR (95% CI)	Without AKI	1.46 (1.13–1.88)	1 (ref)	0.85 (0.62–1.16)	0.75 (0.55–1.01)	0.81 (0.71–0.93)
	With AKI	1.27 (0.87–1.86)	1 (ref)	0.84 (0.59–1.20)	1.16 (0.85–1.59)	1.10 (0.94–1.27)

Although obese patients without AKI had better chances of clinical recovery ($P < 0.001$, log-rank test), the protective effects of obesity were attenuated in those with AKI (P for interaction = 0.047) (Figure 1).
Conclusions: Obese patients with sepsis have a higher risk of developing AKI. The presence of AKI offsets the possible protective effects of obesity.

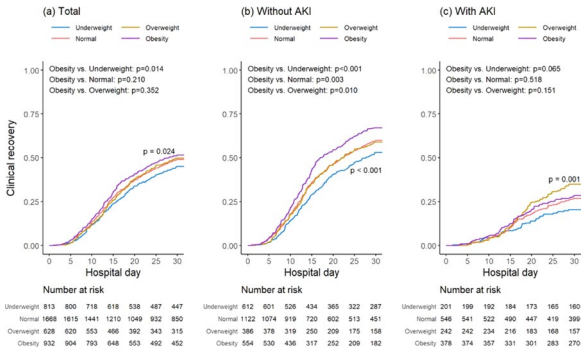

Figure 1 (abstract 000814) Clinical recovery within 30 days according to acute kidney injury status. Clinical recovery was defined as survival to discharge within 30 days.

Introduction: Swallowing disorders in critically ill patients are an important cause of morbidity and mortality with a reported incidence of more than 80%. Some of the factors associated with these disorders are the progression of the disease, mechanical ventilation, specific drugs, nasogastric tubes and delirium. The guidelines recommend evaluation by endoscopic fibroscopy for its diagnosis and guidance of treatment.
We investigated and compared the predictors and outcomes for these disorders in a cohort of critical care patients hospitalized with COVID-19 and non COVID-19 at a single hospital center.
Objectives: To assess the risk factors and outcomes of COVID-19 and non COVID-19 critical care patients with swallowing disorders.
Methods: We conducted a study of an observational, retrospective cohort, which included patients admitted to our intensive care unit from July 2016 to February 2019 for the non COVID-19 group and from April 2020 to July 2021 for the COVID-19 group, both groups underwent endoscopic fibroscopy with positive result for swallowing disorders. A univariate analysis of selected factors and outcomes was performed, the statistical analysis was prepared in SPSS v.21, frequency measurements were analyzed and the risk factor analysis was performed with Fisher test and × 2 test.
Results: A total of 77 positive endoscopic fibroscopy evaluations were performed. The non COVID-19 group 57.5% (n = 33) were males and the COVID-19 group 77.2% were males (n = 44, p 0.06). 75.7% of the patients in the non COVID-19 group had prior neurological alteration ($p < 0.01$). 95.5% of the patients in the COVID-19 group were mechanically ventilated ($p < 0.01$). The predominant swallowing disorders in the non COVID-19 group were alterations in the oral phase and in the COVID-19 group alterations of the pharyngeal phase and tracheal aspiration.

Table 1 (abstract 000815) Clinical and therapeutic outcomes

	Non COVID-19 n 33		**COVID-19 n 44**		***p***
Days of hospitalization 1	36.1	14–55.5	35.8	28.6 – 43.1	0.96
Days of intubation 1	5.9	2–7.7	15.2	12–18.4	< 0.01
Swallowing therapy days 1	19.3	6–30	9.09	5.6–12.54	< 0.01
Feeding route at discharge 2	16	48.4%	35	79.5%	< 0.01
Oral	2	6.0%	0	0%	0.09
Naso enteral tube	11	33.3%	6	6.8%	0.03
Gastrostomy	4	12.1%	3	13.6%	0.42
Mixed					

1 Interquartile range for free distribution variables, quantitative variables.
2 Frequencies and proportions, qualitative variables.
Conclusions: Multiple risk factors have been associated with the development of swallowing disorders in the critically ill, in our study we found similar results to prior studies. An outstanding difference between the groups was the presence of neurological alterations in the non-COVID group which may be the cause for a greater percentage of gastrostomy feeding route at discharge and requirement for longer duration of swallowing therapy. The COVID-19 population showed a better recovery rate after deglutition therapy and follow-up.

Introduction: Prior clinical trials have shown that low-dose, 1 to 20 parts per million (ppm) of inhaled nitric oxide (iNO) leads to short-term (less than 24 h) improvement in oxygenation in critically ill patients with acute lung injury1-2. Recent studies demonstrated antiviral efficacy of iNO when used at high dose (80 ppm and higher) 3–5.

Objectives: This study tested the hypothesis that antiviral high concentration of iNO administered early after the onset of infection might be beneficial in critically ill patients with acute hypoxemic respiratory failure due to coronavirus disease (COVID-19) pneumonia. This study was designed to evaluate the effect of iNO on systemic oxygenation after 48 h among critically ill and mechanically ventilated patients with COVID-19 in a phase II, multicenter (four sites in the United States and one site in Sweden), single-blind, randomized (1:1), controlled, parallel-arm trial.
Methods: The study enrolled intubated and mechanically ventilated adult patients with SARS-CoV-2 infection. Participants in the treatment arm received inhaled NO at 80 ppm for the first 48 h after enrollment. After the first 48 h of treatment, the gas was reduced to 40 ppm and maintained at this concentration until severe hypoxemia resolved (PaO2/FiO2 > 300 mmHg). The primary outcome of this study was the change in arterial oxygenation (PaO2/FiO2) at 48 h. The secondary, safety and exploratory outcomes are shown in the results. Sample size calculation demonstrated n = 100 in each group (n = 200 total). The primary and secondary outcomes analysis was conducted using a Bayesian framework that estimates the treatment effect conditional on several pre-specified additional variables included in the model (defined a priori: age, age2, sex, BMI, APACHE II score and SMD > 0.20: race, study site, hypertension, diabetes, malignancy, and liver disease). All study outcomes were analyzed in the modified intention-to-treat population.
Results: shown in Table and Figure.
Conclusions: The use of high-dose iNO is safe and resulted in sustained improvement of oxygenation at 48 h compared with usual care in adults with acute hypoxemic respiratory failure due to COVID-19.
This trial also suggests that high doses iNO reduce viral load and have beneficial effects on neurological outcomes. Further studies are required to characterize the antimicrobial properties of high-dose iNO and determine the optimal dosage and duration.

	Treatment Group (94)	Control Group (99)	Difference or Odds Ratio (95% CrI)

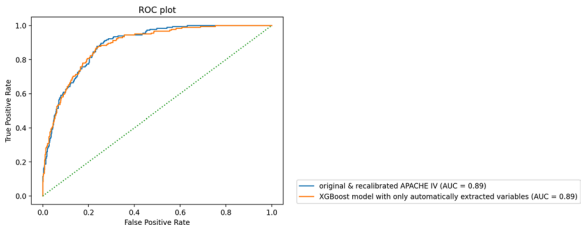
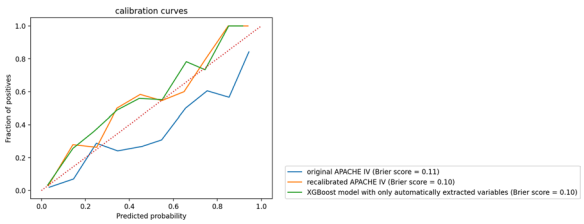
Introduction: Intensive care unit mortality prediction models, frequently used for bechmarking for audit and feedback, traditionally rely on significant manual data entry and curation. The advent of electronic health records and release of intensive care datasets allows for automated data collection. This could circumvent the need for manual data handling and has the potential to facilitate more sophisticated modeling using more data of higher granularity and from wider collection windows. However, automation also requires significant resources. Therefore, it is important to assess the comparative performance of intensive care mortality prediction models based on manually curated versus automatically extracted electronic health record data.
Methods: Data from the freely available highly granular AmsterdamUMCdb intensive care dataset was used for the systematic development and evaluation of mortality prediction models. Using the well-known original APACHE IV model as baseline, aspects in which new models differed included the extent of automatic extraction of variables, classification method, recalibration usage, and size of collection window.
Results: From AmsterdamUMCdb, 13 models were developed based on data from 5,077 admissions divided into a train (80%) and test (20%) cohort. Adding variables or extending variable collectection time windows only marginally improved discrimination and calibration. The best performing model using only automatically extracted variables and therefore no diagnosis or comorbidity information was an XGboost model. This model had similar discrimination and calibration as the APACHE IV references models with an AUC of 0.89 and Brier scores of 0.10.
Conclusions: Performance of intensive care mortality prediction models based on manually curated versus automatically extracted electronic health record data is similar. Importantly, our results suggest that variables typically requiring manual curation, such as diagnosis at admission and comorbidities, are not necessary for accurate mortality prediction. These proof-of-concept results require replication using multi-center data.



ROC plot of main comparator and APACHE IV mortality prediction models. Note that the original and recalibrated variant of the APACHE IV have the same ROC, as their discrimination does not differ.



Calibration curves of main comparator and APACHE IV mortality prediction models evaluated on the test set in 10 deciles

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000818

Introduction: Sepsis is a severe and often fatal infectious disease, and immune imbalance is a critical factor contributing to its high mortality rate. Investigating the mechanisms behind the immune imbalance in sepsis is crucial to promote its precise treatment and reducing mortality.
Objectives: This study aimed to screen and identify critical genes associated with immune imbalance in sepsis, thereby improving clinical decision-making precision and promoting the development of precision medicine.
Methods: We analyzed the GSE65682 dataset from the Gene Expression Omnibus (GEO) using the ssGSEA algorithm to distinguish immune cell infiltration in different sepsis samples, and the E-MTAB-7581 dataset was used to validate the effect of hydrocortisone in different subgroups. We then used the Weighted Gene Correlation Network Analysis (WGCNA) and protein–protein interaction (PPI) to screen genes most related to immune infiltration. Peripheral blood samples from mice were used to confirm the expression changes of hub genes. We focused mainly on *TBX21*, which encodes the transcription factor T-bet and plays a critical role in the balance of Th1/Th2, and Th17/Treg. Therefore, the genetically engineered mice with specific overexpression of *Tbx21* in CD4+T cells were constructed to verify the role of T-bet in the immune imbalance in sepsis.
Results: Sepsis samples were divided into two sub-groups based on their level of immunity. The group with a higher immunity score, when treated with hydrocortisone, showed a significant reduction in mortality ($P = 0.0493$). Additionally, *TBX21*, *PRF1*, *IL2RB*, and *GNLY* were identified as hub genes associated with the immune imbalance in sepsis. The expression of all four hub genes showed significant differences between healthy and septic mice. Furthermore, Kaplan–Meier survival analysis revealed that the high and low expression groups for each hub gene had statistically different outcomes ($P < 0.05$). Genetically engineered mice overexpressing *Tbx21* in CD4+T cells exhibited significantly improved survival compared to the control group after cecal ligation and puncture ($P = 0.0152$).
Conclusions: *TBX21*, *PRF1*, *IL2RB*, and *GNLY* are associated with sepsis severity and clinical immune-related indicators. Overexpression of *Tbx21* in CD4+T cells improves sepsis survival, which may be involved in the simultaneous improvement of Th1/Th2, Th17/Treg imbalance in sepsis by T-bet. These findings may help in the development of precision medicine for sepsis treatment.

Analysis of pediatric population receiving Home Mechanical Ventilation

E. Ha[1]
[1]Pediatrics, ASAN Medical Center, Seoul, Republic of Korea
Correspondence: E. Ha
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000819

Introduction: Home Mechanical Ventilation (HMV) is one of the alternative option that can replace the mechanical ventilation treatment in the intensive care unit. In the early days, HMV were applied to children with neuromuscular disease. However, not only does the number of patients applying HMV increase, but it is also widely applied in more diverse diagnosis over the years.
Objectives: The aim of this study was to provide a descriptive analysis of pediatric population receiving HMV. So we tried to find out the changes of patients' indications of HMV and the outcomes after HMV application.
Methods: This is a retrospective, observational cohort study of consecutive pediatric patients receiving HMV after admission in Pediatric Intensive Care Unit in Asan Medical Center Children's hospital between January 2003 and December 2022. Data were collected from reviewing the electronic medical records.
Results: Total 160 patients were enrolled and the median age was 5.5 years and male patients accounted for 61.3% ($n = 98$). For 20 years, the number of patients applying HMV continued to increase every year, and since 2016, it has more than doubled compared to before. The most common indication for applying HMV was neuromuscular disease (53.1%) and followed by pulmonlolgic disease. Since 2016, HMV has been applied due to heart failure, and these patients accounted for 10.0%. Compared to neuromuscular diseases, the number of patients applying due to heart failure and respiratory failure showed an increasing trend. 30.6% of patients with HMV died, and the main reason of death was exacerbation of underlying diseases (58.5%). 61.3% of the survivors were in continuous use, and the rest improved and weaned HMV. As the number of patients applied HMV increases, the number of patients in use is also increasing, but the mortality rate is gradually decreasing, and the number of patients who are improving and discontinued HMV is increasing. 45.6% of patients who applied due to heart failure and respiratory failure improved and discontinued HMV, but only 0.07% of patients who applied HMV due to neuromuscular problems stopped HMV.
Conclusions: The results of this study showed changes in patients who applied HMV for 20 years. It could be seen that the patient's prognosis changed by applying HMV to more diverse patients. In particular, patients who applied due to heart failure and respiratory failure improved compared to patients who applied ventilators due to neurological problems, showing a greater possibility of stopping HMV. This is considered to be a very important evidence when making a decision on the application of HMV.

Sepsis induced cardiomyopathy assessed by speckle tracking as a predictor of mortality in septic patients. A prospective study in Argentina

F. Daldoss[1], L. Bertorello[2], A. Sosa[3], B. Tort[1], J. Roberti[1], J. Ruiz[1], G. César[1], A. Matarrese[1], M. Castillo[1], J. Osatnik[1], P. Merlo[4]

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000820

Introduction: Sepsis-induced myocardial dysfunction (SIMD) is a frequent condition, often overlooked in intensive care units (ICUs). Despite its significance, the extent of its impact on prognosis remains unclear (1,2). Although ejection fraction (EF) is the most used diagnostic method, left ventricular (LV) global longitudinal strain (GLS) by speckle tracking has shown to be more sensitive in detecting early myocardial dysfunction in septic patients (2). When detected by GLS, SIMD has been associated with increased mortality; however, evidence is not conclusive (3–5).
Objectives: To eterminе whether a decrease in GLS can be used as a predictor of mortality in individuals with sepsis or septic shock in an ICU.
Methods: Prospective cohort study of septic patients admitted to ICU. Myocardial dysfunction was assessed using transthoracic or transesophageal echocardiography within 24 h of septic event (Sepsis 3) (6) using either a General Electric Vivid IQ or PHILIPS CX50 multiplanar TEE probe. Clinical characteristics, cardiac markers including ProBNP and Troponin T were recorded. Relevant variables for multiple regression analysis were selected based on the principle of parsimony and/or $p < 0.1$ values in univariate analysis. Significance was set at $p < 0.05$.
Results: A total of 101 patients were included. Global ICU mortality was 34%, 70% patients met septic shock criteria. The following characteristics were significantly higher in nonsurvivors compared to survivors: age, APACHE II and SOFA scores, proportion of mechanical ventilation, septic shock, PRO-BNP and troponin T levels within the first 24 h, proportion of vasopressor use, heart rate, LVEF by simpson method, and E/e'. Values of LV ventricular longitudinal strain, left ventricle 2 chamber, 3 chamber, 4 chamber strain and GLS were also significantly different (Table 1).
.

Table 1 (abstract 000820) Patients' characteristics

Characteristics	Total n = 101	Survivors n = 66	Nonsurvivors n = 35	P value
Age, years	67.0 ± 15.0	63.8 ± 16.3	73.1 ± 9.6	0.0028
Male, n(%)	59(58.4)	38(57.6)	21(60)	0.814
APACHE	15.1 ± 6.8	14.0 ± 5.8	17.2 ± 7.9	0.0206
Heart beat, /min	95.1 ± 21.5	91.0 ± 20.7	102.9 ± 21.1	0.014
PRoBNP base, pg/ml	6745.2 ± 10,774.2	4279.5 ± 5721.4	11,078.9 ± 15,420.4	0.0033
Troponine T at baseline,pg/ml	95.3 ± 176.2	55.0 ± 80.3	164.0 ± 258.3	0.0036

In univariate analysis, age, SOFA, EF and GLS were associated with risk of ICU mortality. In the multivariate analysis, controlling SOFA, age and vasopressor therapy, GLS remained the independent predictor of ICU mortality in septic patients (Odds ratio 0.77, 95%CI 0.6297–0.9391; $p = 0.010$). Receiver operating characteristic curve showed an area under curve of 0.78 (Sensitivity: 87.1%, Specificity: 60.3%) using LV GLS of − 15.1% as a predictor of ICU mortality (Table 2).

Multivariate analysis

Variable	OR	SE	P	95%CI
Age	1.11	0.037	0.003	1.0349– 1.18176
SOFA	1.22	0.139	0.081	0.9758 – 1.5259
Vasopres. inotr	8.80	5.800	0.001	2.4205—32.026
LV GLS	0.77	0.078	0.010	0.6297 – 0.9391

Conclusions: Our findings show GLS is a reliable predictor of ICU mortality. These results align with previous research that has shown no correlation between systolic cardiac dysfunction diagnosed by EF and mortality in septic patients (7). GLS can be a valuable tool for diagnosing and predicting outcomes in individuals with SIMD. Further large-scale studies are necessary to establish the optimal cutoff point in this population.

Association between renal replacement therapy initiated before or after extracorporeal membrane oxygenation cannulation with in-hospital mortality in COVID-19 patients

A. Franci[1], F. Galas[1], H. Fernandes[1], L. Pastore Junior[2], A. Rosario[2], L. Baracioli[1], R. Saretta[1], M. Mourao[3], J. Moraes[1], M. Dias[1]; L. Drager[1]; R. Kalil-Filho[1]

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000821

Introduction: Extracorporeal membrane oxygenation (ECMO) can be a lifesaving measure for patients with severe acute respiratory distress syndrome (ARDS) and was largely employed to support patients with severe forms of COVID-19 infection who evolved with refractory hypoxemia and hypercapnia.[1] Acute kidney injury (AKI) is a frequent complication among patients on ECMO, and around 50% of these patients require renal replacement therapy (RRT) [2] resulting in increased morbidity and mortality.[3] However, the association between timing of RRT initiation (before or after ECMO cannulation) and outcomes is still a matter of debate with conflicting data in the literature. [4–6].
Objectives: The main objective of this study was to evaluate the impact of AKI and timing of RRT initiation on hospital mortality in COVID-19 ECMO-supported patients.
Methods: This was a retrospective study which included consecutive hospitalized adult patients, from April 2020 to August 2021, with a confirmed diagnosis of COVID-19 and severe ARDS requiring support with veno-venous (VV) ECMO, in two hospitals in Brazil. All patients who required RRT were submitted to continuous RRT (CRRT) directly connected to the ECMO circuit. Univariate analysis for the association of AKI, need for RRT, RRT initiated before and after ECMO cannulation with in-hospital mortality were performed using the chi-square and Fisher exact tests when appropriate. These variables were then included in a multivariable stepwise Cox proportional hazards regression analysis model adjusting to patients' baseline characteristics such as age, sex, comorbidities (hypertension, diabetes, dyslipidemia, obesity, coronary artery disease, chronic kidney disease, pulmonary disease and malignancy) and the ICU admission SAPS-3.
Results: Eighty-five COVID-19 critically ill VV-ECMO-supported patients were included during the study period. The mean age was 59 ± 13 years, 15% were women, more than 85% had at least one previous chronic condition, mean SAPS-3 at ICU admission was 54 ± 12 and overall in-hospital mortality was 47%. AKI was diagnosed in 44 (51.8%) patients, 30 (35.3%) patients required RRT, 16 initiated RRT before and 14 after ECMO cannulation. Patients who evolved with AKI were older (63×54 years, $p = 0.001$), had higher SAPS-3 (57×52 points, $p = 0.039$), and had a higher prevalence of hypertension ($64\% \times 40\%$, $p = 0.030$), coronary artery disease ($18\% \times 3\%$, $p = 0.031$) and cancer ($23\% \times 5\%$, $p = 0.028$). There were no significant baseline characteristics differences between patients who initiated RRT before or after ECMO cannulation. In-hospital mortality related to each group of patients is shown in Figure 1. Results from the cox proportional hazards regression analysis are depicted in Table 1, showing that RRT initiated after, but not before ECMO cannulation, remained independently associated with higher in-hospital mortality.

Table 1 (abstract 000821) Multivariable stepwise Cox proportional hazards regression analysis with predictors associated with in-hospital mortality

	Multivariable analysis		
	HR	***95% CI***	***p-value***
Age, per additional year	1.04	1.01 – 1.07	0.018
SAPS-3	1.04	1.01 – 1.07	0.008
AKI	2.06	0.95 – 4.49	0.069
RRT after ECMO	2.73	1.22 – 6.13	0.015
RRT before ECMO	1.05	0.41 – 2.73	0.918

SAPS-3: Simplified Acute Physiology Score III; AKI: acute kidney injury; RRT: renal replacement therapy; ECMO: extracorporeal membrane oxygenation.
Conclusions: In this retrospective analysis, RRT initiated after ECMO cannulation was associated with poor in-hospital outcomes, independently of patients' baseline characteristics, whereas AKI and RRT initiated before ECMO cannulation were not. There is still conflicting data surrounding this issue and efforts should be made to clarify and guide clinical practice on the indication for RRT in ECMO-supported patients. This could lead to a more rational prescription of RRT, identifying patients more likely to benefit from this therapy, and ultimately optimization of technical and personnel resources.

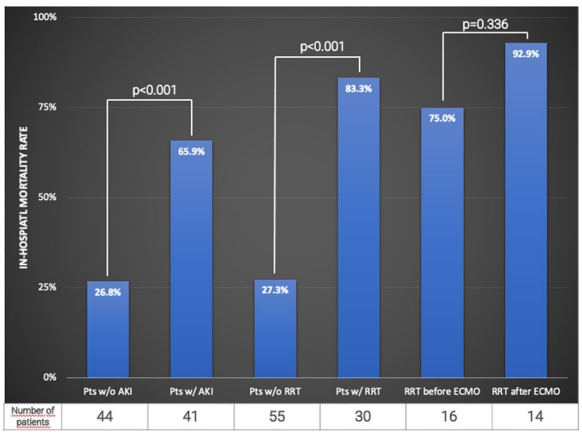

Figure 1 (abstract 000821) In-hospital mortality comparison between patients (pts) with (w/) and without (w/o) acute kidney injury (AKI); patients with and without need for renal replacement therapy (RRT); and RRT initiated before and after extracorporeal membrane oxygenation (ECMO)

Fluid responsiveness requires context: Coexistence of fluid responsiveness and fluid intolerant states in critically ill patients

F. Munoz[1], P. Born[1], C. González[1], M. Bruna[2], R. Ulloa[3], V. Philp[1], R. Mondaca[1], J. P. Blanco[1], J. Bakker[4], F. Miralles[5], P. Rola[6], E. D. Valenzuela Espinoza[1], G. Hernandez[1], R. Castro[1], G. A. Ospina-Tascón[7], E. Kattan[1]

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000822

Introduction: Fluid responsiveness (FR) is frequently assessed to guide fluid administration in order to optimize the hemodynamic state of critically ill patients. However, fluid overload is associated with higher mortality, acute kidney injury, and prolonged duration of mechanical ventilation. The novel concept of fluid intolerance (FI) integrates hemodynamic, echographic, and clinical signals to identify the deleterious effects of fluids during the resuscitation process. However, the degree of FR and FI signals coexistence has yet to be established.
Objectives: To describe the coexistence of FR and FI signals in mechanically ventilated critically ill patients within the first 24 h since ICU admission.
Methods: A multicenter prospective observational study was performed at Hospital Clínico UC Christus and Hospital de Quilpué, Chile. The study was approved by the local IRB's. Mechanically ventilated patients > 18 years, requiring vasopressor treatment, an ICU stay < 24 h, and adequate echographic windows were consecutively recruited and assessed at a single time point. Measurements included demographics, hemodynamics, tissue perfusion, FR and FI status. FI was defined by the presence of any of the following: CVP > 12 mmHg, Venous excess ultrasound score (VExUS) equal to or higher than 1, Lung ultrasound score > 10, and E/e' ratio > 10. Results are shown as median [IQR] or n(%). Mann–Whitney U or Fisher's exact test were used when appropriate. A $p < 0.05$ was considered statistically significant.
Results: 50 patients were included, of which 52% were female. Diagnosis: sepsis 34%, neurocritical disease 12%, respiratory failure 22%, hemorrhagic shock 10%, post surgery 16%, other 6%. Age 59 [42–69] y, SOFA score 9 [7–11], and APACHE-II score 16 [11–20]. At recruitment, patients had a fluid balance of 1300 [100–3247] ml, norepinephrine requirements of 0.1 [0.07—0.15]mcg/kg/min, lactate 1.6 [1.1—3.7] mmol/L and CRT 3 [2–4] s.
To test FR, pulse pressure variation was used in 82%, stroke volume variation in 8% and passive leg raising against velocity time integral (VTI) in 8% of cases. 46% of the study population was categorized as Fluid Responsive (FR+). FR+ and FR− had a similar fluid balance (1929 [531–4913] ml vs 1205 [89–2865] ml ($p = 0.5$), respectively). As seen in Fig 1, the presence of at least one signal of FI was similar in FR+ and FR- groups (60% vs 55%, $p = 0.7$). 30% of FR+ patients had an altered VExUS score, while 41% in the FR- group ($p = 0.4$). Echocardiographic LV and RV function was similar in both groups (FAC 67 [48–70.5] % vs 65.8 [56–74.75] %, $p = 0.38$), (TAPSE 19 [18–25] vs 23 [19–25], $p = 0.15$).
Conclusions: Fluid intolerance signals are present in both fluid responsive and unresponsive patients. In FR+ patients, contextualization of fluid challenges according to FI signals might avoid potential harm. Further studies should assess the clinical relevance of these results and the impact of personalized fluids resuscitation strategies.

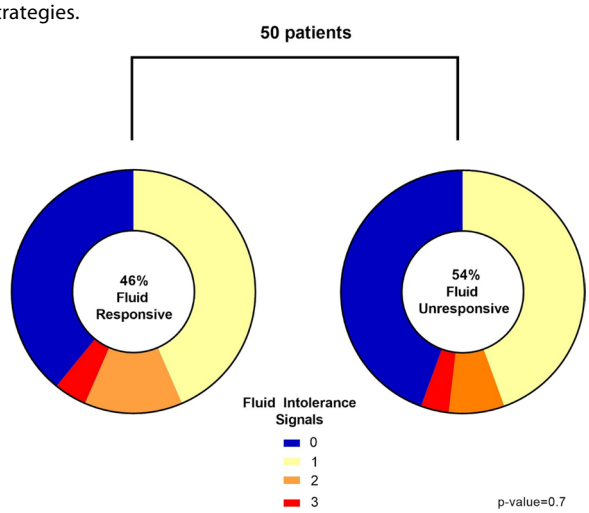

Fig. 1 (abstract 000822) Distribution of fluid intolerance signals in both fluid responsive and fluid unresponsive groups

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000823

Introduction: The incidence of Hospital Acquired Infection (HAI) is high in intensive care units (ICUs) and HAI adversely affects the prognosis of the patient. Hand hygiene (HH) is the most effective and economic way to prevent HAI. HH is more important in countries with limited medical resources such as Iraq. This study was conducted to find improvements from the survey of HH at ICUs in Iraq.
Methods: The Iraq Medical City and Soonchunhyang University Medical Center has performed survey of the project supported by Korea International Cooperation Agency on HH compliance at ICUs (32beds) in Iraq Medical City from from. Survey materials were developed based on the World Health Organization Guideline. The survey on knowledge and perception of HH and hand contamination test was conducted. Based on hand plate criteria, hand contamination was classified into low (1–9 Colony Forming Unit, CFU) and high (> 10 CFU) groups. The HH compliance monitoring was performed by direct observation. Whether to perform only hand rub or wash is expressed as "compliance (yes/no)", and in all 6 steps as "compliance(yes and 6 steps)".
Results: The level of HH knowledge and perception of 30 health workers at ICUs were 55.8 ± 10.5 and 58.0 ± 29.0, respectively. In the low hand contamination group, knowledge and perception scores were high, but only perception scores were statistically significant (60.0 ± 0.0 vs 55.3 ± 11.0, P = 0.42, 82.7 ± 12.9 vs 55.3 ± 29.1, P = 0.03). Of 125 cases, compliance (yes/no) was 83%, but compliance (yes and 6 steps) was 18%. Technicians had the lowest rate of compliance (yes/no) (70%) and a compliance (yes and 6 steps) of physical therapist, technician and janitor was 0%. Among the 6 steps of HH procedure, the fingertips (30%) was the lowest.
Conclusions: This study is meaningful to understand the current status of HH activities at ICUs in Iraq. Overall hand hygiene knowledge and perceptions and the 6 step hand hygiene compliance were low. In the future, there will be a need for training and monitoring with a focus on these areas.

Table 1 (abstract 000823) Result of HH knowledge and perception score by Low and high CFU

	Total (N=30)	Low(1-9) CFU (N=3)	High(>9) CFU (N=27)	P-value
HH knowledge	55.8 ± 10.51	60.0 ± 0.0	55.3 ± 11.0	0.42
HH perception	58.02 ± 29.02	82.7 ± 12.9	55.3 ± 29.1	0.03

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000824

Introduction: Spontaneous breathing trials (SBT) may be performed with or without pressure support (PS). Although previous studies have shown that SBT performed with PS and/or PEEP may decrease respiratory effort compared to T-piece, no study has performed a comprehensive evaluation of the physiological effects of inspiratory PS during a SBT.
Objectives: To determine the physiological effects of adding inspiratory PS during a SBT in critically ill patients.
Methods: This was a prospective physiological study approved by the Institutional Scientific Ethics Committee of Pontificia Universidad Católica de Chile. Inclusion criteria were age > 18 years, mechanical ventilation (MV) for at least 48 h for an acute respiratory failure (PaO2/FiO2 < 300 mmHg), and whose attending physician planned to perform a SBT. Informed consent was obtained from the legal guardian. Before performing the SBT, a catheter with esophageal and gastric balloons, and electrodes to record the electrical activity of the diaphragm (EAdi), was placed (Neurovent Research Inc). In addition, an electrical impedance tomography (EIT) belt was placed around the chest (Enlight, Timpel). All patients underwent a SBT with positive end-expiratory pressure (PEEP) of 0 cmH2O and PS of 0 cmH2O for 30 min, after which the PS was increased to 8 cmH2O for another 30 min. At the end of each phase waveforms from esophageal and transdiaphragmatic pressures, EAdi, and EIT were analyzed together with usual clinical signs and arterial and venous blood gases.
Results: Fifteen patients (6 female) aged 59 ± 15 years were included. Patients had been on MV for 7 ± 3 days. Inspiratory PS significantly reduced the work of breathing, demonstrated by a decrease in esophageal pressure swings and pressure–time product per minute of 48% ($p = < 0.0001$) and 45% ($p = < 0.0001$), respectively. Furthermore, PS significantly reduces respiratory rate ($p = 0.004$) and rapid shallow breathing index (RSBI) ($p = 0.002$) and redistributed ventilation towards non-dependent areas, demonstrated by the increased anterior-to-posterior ventilation ratio ($p = 0.001$). On the other hand, respiratory drive also decreased, demonstrated by a reduction in EAdi ($p = 0.038$) and P0.1 ($p = 0.0001$). However, no differences were found in tidal volume, minute ventilation, gas exchange, hemodynamics, or cardiovascular stress biomarkers.

Variable	SBT: PEEP 0 PS 0	SBT: PEEP 0 PS 8	P value

Respiratory rate, bpm	26 ± 6	22 ± 5	**0.0044**
Tidal Volume, ml	370 [321–525]	437 [362–488]	0.1793
RSBI	67 ± 25	53 ± 19	**0.0028**
ΔEAdi, μV	12 [7.0–16.0]	7 [4.2–14.0]	**0.0389**
Pdi/ΔEAdi cmH2O/μV	0.74 [0.58–1.26]	0.67 [0.59–1.36]	0.2661
ΔEELIglob, UA	− 6.5 [− 20.9–2.1]	− 5.1 [− 18.5–8.3]	0.5016
A/P Ratio	0.51 ± 0.29	0.76 ± 0.39	**0.0011**
PaO2/FiO2, mmHg	219 [209–272]	229 [203–250]	0.2952
PaCO2, mmHg	39 [36–43]	37 [34–39]	0.0840
pH	7.43 [7.41–7.47]	7.46 [7.44–7.46]	0.1055
P 0.1	0.9 [0.5–1.7]	0.5 [0.3–0.85]	**0.0001**
SvcO2, %	77 ± 7	76 ± 5	0.9102
Mean arterial pressure	99 ± 15	99 ± 18	0.7515
Heart rate, bpm	90 ± 14	87 ± 14	0.1875
NT-proBNP, pg/ml	271 [120–369]	260 [117–365]	0.9999
Troponin C, pg/ml	12.6 [6.9–28.4]	11.9 [6.8–29.1]	0.6250

Conclusions: Increasing inspiratory support from 0 to 8 cmH2O during a spontaneous breathing trial in patients with acute respiratory failure reduces the work of breathing and respiratory drive, while also increasing dynamic lung compliance.

Association between single lactate level and lactate dynamics, and neurological outcome in out-of-hospital arrest (OHCA) patients treated with TTM

J. Lee[1]
[1]Emergency Medicine, The Catholic University of Korea Seoul St. Mary's Hospital, Seoul, Republic of Korea
Correspondence: J. Lee
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000826

Introduction: Lactate is a product of pyruvate reduction during glycolysis. Increased serum lactate levels in cardiac arrest patients are attributed to anaerobic glycolysis due to tissue hypoxia. Therefore, the level of lactate and lactate clearance rate are likely to be associated with cardiac arrest outcomes. However, the prognostic values of these lactate-related variables on neurological outcomes have not been consistent among different clinical studies.
Objectives: We aim to evaluate the association between serum lactate variables and long-term neurological outcome, and their interactions with cardiac arrest etiology and arrest rhythm.
Methods: This retrospective observational study based on a prospectively collected registry of out-of-cardiac arrest (OHCA) patients was conducted in a single tertiary hospital from February 2009 to September 2022. During the study period, serum lactate levels were serially measured at 0, 12 and 24 h after return of spontaneous

circulation (ROSC). We also calculated lactate clearance ([lactate level at 0 h—lactate level at 12 or 24 h]/lactate level at 0 h × 100) and the time-weighted mean lactate as a marker of cumulative lactate production over time. The primary outcome was poor neurologic outcome (Cerebral Performance Category 3–5) after 6 months. Prognostic performance was assessed by the area under the receiver operating characteristic (ROC) curve (AUC), and the adjusted odds ratios (ORs) of poor neurological outcomes were calculated in variables multivariate logistic regression models. Interactions between lactate variables and cardiac arrest etiology and arrest rhythm were evaluated by subgroup analysis.

Results: Among the 413 patients with TTM after OHCA, a total of 351 patients were included in this study. After 6 months, 122 patients exhibited a good neurological outcome and 229 patients exhibited a poor outcome. Serum lactate levels at all time points and time-weighted mean lactate levels in the poor outcome group were higher than those in the good outcome group (all p-values < 0.001). Lactate clearance statistically differed between outcome groups at 24 h, but not at 12 h (p = 0.708). ROC analysis revealed that serum lactate levels at 0 h, 12 h and 24 h, time-weighted mean lactate, and lactate clearance at 12 h and 24 h had an AUC of 0.68 (95% confidence interval [CI], 0.63–0.73), 0.68 (95% CI, 0.63–0.73), 0.77 (95% CI, 0.72–0.81), 0.74 (95% CI, 0.69–0.78), 0.52 (95% CI, 0.47–0.58) and 0.61 (95% CI, 0.55–0.66), respectively. In multivariate models, higher serum lactate levels at all time points were associated with poor neurologic outcome (OR 1.09 [95% CI, 1.02–1.16], OR 1.16 [95% CI, 1.03–1.30], and OR 1.38 [95% CI, 1.17–1.63], respectively), whereas among lactate dynamics, time-weighted mean lactate was only an independent predictor of neurologic outcome (OR 1.29 [95% CI, 1.12–1.49]). AUCs of single lactate levels and lactate dynamics in OHCA with non-cardiac etiology and non-shockable rhythm were higher than those with cardiac etiology and shockable rhythm.

Conclusions: Single lactate levels, particularly at 24 h following ROSC and time-weighted mean lactate level during 24 h were independent predictors of neurologic outcome in OHCA patients treated with TTM. However, lactate clearance was not associated with neurologic outcome. The prognostic ability of these lactate-related variables varies depending on the etiology of cardiac arrest and the initial rhythm.

The effect of the academic turnover on the clinical outcomes of the sepsis patients

S. Lee[1], H. Kim[1], W. Kim[1], K. Sungjin[1], S. Ahn[1], J. Park[1], H. Cho[1]
[1]Emergency Department, Korea University Ansan Hospital, Jeokgeum-ro, Danwon-gu, Ansan-si, Gyeonggi-do, South Korea, Ansan-si, Republic of Korea
Correspondence: S. Lee
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000828

Introduction: Many studies have been conducted on the effect of the academic turnover period. Little has been studied on whether there is a turnover effect in sepsis. It is important to recognize sepsis early and treat it appropriately according to the sepsis bundle. It can be assumed that the prognosis of sepsis patients will deteriorate if a doctor who lacks experience in turnover period quickly does not recognize sepsis and the proper treatment is delayed. We hypothesized that physician turnover has resulted in worse outcomes for sepsis patients admitted in the academic turnover period.

Methods: This study was performed at the general ED of a tertiary teaching hospital with an annual census of 50,000 patients. We used observational data from the prospectively collected sepsis registry from January 2018 to December 2021. In Korea, the post graduate medical education (PGME) consists of a one-year internship, followed by four years of residencies, and one or two years of fellowships. Most new trainees and staffs start their duty on March 1st. Therefore, March is referred to as the turnover period. Patients hospitalized in February were excluded from the analysis because the academic turnover period overlapped. The primary outcome was 30-day mortality. Secondary outcomes included Survival Sepsis Campaign (SSC) bundle adherence. The 30-day mortality, SSC bundle adherence, and hospitalization day were compared between the turnover period and the other periods.

Results: A total of 900 sepsis patients were included in the study, including 105 in the Turnover period. There was no significant difference in APACHE II score and SOFA score between the turnover period and non-turnover period. The 30-day mortality of patients in the turnover period was higher than in the non-turnover period (49.0% vs 28.1%, p < 0.001). However, there was no significant difference in SSC bundle adherence (41.9% vs 46.5%, p = 0.405). Multivariable Cox proportional hazard regression showed that the turnover period was associated with mortality in sepsis patients after adjusting for confounders (adjusted HR, 1.880; 95% CI 1.357–2.604). Length of ED stay, length of hospital stay, and length of ICU stay showed no significant difference.

Table 1 (abstract 000828) Multivariable Cox proportional hazard regression analysis of 30-day mortality

Variables	aHR (95% CI)	p-value
Age	1.025 (1.014–1.037)	< 0.001
Malignancy	1.724 (1.322–2.248)	< 0.001
Presence of Shock	1.476 (1.062–2.052)	0.021
SOFA Score	1.090 (1.043–1.139)	< 0.001
Initial Serum Lactate	1.119 (1.082–1.157)	< 0.001
Overall SSC Bundle Adherence	0.722 (1.357–2.604)	0.0136
Admission in Turnover Period	1.880 (1.357–2.604)	< 0.001

Conclusions: Academic turnover was associated with 30-day mortality in sepsis patients; however, SSC bundle adherence in the ED was not significantly different depending on the periods. These results suggested that the cause of the increase in mortality in the turnover period may be related to unmeasured in-hospital management. To our

knowledge, this is the first study to report a positive physician turnover effect in patients with sepsis.

Acute respiratory distress síndrome (ARDS) vs COVID-19-associated ARDS (CARDS): clinical characteristics and outcomes in a cohort of mexican patients

A. Esquivel Pineda[1], P. Palacios Moguel[1], J. S. Aguirre-Sanchez[1], B. A. Martinez Diaz[1]
[1]Intensive Care Unit, ABC Medical Center, Ciudad de México, Mexico
Correspondence: A. Esquivel Pineda

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000831

Introduction: Classic ARDS exhibit similarities to CARDS, however, it is the latter that has a rapid progression and multiorganic involvement leading to high rates of fatal outcomes. Despite the fact that the start of the COVID-19 pandemic was 4 years ago, there are no comparative studies on ARDS in the Mexican population. We investigated and compared the clinical, echocardiographic and laboratorial outcomes in a cohort of critical patients hospitalized with CARDS and ARDS at a single hospital center.
Objectives: To assess and establish a relationship between the clinical, echocardiographic and laboratorial characteristics and describe the outcomes associated with mortality in CARDS and ARDS critical care patients.
Methods: We conducted a comparative, observational, retrospective study in the ICU of a third-level hospital in Mexico City from March 2020 through March 2022. Clinical, echocardiographic, and laboratory variables were compared between patients with CARDS and those with ARDS due to other etiology. A univariate analysis of selected factors and outcomes was performed, the statistical analysis was prepared in SPSS v.21.
Results: We enrolled 140 patients with a diagnosis of ARDS. The study group of COVID-19 etiology were younger males, higher body mass index, progressed to organ failure, required more frequently renal replacement therapy, and had higher SOFA score. There was no difference in rates of right ventricular dysfunction evaluated by echocardiography.

Table 1 (abstract 000831) Patient characteristics by group

Characteristic	ARDS (n = 61)	CARDS (n = 79)	p
Sex a Male Female	34 (55.7) 27 (44.3)	62 (78.5) 17 (21.5)	< 0.01

Table 2 (abstract 000831) Outcomes associated with mortality

Outcomes	ARDS (n = 12)	CARDS (n = 33)	p
Mechanical ventilation a	9 (75)	33 (100)	< 0.01
Renal replacement therapy a	1 (8.3)	13 (39.3)	0.04
RV dysfunction a	2 (16.7)	2 (6.1)	0.26

Outcomes	ARDS (n = 12)	CARDS (n = 33)	p
Length of mechanical ventilation b	1 (43.7)	22 (52)	< 0.01
ICU length of stay b	1 (28.1)	28 (47.9)	< 0.01
In-Hospital length of stay b	6 (31.8)	29 (46)	< 0.01

Data presented as: a total of patients (%), b mean (standard deviation).
Conclusions: In our population CARDS showed higher morbidity and mortality compared to ARDS. The need and duration of MV, length of stay, need of renal replacement therapy and mortality all were higher in the CARDS group, similar to global findings. An outstanding difference to the reported studies in other countries was the lack of risk for right ventricle dysfunction.

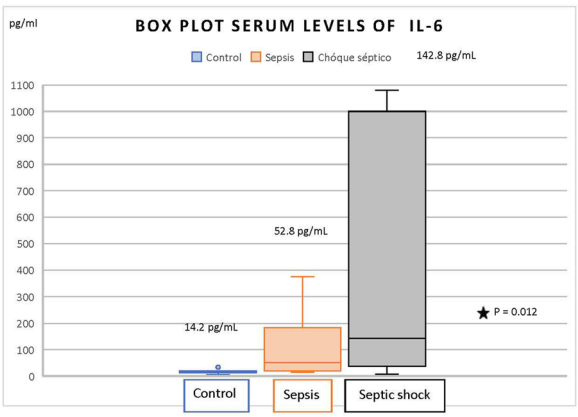
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000833

Introduction: Some cytokines including IL-6, IL-1, IL8 and TNF-a are important activators of the acute phase inflammatory response. Several biomarkers have been described, such as procalcitonin and CRP related to the severity of sepsis, however they have low sensitivity and specificity. Serum IL-6 level have been reported in healthy people ranging from 0.1–9.7 pg/mL. Elevated serum IL-6 values have been reported in patients with sepsis and septic shock. In critically ill patients, particularly with septic shock, they may exceed 1000 pg/mL.
Objectives:

1. Quantify the serum levels of interleukin 6 in patients with sepsis, septic shock and the control group (without infection) on admission to the intensive care unit.
2. Associate serum interleukin 6 values with the severity of sepsis in the intensive care unit of Hospital Ángeles Mocel.
3. To compare the serum levels of interleukin 6 in the different subgroups of patients with sepsis and septic shock taking into account the source of infection: respiratory, abdominal, urinary, neurological, and soft tissues.
4. To identify, through ROC curve analysis, the value with the highest sensitivity and specificity of interleukin 6, in patients with sepsis.

Methods: A prospective, observational and descriptive study was conducted, from January 2021 to January 2022, including information on patients who were admitted to the critical unit of Hospital Ángeles Mocel and who met the following criteria; Indistinct gender, age over 18 years, and a minimum stay of 24 h with a diagnosis of sepsis or septic shock. 3 groups were analyzed; sepsis, septic shock and control.
Serum interleukin 6 values were measured within the first 24 h of admission to the intensive care unit. APACHE II and SOFA scores were calculated in all patients upon admission. The samples were analyzed by ELISA test in the laboratory of Hospital Ángeles Mocel. The statistical analysis was carried out, taking into account the quantitative and qualitative variables, the Excel professional and VassarStats programs were used for the analysis of the results and the graphs.
Results: Information from 32 patients was included. We identified that the mean value of interleukin 6 in the control group patients was 16.5 pg / mL, the sepsis group 103 pg/mL and the septic shock group 409 pg / mL (p = 0.012).
The average values of interleukin 6 were analyzed in the different subgroups depending on the origin of the infectious focus. The highest value was reported in patients with abdominal sepsis (179 pg/mL) and abdominal septic shock (714 pg/mL).
The ROC curve for interleukin 6 showed that at values of 20 pg/mL, the sensitivity of IL-6 in the diagnosis of sepsis corresponds to 88% and the specificity to 85%, with a VVP of 96%.
Conclusions: Interleukin 6 is a biomarker with high sensitivity and specificity for the diagnosis of sepsis that could be used as a predictor of disease severity.
Our study is the first study in Mexico that quantifies serum levels of interleukin 6 in different subgroups of patients with sepsis and septic shock.
The main limitation of our study was the number of samples and the determination of interleukin 6 was performed in a single moment.

Graph 1. Box plot representing the serum levels of interleukin 6 in patients with sepsis, septic shock and control group of the ICU of the Hospital Angeles Mocel.



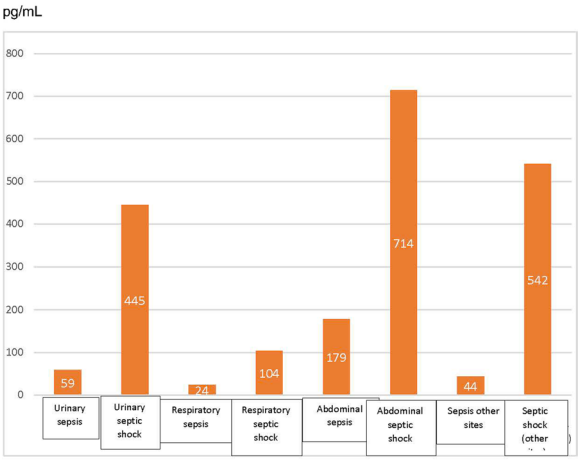
Box plot representing the serum interleukin 6 values (median, first and third quartile) in patients with sepsis, septic shock and control in the ICU of Hospital Angeles Mocel.

It was observed that the difference between the median of control and sepsis/septic shock patients is representative with a p value less than 0.05.(★).

Graph 1 (abstract 000833) .

Box plot representing the serum interleukin 6 values ??(median, first and third quartile) in patients with sepsis, septic shock and control in the ICU of Hospital Angeles Mocel
It was observed that the difference between the median of control and sepsis/septic shock patients is representative with a p value less than 0.05.()

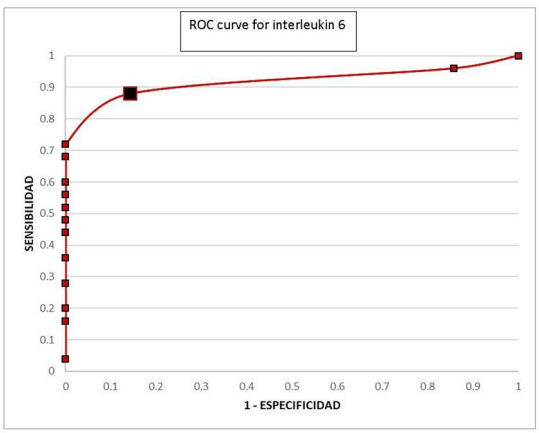
Graph 2. Serum IL 6 values in the different subgroups of patients with sepsis and septic shock in the ICU of Hospital Angeles Mocel.



Bar graph that describes the serum levels of interleukin 6, in the different subgroups of patients with sepsis / septic shock; urinary, respiratory, abdominal, other sites (neurologic and soft tissue). The average value of interleukin 6 measured in pg/mL is represented within the bars.

Graph 2 (abstract 000833) .

Graph 3. ROC curve for interleukin 6 in patients with sepsis



It was observed in the ROC CURVE that the point with the highest sensitivity was 20 pg/mL. Reported sensitivity of 88% and specificity of 85%.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000834

Introduction: Critical care syndromes demonstrate significant underlying biological heterogeneity. To address this issue, researchers are increasingly using enrichment methods to identify putative treatment-responsive subphenotypes. A parsimonious model for the allocation of acute respiratory distress syndrome (ARDS) subphenotypes has been developed that utilises the plasma cytokines interleukin-6 (IL-6) and soluble tumour necrosis factor receptor 1 (sTNFR1) along with bicarbonate from an arterial blood gas. In order to use models

like this to guide treatment decisions, automated platforms that can quantify these plasma cytokines rapidly are needed. This scoping review aims to identify and collate data on such platforms as an aid to critical care researchers who are planning trials that stratify patients based on plasma biomarkers.

Methods: A protocol for this scoping review was previously published online (https://doi.org/10.17605/OSF.IO/FU546). Searches of MEDLINE, Embase, OpenGrey, and the Espacenet patent database were conducted. References relating to automated devices that could be used to quantitatively measure human proteins in the blood, plasma, or serum were included. "Proof of concept" studies, animal studies, and semi-quantitative assays were excluded. Screening was completed by two independent reviewers and disagreements were resolved with a third reviewer.
Results: 489 records met the inclusion criteria (Figure 1). 151 protein measurement devices across 59 manufacturers and several indications were identified. The most cited devices were the Cobas series (Roche, Basel, Switzerland), the ADVIA Centaur series (Siemens, Munich, Germany), the ARCHITECT series (Abbott Laboratories, Abbott Park, Illinois), the AU5800 (Beckmann-Coulter Inc, Pasadena, California), and the LUMIPULSE G1200 (Fujirebio, Tokyo, Japan). Together these comprise most high-throughput hospital laboratory immunoassay devices. All support IL-6 measurement following the COVID-19 pandemic. Multiplex devices supporting simultaneous cytokine measurements were also identified from 7 manufacturers: Ella (BioTechne, Minneapolis, Minnesota), Evidence series (Randox Laboratories, Crumlin, Northern Ireland), IMMULITE 2000 XPi (Siemens, Munich, Germany), AFIAS (BodiTech Med Inc, Chuncheon, South Korea), sqidlite (SQI Diagnostics, Toronto, Canada), READ (EnLiSense, Allen, Texas), and BV (MeMed, Tirat Carmel Park, Israel). All multiplex devices except the MeMed BV can quantify IL-6. The Randox multiSTAT (part of the Evidence series), the BioTechne Ella, and the sqidlite can quantify both IL-6 and sTNFR1.
Conclusions: Multiple automated protein quantification devices are available. Researchers should initially leverage existing multiplex devices for precision medicine trials in critical care. In future, as evidence mounts for critical care subphenotypes, more relevant analytes (such as sTNFR1) should be supported on large high-throughput laboratory analysers.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000836

Introduction: Decreased muscle mass is associated with mortality and morbidity in various conditions including sepsis. This study aimed to investigate whether the measurement of thigh muscle mass using point-of-care ultrasound with panoramic view in sepsis patients in the emergency department is associated with mortality.
Methods: Between March 2021 to October 2022, this observational study included adult sepsis patients at the emergency department and who underwent lower extremity point-of-care ultrasounds. The cross-sectional area of the quadriceps femoris (CSA-QF) was measured on point-of-care ultrasound using panoramic view to evaluate thigh muscle mass. The primary outcome was 28-day mortality. Multivariable Cox proportional hazard model was performed.
Results: The study included 112 patients with sepsis, mean CSA-QF was significantly lower in the non-surviving group compared to surviving group (49.6 [34.3–56.5] vs. 63.2 [46.9–79.6] cm2, $p=0.002$). Each cm2 increase in the mean CSA-QF was independently associated with decreased risk of 28-day mortality (adjusted hazard ratio 0.961, 95% Confidence Interval (CI) 0.928–0.995, $p=0.026$) after adjusting for potential confounders. The area under the receiver operating characteristic curve of mean CSA-QF for 28-day mortality was 0.722 (95% CI 0.606–0.838, $p<0.001$). Additionally, each cm2 increase in the mean CSA-QF was independently associated with decreased use of mechanical ventilator use within 24 h (adjusted odds ratio 0.95, 95% CI 0.92–0.99; $p=0.020$).
Conclusions: The measurement of quadriceps femoris mass using point-of-care ultrasound with panoramic view may be a promising tool for identifying risk factors for mortality in sepsis patients in the early stages of emergency department.

Introduction: Males tend to develop more severe COVID-19 symptoms and are more likely to die. Females have worse functional outcomes after discharge and are more likely to develop long-COVID syndrome. How sex differences influence the host response to SARS-CoV-2 infection and how this relates to outcome remains poorly understood. Understanding and identifying sex-based differences, and the mechanisms involved is crucial to help predict patient outcomes and facilitate clinical decision making in terms of treatment and precision therapies for hospitalized COVID-19 patients. Although, several proteomic studies have been conducted to identify biomarkers that predict COVID-19 severity, most of them corrected for sex in their analysis.
Objectives: This study aimed to identify sex-specific differences in the host response to SARS-CoV-2.
Methods: This project is part of a multi-center prospective study conducted at the University Medical Center Groningen. Longitudinal plasma samples, demographic and clinical information from patients with COVID-19 admitted to the general ward (severe COVID-19, n = 169), and the intensive care unit (critical COVID-19, n = 131) were collected. Forty-one circulating host response markers related to inflammation, endothelial dysfunction, adipokines, coagulation, and organ injury were measured in the plasma using Luminex multiplex assays. Differential abundance analysis was performed in a sex-stratified manner with a linear model including age, body mass index, medical center, diabetes, and corticosteroid administration as covariates.
Results: Most of critical COVID-19 patients (71%) and 54% of severe COVID19 patients were male, corroborating that males tend to develop more severe disease. Differential abundance analysis identified 16 proteins that were higher in male critical-COVID-19 compared to male severe-COVID-19 patients (IL-8, D-dimer, S100B, IL-6, Angpt2, MMP8, TNFR1, uPAR, uPA, Osteopontin, IL-13, TNFa, Pentraxin-3, P-selectin, Fractalkine, and SP-D). In contrast, only 7 proteins were higher in the plasma of female critical versus severe COVID-19 patients (IL-8, D-dimer, IL-6, Angpt2, Tie2, uPAR, and SP-D). Using a similar analysis, we identified 4 plasma proteins to be associated with mortality in males (D-dimer, IL-6, Pentraxin-3 and S100B) while we did not identify any plasma proteins to be associated with the mortality of females.

Conclusions: These results suggest that as well as common mechanisms in both sexes, differences in the host response to SARS-CoV-2 might underlie the increased susceptibility in men and highlight the need for a sex-based approach to the treatment and management of male and female COVID-19 patients.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000839

Introduction: Traumatic brain injury (TBI) is a complex condition that results in physical, cognitive, and emotional impairments. Despite extensive research, effective treatments for TBI remain elusive. Reverse translation research, utilizing clinical data to guide animal studies, is a valuable approach for identifying therapeutic targets for TBI. In this study, we aimed to investigate the correlation between Lipocalin-2 (LCN2) and interleukin-6 (IL-6) in TBI and explore the possibility of cross-regulation between them.

Methods: Plasma samples from acute TBI patients (n = 26) and healthy controls (n = 22) were analyzed for 23 cytokines and LCN2 using Luminex assay. Hierarchical clustering was performed to group the samples. Brain tissue samples from chronic traumatic encephalopathy (CTE) patients were analyzed for LCN2 and IL-6 mRNA expression and correlation. Acute and chronic TBI animal models were established, and mRNA expression and immunostaining were performed for IL-6 and LCN2. In vitro scratch injury models in astrocytes, microglia, or co-cultures were used to measure IL-6 mRNA expression. Recombinant LCN2 or IL-6 proteins were added to measure the expression of IL-6 or LCN2 mRNA, respectively. LCN2 transgenic mice were also used to measure the upregulation of LCN2 and IL-6.

Results: LCN-2 and IL-6 showed a strong correlation (correlation efficient, 0.804) in plasma samples from acute TBI patients, and hierarchical clustering grouped them together. The expression of IL-6 and its receptors is also upregulated (at mRNA level) in patients with CTE, a few different mouse models of traumatic brain injury, and in vitro scratch injury model. These results suggest an augmented IL-6 signaling in the injured brain. As both LCN2 and IL-6 are secreted proinflammatory mediators, we next explored the possibility of cross-regulation between LCN2 and IL-6. In cultured glial cells, LCN2 enhanced the expression of IL-6 in glia. LCN2 enhancement of IL-6 expression was confirmed in LCN2 transgenic mice; the LCN2 transgenic mice showed elevated levels of IL-6 mRNA and protein release.

Conclusions: The results suggest an important pathological role of LCN2-IL-6 axis forming a neuroinflammation amplification loop in brain injury conditions. The study implies the usefulness of LCN2 and IL-6 as closely related double biomarkers for TBI.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000840

Introduction: Sepsis is a major cause of worldwide mortalities requiring physician's urgent attention. To effectively simplify the decision-making process, the Surviving Sepsis Campaign (SSC) proposes time-point bundle-based approaches, but their universal efficacy is still in question. Despite their adaptation, mortalities vary significantly between hospitals, but whether these variations stem from the innate design of the bundles or hospital factors is unclear.

Objectives: This study attempts to identify hospital-level determinants of mortalities in sepsis patients and examine whether the determinants differ at the patient- and hospital-level.

Methods: Data is pulled from a prospectively collected, ongoing multicenter registry of sepsis patients. Participating hospitals are ranked based on risk-standardized mortality rates (RSMR), adjusting for patient- and hospital-level factors. Associations between the ranks and per-hospital bundle-satisfaction rates are examined. Studied bundles are 1-, 3-, and 6-h bundles with five elements each: measuring serum lactate level, drawing serum samples, administering antibiotics, bolus intravenous fluids, and vasopressors. Adjusted odds ratios of mortality (AOR) for each bundle component are derived and compared to the above associations. Uni- and bivariate analyses used a pairwise deletion, and multivariate analysis used a listwise deletion method.

Results: 11,926 patients from 19 hospitals were included in the analysis. 3,396 (28%) patients suffered in-hospital mortality. Per-hospital crude mortality rates ranged from 20.6% to 46.6%, while per-hospital RSMR ranged from 26.5% to 27.4%. Per-hospital bundle satisfaction rates varied for each element and time point. At each time point, the rates were generally lower for antibiotics and vasopressor administration and higher for bolus intravenous fluid administration and checking serum lactate levels. The rates generally increased as time points delayed. Ranks based on RSMRs showed significant correlations with 3-h lactate bundle (Spearman's rho = 0.37, p = 0.042) and 6-h lactate bundle (Spearman's rho = 0.47, p < 0.01), but not with other bundles. On the patient-level, 1-h intravenous fluids (AOR 0.49; 95% CI: 0.28–0.85), 1-h vasopressor (AOR 0.82; 95% CI: 0.71–0.95), and 6-h serum sampling (AOR 0.66; 95% CI: 0.49–0.87) showed significant associations with mortality.
Conclusions: Bundles having significant associations with mortality were different for hospital- and patient-levels. Despite the limitations of this study, including a major limitation of a small number of participating hospitals, this might suggest that bundle guidelines and their priorities should be differentially set for individual case- and institution-wise approach to sepsis.

Introduction: The use of continuous nebulization therapy as a means of drug delivery to adult asthma patients has been shown to be an effective treatment option [Buck M]. Some studies suggest that it is, in fact, a better treatment option for acute asthma patients than the intermittent treatment [Rodrigo GL].
Objectives: The aim of this study was to examine the effect of continuous nebulization at different flow rates on aerosol drug delivery in a ventilated adult patient model.
Methods: mechanical ventilator (Servo-I, Maquet, SE) was connected to a dual limb circuit (RT380, Fisher & Paykel, NZ) and a humidifier (MR850, Fisher & Paykel, New Zealand). The ventilator was set to simulate ventilation of a 75 kg adult, using low tidal volume (Vt: 6 mL/kg PWB (450 mL), I:E: 1.0:1.0, RR: 15BPM). An adult closed suction catheter mount (Halyard Health Inc., US) was placed between the wye and the endotracheal tube (ETT) (8.0 mm, Flexicare Medical Ltd., UK). A vibrating mesh nebulizer (VMN) (Aerogen Solo and Pro-X controller, Aerogen Ltd., IE) was placed at the dry side of the humidifier. A continuous nebulization tube set (Aerogen Ltd., IE) was connected to the VMN. A syringe pump (Smith Medical, US) was set at flow rates of 2 mL/hr and 10 mL/hr for a total of 3 h, delivering 5 mg/mL and 1 mg/mL of Albuterol Sulfate solution (Sigma Aldrich, US) respectively. A capture filter (RespirGard II 303, Vyaire, US) was placed between the ETT and a test lung (IMT Medical, Bachs, CH). The filter was analysed every 30 min during the 3-h test period using UV spectrophotometry (276 nm). Results are expressed as a percentage of the nominal dose placed in the nebulizer's medication cup (%). All testing was performed in triplicate.
Results: Results presented in Figure 1.
Conclusions: Both the cumulative (µg) and inhaled dose (%) delivered were greater at the higher delivery flow rate of 10 mL/hr over the three-hour treatment period. However, at the lower delivery flow rate of 2 mL/hr, there was less variation in the inhaled dose (%) delivered to the simulated ventilated adult patient. For both pump flow rates, there was no statistically significant difference between the inhaled doses (%) over the 3-h treatment (p = 0.820 for 2 mL/Hr and 0.718 for 10 mL/Hr). The findings presented in this study highlight the effects of delivery flow rate on the bronchodilator cumulative dose delivered via continuous nebulisation therapy over a three-hour treatment period.

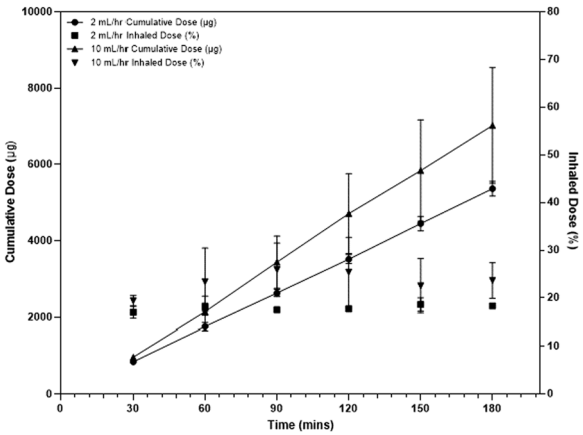

Figure 1. Summary of the cumulative dose (µg) and inhaled dose (%) delivered at 2mL/hr and 10mL/hr over a 3-hour treatment period.

Figure (abstract 000841) .

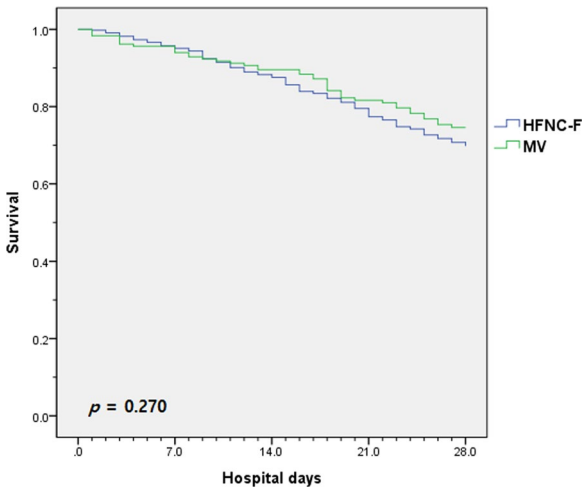
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000843

Introduction: After the COVID-19 pandemic, the use of High-flow nasal cannula (HFNC) among patients with hypoxic respiratory failure increased rapidly. Given that delayed intubation in the HFNC failure group is known to be associated with increased mortality, it is crucial to ascertain the optimal time for intubation in this group.
Methods: We conducted a 22 multicenter, retrospective, observational study from January 2020 to August 2021 in Korea. COVID-19 patients with acute respiratory failure over 19 years of age using respiratory support (HFNC, mechanical ventilation (MV)) were enrolled. Patients were divided into three groups: HFNC success (HFNC-S) group, HFNC failure (HFNC-F) group, and mechanical ventilation (MV) group for those who underwent intubation immediately without HFNC. We evaluated whether the failure of HFNC influences the mortality of COVID-19 pneumonia patients by comparing the clinical characteristics and mortality of these three groups.
Results: There were a total of 1028 patients enrolled, with 397 in the HFNC-S group, 448 in the HFNC-F group, and 183 in the MV group. The median age was 70, 60.4% of patients were male, and the 28-day mortality rate was 16.8%. Intubation rate among 845 patients using HFNC was 49.5%. HFNC-F group had higher systemic blood pressure (135.0 (122.0–148.0) vs. 128.0 (108.5–143.5), $p = 0.001$), higher diastolic blood pressure (76.0 (68.0- 85.0) vs. 71.0 (60.5–80.0), $p = 0.001$), lower D-dimer (1.32 (0.58–5.56) vs. 3.55 (1.04–19.42), $p < 0.001$), and lower lactate (1.57 (1.14–2.20) vs. 1.86 (1.35–2.66), $p < 0.001$) compared to MV group. However, there was no statistically significant difference in the 28-day mortality rate (26.8% versus 23.0%, $p = 0.270$). In multivariate Cox regression, age and SOFA were associated with 28-day mortality in HFNC-treated patients.
Conclusions: Among COVID-19 patients with hypoxic respiratory failure, the difference in 28-day mortality between the HFNC-F and MV groups was not statistically significant. In these patients, HFNC could be used as a first-line respiratory support device.



Kaplan–Meier survival estimates for the HFNC-F and MV group

Mortality review in intensive care using a bespoke mortality database, have things changed since the COVID pandemic?
J. Macallan[1], A. Myers[1], T. Samuels[1], F. Lamb[1]
[1]Critical care, East Surrey Hospital, Redhill, United Kingdom
Correspondence: J. Macallan.
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000845.

Introduction: Our intensive care unit uses a bespoke database to review our patient mortality (1). National guidance recommends that regular, multi-disciplinary mortality reviews are held by intensive care units (2). Local guidance regarding mortality reviews and categorisation of deaths was updated in 2020. All mortality cases where care was felt to be below standard should be discussed at mortality reviews and further case selection should be tailored to the clinical team (3).
Objectives: To evaluate our current mortality review process and to assess any impact that the COVID pandemic has had on this process.
Methods: Retrospective data cases from this database recorded between January 2017 and March 2023 were examined. We reviewed the time between death and presentation of cases at a mortality review between March 2022 and March 2023. Contingency analysis was performed using Fishers Exact test.
Results: A total of 871 cases were examined. Table 1 compares the data from the cases in their respective time periods. There is no significant difference between the cases reviewed and presented between the two 3-year time periods (p = 1.0). Post-hoc analysis demonstrates a significant difference between the cases reviewed and presented for the years starting Mar 20 and Mar 21 (p = 0.005). The median time between patient death and presentation at a mortality review meeting for March 2022–23 was 46 days (IQR 27–92 days).
Table 1

Time period	Total cases	Reviewed	Presented	Number of recommendations
Jan 2017 to Mar 2020	437	405 (92.7%)	244 (55.8%)	254
Mar 2020 to Mar 2023	434	317 (73%)	191 (33.2%)	164
Mar 20- Mar 21	155	127 (81.9%)	54 (34.8%)	91 (47 cases)
Mar 21- Mar 22	128	107 (83.6%)	91 (71.1%)	46 (36 cases)
Mar 22- Mar 23	154	86 (55.8%)	49 (31.8%)	29 (23 cases)

Conclusions: There has been a decrease in the overall number of cases being reviewed and presented from March 2020 onwards, but this was not statistically significant compared to the previous 3 years. Nevertheless, this decrease may reflect the additional burden and workload placed on intensive care staff by the COVID pandemic (e.g. fewer recommendations were made, which may reflect the homogeneity of the COVID pandemic population). The significant decrease in the number of cases reviewed and presented following the Mar 20- Mar 21 period is most likely explained by the widespread staff burnout experienced throughout critical care.

Reviewing and presenting all mortality cases would create a significant workload and is not in line with guidance. Our database approach allows us to identify which category cases belong to and to target those cases which require review. The time taken between death and presentation of cases has improved since our initial work which is encouraging (1). Further work is needed to ensure that we are reviewing mortality cases appropriately and effectively to facilitate learning and improvement from these.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000848

Introduction: Venous congestion is associated with mortality and can be measured by VExUS (Venous Excess Ultrasound Score). It´s described that excessive fluid therapy obtains poor results in resuscitation, however, this isn´t documented other than in the patient´s registry with high fluid balances, for which VExUS could provide support in the diagnosis of fluid overload and link with worse outcomes in patients with acute respiratory distress syndrome (ARDS).
Objectives: To determine the association with mortality presented by venous congestion by VExUS in patients with ARDS in the Intensive Care Unit (ICU).
Methods: It´s an observational, descriptive, retrospective study of a nested sample (N = 23). For the qualitative variables, frequencies and percentages were calculated. For continuous and discrete quantitative variables, Student's T test was used for normal distribution and Mann Whitney U test for free distribution. For categorical and nominal variables, the Pearson Chi Square test was performed, for quantitative variables of free distribution the measure of association was median and interquantile range, the type of distribution was determined using the Shapiro Wilk test. It ended with a Kaplan Meier graph, calculating the Long Rank. In addition to analyzing intervention with furosemide through the calculation of median survival.

Results: Patients with a degree of VExUS ≥ 1 had a survival of 28.6% and 71.4% died. In non-congestive patients (N = 16) 13 patients (81.3%) survived and 3 patients died (18.8%) with 95% CI (Figure 1).
In the secondary outcomes it was demonstrate that the portal vein pulsatility index (PI) of 32.8% and a central venous pressure (CVP) of 12.13 mmHg had a weak positive correlation of 0.383 by Pearson's r. It was also determined that a VExUS ≥ 1 together with a pulmonary artery occlusion pressure (POAP) of 12.39 had a Pearson's r of 0.442. To emphasize the importance of perfusion, a VExUS of 2.04 and a renal resistive index > 0.687 had a Pearson's r = 0.132. Patients who received furosemide had greater survival versus those who did not receive (Figure 2).
Conclusions: VexUS it´s a useful tool in the patient with ARDS that allows the identification of fluid overload and, according to this study, it is a factor predictor that can help in making clinical decisions at the patient's bedside about fluid therapy and de-resuscitation.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000849

Introduction: The application of diaries in the intensive care unit (ICU) is a valuable intervention in the prevention of long-term mental health-related impairments among patients and their relatives (1). An ICU diary is a tool where medical staff or family members record patients' experiences during ICU hospitalization, thus facilitating patients to recollect the hospitalization experience they had during ICU.
Although a digital ICU diary seems to have several advantages over a paper diary, it is challenging to properly implement and maintain this digital intervention in clinical practice. Knowledge of the influencing factors is essential in the development of a tailor-made implementation strategy to integrate the digital diary in the ICU (2).
Objectives: This study aimed to explore the determinants (facilitating and hindering factors) for the implementation of a digital diary in the ICU from the perspectives of ICU professionals, ICU survivors and their relatives.
Methods: A multicenter qualitative design consisting of focus group interviews with ICU professionals and interviews with ICU survivors and relatives was conducted between October 2022 and February 2023. The Consolidated Framework for Implementation Research (CFIR) (3) guided data collection and analysis of determinants. The CFIR identifies five domains (innovation, outer setting, inner setting, individuals and implementation process). We used directed content analysis methods to identify the determinants that could influence the implementation of a digital diary.
Results: We conducted five focus group interviews among ICU professionals (n = 31) and 10 individual or duo interviews including five ICU survivors and nine relatives. Determinants were found in all five CFIR domains. ICU professionals reported as the top three facilitators: 1) a user-friendly and easily accessible diary; 2) sufficient training and information; and 3) feedback from experiences of patients and relatives. Barriers included: 1) the preference for and advantages of a paper diary; 2) many steps required to access the diary; and 3) resistance to writing the diary by professionals. In contrast, professionals' writing in the diary was highly appreciated among survivors and their relatives. An ambiguous factor seemed sharing the diary with others, as it was reported by ICU survivors and relatives both as valuable and as a privacy issue. Finally, they found the digital diary less personal and less intimate than a paper diary.
Conclusions: This study provides insight into the most important determinants influencing the implementation of a digital diary in the ICU. Strikingly, some factors are both a barrier and a facilitator, such as writing diary entries. When developing the implementation strategy, the found facilitators can be used to overcome the barriers for ICU professionals, ICU survivors, and relatives.

Early vasopressin, prognostic impact in septic shock patients

G. Castañeda[1], R. Ruiz Cacho[1], J. Cui[1], C. Alvarez[1], C. Ramirez[1], N. Cango[1], P. García Olivares[1], J. Cedeño Mora[1], M. Artabe[1]; A. Rodriguez[1]
[1]Intensive care unit, H.G.U Gregorio Marañón, Madrid, Spain
Correspondence: G. Castañeda
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000850

Introduction: Septic shock is the most common cause of death in intensive care units and it has a mortality rate of 40 to 60%. Both catecholamine and non-catecholamine vasoactive agents are used in these scenarios. The non-catecholamine agent vasopressin is suggested to either increase MAP or reduce Noradrenaline dose requirements. However, to date, there remain unsettled questions regarding the overall mortality benefit of vasopressin in patients with septic shock.
Objectives: To analyse the prognostic impact of early vasopressin (VAP) use in septic shock patients requiring increasing doses of Noradrenaline (NAD).
Methods: Retrospective observational study, conducted on critically ill patients admitted to the Intensive Care Unit of Gregorio Marañón Hospital, between March and December 2022. As a stablished protocol, all patients received VAP when NAD exceeded 0.2 µg/Kg/min. Epidemiological data, comorbidities, severity, clinical features, invasive support, complications and outcomes were collected.
Descriptive analyses were expressed as means (standard deviation) for normally distributed quantitative variables, medians (interquartile range) for non-normally distributed variables, and as percentages for categorical data. The NAD dose impact on mortality at wich VAP was introduced was evaluated with simple logistic regression, and the dose with the best ability to discriminate the area under the curve (ROC curve). Mortality association was determined by a multiple logistic regression study, adjusted by confounding factors.

Results: Seventy patients were included, 53% were male, mean age 61 ± 16. Charlson Index 3 (2–4), and to evaluate severity of illness, APACHE II 26 ± 7, SOFA 12 ± 3. 80% required invasive mechanical ventilation for 4 days (1–15 days). Time from septic shock diagnose to NAD initiation was 3 h (1-5 h), time from septic shock diagnose to VAP initiation, 8 h (5-15 h). NAD dose when initiating VAP was 0.6 ± 0.4 µg/Kg/min. Gobal mortality was 49%.
At the univariant analysis, NAD dose when initiating VAP was related to mortality (OR 82.75; CI 95% 7.80–877.37). The NAD dose when initiating VAP has prognostic capability (ROC 0.84; CI 95% 0.74–0.94), being 0.40 µg/Kg/min the best mortality discriminating dose. Patients with NAD > 0.40 µg/Kg/min when initiating VAP, had higher mortality risk (RR 19.33; CI 95% 5.78–65.69).
In the multivariate analysis adjusted by age, severity, comorbidity, vasopressor timing and lactate, delayed VAP treatment related to NAD dose, was related to a higher mortality risk (Table 1).
Conclusions: Early-vasopressin use (with intermediate NAD dose), could improve septic shock patients pronostic.

Variable	Significance
Age	OR 0,98 (0,94 – 1,03)
Charlson	OR 1,15 (0,87 – 1,51)
APACHE II	OR 1,08 (0,96 – 1,23)
Lactate	**OR 1,57 (1,16 – 2,10)**
SOFA at ICU admission	OR 1,25 (0,92 – 1,70)
NAD treatment till shock diagnose	OR 0,99 (0,86 – 1,14)
VAP treatment till shock diagnsose	OR 0,24 (0,82 – 1,13)
NAD > 0,4 ug/Kg/min at VAP treatment	**OR 15,40 (2,87– 82,51)**

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000853

Introduction: The EEG signal recollects the process of cortical and subcortical neural networks. Intermittent 30-min routine EEG is the most standard strategy, but multiple centers have assumed continuous EEG (cEEG) monitoring, boosting the examination of the change of brain activity over time.The EEG signal is intricate, and the statement from EEG specialists may be hard to analyze for the intensive care unit (ICU) physicians. Wide-consensus classification of EEG patterns in critical care has been included in the American Clinical Neurophysiology Society (ACNS) standardized terminology. This nomenclature, initially published in 2013 and revised in 2021, has been increasingly adopted in clinical publications, and it contributes to a uniform description of the basic EEG patterns.
Objectives: Analyze the characteristics of a sample of patients admitted to the ICU with refractory status and assess the impact of continuous electroencephalography monitoring.
Methods: Our team collected prospectively in a database every patient with convulsive admitted to the Intensive Care Department. Quantitative variables are represented as mean and standard deviation if they meet normality criteria according to the Kolmogorov–Smirnov test and otherwise as median and interquartile range. Qualitative variables are expressed as frequencies and percentages. In the analytical phase of the study, a hypothesis contrast was performed for the difference in means using the Student's t statistic. The statistical measure was performed using SPSS.
Results: In 2022, the group of neurocritical patients cared for 25 patients with convulsive status admitted to the ICU. The mean age was 57; hospital admission time was 47 days (SD 9.4), ICU 10 days (IQR 5.35), and a mortality of 27%. 76% required invasive mechanical ventilation, with a median of 6 days of connection to the ventilator (IQR 2, 33). Only 28% of patients required a tracheotomy. Structural pathology was evidenced in 69%. Continuous EEG monitored 50% of the patients at some point during admission. 90% of these implied a change in the therapeutic regimen. In continuously monitored patients, the mean duration of mechanical ventilation was 17 days, the mean ICU stay was 20.8 days, and the mean hospital stay was 48.5 days. In patients monitored by conventional EEG, the mean duration of mechanical ventilation was 20 days, the mean ICU stay was 24 days, and the mean hospital stay was 51.7 days. Despite the differences observed, no statistically significant differences were found between the two groups concerning the time on mechanical ventilation or the mean stay in the ICU or hospital.
Conclusions: Continuous EEG monitoring allows the optimization of pharmacological management in most cases. We observed in our sample a shorter duration of mechanical ventilation time and ICU and hospital stay. The lack of statistical power is likely due to the sample size. More research is required on this modality of neuromonitoring and its impact on the clinical outcomes of patients with refractory seizure status.

Driving resumption of critical illness survivors: a retrospective cohort study

C. Apps[1], K. Brooks[1], J. C. Larose[1], L. Rose[2], J. Meyer[1]
[1]Critical Care, Guy's and St Thomas' NHS Foundation Trust, London, United Kingdom; [2]Florence Nightingale Faculty of Nursing, Midwifery and Palliative Care, King's College London, London, United Kingdom
Correspondence: C. Apps
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000855

Introduction: Driving resumption is an important component of recovery for many survivors of critical illness, enabling return to work, social activities, and independence. Currently, little data exists about the resumption of driving of survivors of critical illness.1
Objectives: To review the resumption of driving in a cohort of critical illness survivors who attended a critical care recovery clinic of a large

tertiary centre in the United Kingdom approximately three months following hospital discharge.
Methods: A single centre retrospective cohort study with data extracted from the medical record. Variables associated with driving resumption were modelled using logistic regression.
Results: We obtained data on 1,341 patients who attended the critical care recovery clinic between December 2017 and July 2022. Of these, 765 (57%) patients held a UK driving licence prior to admission. Patients holding a UK driving license had a mean (SD) age of 54 (14.3) and mean (SD) APACHE II score on ICU admission of 15 (4.9); 199 (26%) required ECMO. The median (IQR) lengths of ICU and hospital stay were 14 (8, 28) and 32 (17, 53) days respectively.
Of the 550/765 patients with data on driving status, 336 (61%) had resumed driving and 55 (10%) patients reported being advised not to drive. Shorter hospital length of stay (odds ratio (OR) 0.985, 95% confidence interval (CI) 0.978 to 0.992) was associated with driving resumption controlling for age and APACHE II score on ICU admission, requirement for ECMO, and ICU length of stay (Table 1).
Qualitative description of reasons why driving had not been resumed within the medical record included physical, psychological, and practical reasons. These included physical weakness, difficulty mobilising beyond the house, fatigue, breathlessness, reduced lower limb sensation, seizures, challenges associated with an ostomy, lack of confidence in driving ability, no need to drive, and no access to a car.
Table 1

Variable	OR	95% CI
Age	0.991	0.976—1.006
APACHE II score	0.987	0.949—1.027
ECMO	1.398	0.891—1.027
ICU LOS	0.995	0.986—1.004
Hospital LOS	0.985	0.978—0.992

Conclusions: Neary two thirds of patients in our cohort had resumed driving. Driving resumption was associated with shorter hospital length of stay. Reasons for not resuming driving were multifactorial but were frequently due to ongoing physical consequences of critical illness.

Renal replacement therapy in severe COVID-19, favourable longer-term outcomes in a single-centre study
H. Mahroof[1], A. Y. K. C. Ng[2], J. Martin[3], A. Conway Morris[4]
[1]John Farman ICU, Cambridge University Hospitals NHSF Trust, Cambridge, United Kingdom; [2]Department of Medicine, University of Cambridge School of Clinical Medicine, Cambridge, United Kingdom; [3]Intensive Care, Addenbrooke's Hospital, Cambridge, United Kingdom; [4]Division of Anaesthesia, Department of Medicine, University of Cambridge, Cambridge, United Kingdom
Correspondence: H. Mahroof
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000858

Introduction: Acute kidney injury (AKI) is a frequent complication seen in patients with COVID-19 infection admitted to intensive care. Increasing number of organ failures is associated with a higher ICU mortality. UK ICU data shows that 1 in 4 COVID ICU patients require renal replacement therapy (RRT), carrying > 60% mortality, leading to some prognostic nihilism preventing escalation to RRT in some patients.
Objectives: To assess the outcome of COVID-19 ICU patients managed with RRT in ICU to assess their mortality on ICU, at 4, 26 and 52 weeks, and their dependence on RRT at 26 and 52 weeks, post ICU discharge for the survivors.
Methods: Contemporaneous electronic medical records were retrospectively reviewed for all patients admitted to ICU with COVID-19 as the main or significant presenting problem over 2 years from March 2020, at a large UK university hospital. AKI was defined as per the KDIGO criteria and renal biochemistry, along with review of medical notes to assess need for RRT.
Results: 106 patients with COVID-19 and requiring RRT were identified, ICU mortality was 61% with 41 surviving to ICU discharge, including 5 patients with previous dialysis dependence. Non-survivors were older (mean age 65 vs 56) and had more severe disease (as evidenced by greater rate of ventilation, higher rate of prone positioning and greater requirement for vasopressors). Of the 41 ICU survivors, 40 (98%) survived to day 28 and 39 (95%) survived to 1 year. Creatinine returned to baseline in 14 (36%) and was less than double baseline in 35 (90%) of 1-year survivors (Figure 1). Only one new dialysis dependence developed in survivors.
Conclusions: Patients with COVID-19 and requirement for renal replacement therapy demonstrated a similar mortality rate to that previously reported in the literature. However survivors demonstrated mostly modest deterioration in renal function relative to baseline and excellent 1-year survival. RRT in ICU was not a predictor of subsequent need to dialysis. Therapeutic nihilism in this cohort is misplaced.

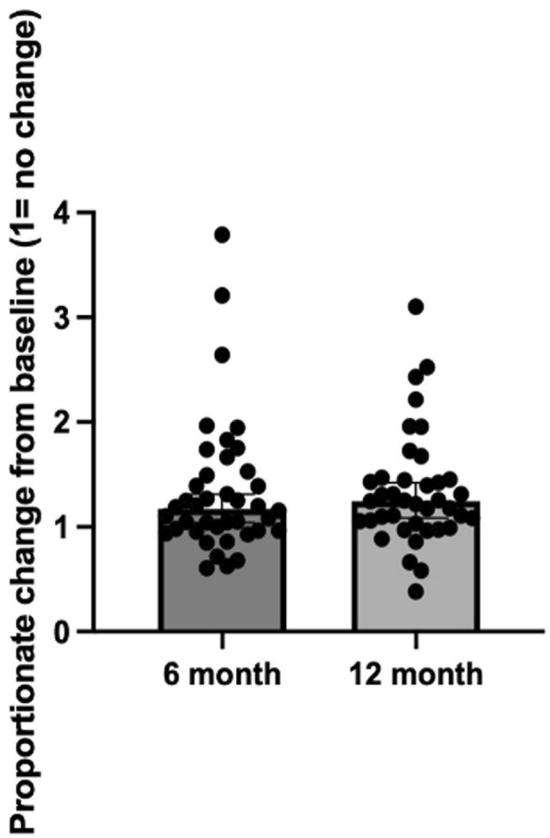

Figure 1: Proportionate change in creatinine from baseline to 6 and 12 months for survivors to 12 months

Spectrum of organisms causing blood stream infections in 2 major UK ICUs with resistance patterns over last 8 years

H. Mahroof[1], A. Y. K. C. Ng[2], J. Martin[3], A. Conway Morris[4]
[1]John Farman ICU, Cambridge University Hospitals NHSF Trust, Cambridge, France; [2]Department of Medicine, University of Cambridge School of Clinical Medicine, Cambridge, United Kingdom; [3]Intensive Care, Addenbrooke's Hospital, Cambridge, United Kingdom; [4]Division of Anaesthesia, Department of Medicine, University of Cambridge, Cambridge, United Kingdom
Correspondence: H. Mahroof
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000859

Introduction: Blood stream infections (BSI) are a source of significant morbidity and mortality in ICU patients. Whilst good clinical practices, including line insertion and management have helped reduce BSI, timely appropriate use of antimicrobial agents in suspected BSI is important. Incisive knowledge of local microbiological BSI biome is a useful indicator to base antimicrobial decision making, de-escalation and antibiotic stewardship.
Objectives: To assess all confirmed BSIs 2 large ICUs (General and Neuro ICU) at a single centre large UK university hospital over 8 years from 2015 to end of 2022. To further assess sensitivities and resistance patterns to common antibiotics and in addition to assess such patterns within some common ICU BSI organisms.
Methods: All BSI positive culture records from the above 2 ICUs over 8 years to end of 2022 were reviewed and analysed. The antibiotic sensitivity or resistances reported were also reviewed and their evolution over the 8 years were assessed.
Results: Positive blood cultures were equivalent between the units when adjusted for patient length of stay (10 per 1000 bed days). Rates increased during the COVID pandemic (2020–2021) to 13/1000 bed days in the General but not Neuro ICU. However review of organisms revealed 50% were likely contaminated cultures (Coagulase-negative Staphylococci and Diptheroids/Corynebacteria- Figure 1), giving a 'true' BSI rate of 5 and 4/1000 bed days respectively, with the 'spike' in BSI during COVID confirmed (rising to 6/1000 bed days in the General unit). The dominant organisms differed between the units (Figure 1). Resistance rates showed considerable variability, from < 5% for meropenem and amikacin to > 70% for ciprofloxacin, with evidence of rising resistance to some agents over time.
Conclusions: Despite differences in patient demographics we observed similar rates of BSI between units. The majority of positive cultures were likely contaminants, emphasising the need to improve technique for drawing blood cultures. COVID was associated with a rise in BSI, with Enterococci and Enterobacteriaceae being the most prevalent groups of organisms in this spike. Resistance rates for some antimicrobials are rising.

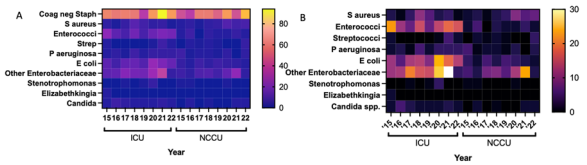

Figure 1: heat maps demonstrating the distribution of organisms identified from blood cultures. Panel A includes all organisms, whilst panel B focuses on highly pathogenic organisms only.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000860

Introduction: Post-traumatic stress disorder (PTSD) is common among survivors of critical illness. Coronavirus disease (COVID-19) in its most severe forms may require critical care and different levels of life support. Determining the impact it has had on the mental health of these patients may help to define appropriate mental health resources for the COVID-19 survivors.
Objectives: To evaluate the prevalence of PTSD and factors associated with its development among critically ill COVID-19 survivors.
Methods: This cross-sectional study among critical ill COVID-19 survivors at 1-year of intensive care unit (ICU) discharge. A validated instrument was used: the Post-Traumatic Stress Disorder Checklist-5 (PCL-5) based on the Diagnostic and Statistical Manual of Mental Disorders (DSM-5) for screening PTSD which was administered through a phone-based questionnaire. The PCL-5 can determine a provisional diagnosis of PTSD using a cut-point score of 31–33. Categorical variables are expressed as counts and percentages and were compared using the $\chi 2$ test and Fisher test; continuous variables are expressed as medians and interquartile range (IQR) and were compared using Mann–Whitney U test. A two-sided level of significance of 5% was used. Data analysis was performed using STATA version 13 ® (StataCorp LCC).
Results: A total of 388 patients 1-year after ICU discharge were analyzed; of whom 24/388 (6.18%) died; 86/364 (23.62%) did not respond to the telephone call; and 8/278 (2.88%) refused the survey, leaving

a cohort of 270 patients. 62.59% were male and the median age was 59 (48.5–66) years old, with no differences between groups. PTSD had a prevalence of 9.63% (24/270), with a median PCL-5 Score among those who did not develop the syndrome of 6 (1–14) pts vs 40.5 (34–53) pts among those who suffered the syndrome, $p < 0.001$. Patients with PTSD presented a higher consumption of psychopharmacological drugs during the month prior to the interview (72% vs 36.68%; $p < 0.001$), mainly antidepressants as a new indication (32%, 13.58%; $p = 0.02$). Factors associated with the development of PTSD were delirium in ICU (69.23% vs 43.85; $p = 0.014$); and periods of higher critical care burden (1st, 2nd and 3rd pandemic waves: 96.15% vs 4th, 5th and 6th pandemic waves: 3.85%; $p = 0.006$) (Table 1). Patients with PTSD had a worse perception of their health status as estimated by the EuroQOL Thermometer (52.5 [45–70] vs 72.5 [50–90]; $p = 0.003$).

Conclusions: PTSD affects a part of the critical ill COVID-19 survivors that is similar to other critical illnesses. It is a problem that conditions a higher consumption of psychopharmacological drugs and its development is associated with ICU delirium and with periods of higher critical care burden of the pandemic.

Effects of person-centered care and intensive care experience on post-intensive care syndrome in critical care survivors: a multi-center cohort study

J. Kang[1], H. J. Cho[1]
[1]College of Nursing, Dong-A university, Busan, Republic of Korea
Correspondence: J. Kang
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000861

Introduction: Critical care Survivors experience post-intensive care syndrome, which consists of mental, physical, and cognitive sequelae, for an extended period of time after discharge, which negatively impacts their and their families' quality of life. Risk factors for post-intensive care syndrome are diverse and mostly unmodifiable, such as demographic characteristics and pre-ICU health conditions. However, the intensive care experience of patients identified in a recent meta-analysis study as one of the risk factors is modifiable and sensitive to nursing care.

Objectives: This study aimed to examine the effects of person-centered critical care and intensive care experiences on the post-intensive care syndrome of critical care survivors.

Methods: In this prospective, multicenter cohort study, 891 adults who had been admitted to one of 19 intensive care units in Busan, Korea, for more than 24 h between May 2019 and July 2021 were included. At the time of ICU discharge, participants completed a person-centered critical care nursing questionnaire and an intensive care experience questionnaire. The Intensive Care Experience questionnaire consists of four sub-tools: "awareness of surroundings," "frightening experiences," "satisfaction with care," and "recall of experiences." Participants responded to the Post-Intensive Care Syndrome questionnaire via telephone interviews at 3, 6, and 12 months after hospital discharge. We analyzed the data of 618 participants who responded at least once out of a total of three follow-ups; missing values were processed using the multiple imputation method (Fig 1). Pearson's correlation was used to analyze the relationship between person-centered care and the intensive care experience as perceived by the participants. Using a structural equation model, the effect of person-centered care and each component of the intensive care experience on the change in post-intensive care syndrome after discharge was analyzed.

Results: The baseline data of the participants is shown in Table 1. The greater the participants' perception of person-centered care, the greater their perception of their surroundings and satisfaction with care, and the less frightening their experience. There was no significant correlation between person-centered care and the recall of experiences. In the control of demographic and clinical variables, frightening experience had a significant effect on the initial value of post-intensive care syndrome ($B = 0.132$, $p = 0.011$), and person-centered care had a significant effect on its change ($B = -0.151$, $p = 0.035$; Table 2).

Conclusions: The findings of this study suggest that a frightening experience in the intensive care unit may lead to post-intensive care syndrome, while person-centered care can alleviate it.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000864

Introduction: Hemodynamic optimization through fluid resuscitation is commonly used in critically ill patients with hypoperfusion. Recognition of patients who will benefit from volume administration still seems challenging. Some biomarkers have been related to hypovolemia states, so it is important to assess their ability to predict fluid responsiveness; likewise, the POCUS is a tool that helps to identify these patients; however, its accessibility is limited, and it has less predictive capacity than other tools.

Objectives: To determine the relationship in the evaluation of fluid responsiveness by means of passive leg raising (PLR) compared with hypoperfusion biomarkers and ultrasound parameters.

Methods: Observational, analytical, prospective study of a nested sample of patients with sepsis and/or septic shock admitted to an intensive care unit (ICU) at a Mexico City reference hospital, who were evaluated during the first 48 h of their admission.

Results: Data from 22 consecutive admissions were collected. Descriptive statistics were used to obtain the area under the ROC curve, comparing the PLR dichotomy variable vs hypoperfusion biomarkers (Table 1) or ultrasound parameters (Image 1). It was identified that the echocardiographic parameters were the best variables related to PLR in patients with sepsis and/or septic shock, being the velocity–time integral (VTI) the best parameter with an AUC ROC of 0.918, followed by the VTI variation with an AUC ROC of 0.801, inferior vena cava diameter (IVC) AUC ROC 0.788, peak lateral tricuspid annular systolic velocity (S1) of 0.778 AUC ROC, portal vein pulsatility AUC ROC 0.685 and

finally renal resistive index of 0.561 AUC ROC (image 1). Not finding a relationship between PLR and hypoperfusion biomarkers (Table 1).

Table 1 (abstract 000864) ROC curve for PLR versus hypoperfusion biomarkers. ScvO2: Central venous oxygen saturation, pCO2 gap: venous content CO2 minus arterial content CO2, CavO2: arteriovenous oxygen content difference

	Hypoperfusion biomarkers	AUC-ROC
Passive Leg Raising	Serum lactate	**0.676**
	ScvO2	**0.431**
	pCO2 gap	**0.401**
	pCO2 gap/CavO2	**0.474**

Conclusions: Ultrasound variables can predict the outcome of fluid responsiveness assessment by PLR, while hypoperfusion biomarkers are weak in predicting this relationship. Ultrasound determinations can be an acceptable surrogate for PLR when real-time cardiac output measurement is not available.

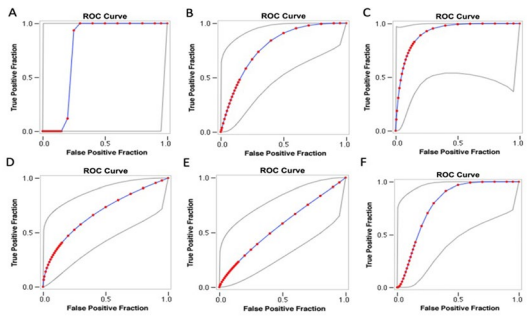

Image 1. ROC curve for PLR versus ultrasonographic measurements. A. PLR vs S1; B. PLR vs IVC; C. PLR vs VTI; D. PLR vs portal vein pulsatility; E. PLR vs renal resistive index; F. PLR vs VTI variation.

Clinical-epidemiological review of CRRT in septic shock patients in a district hospital ICU setting

D. da Costa Oliveira[1], P. Reis Pereira[2], D. Bento[1], S. Carvalho[1], A. Santos[1], F. Esteves[1]
[1]Intensive Care Unit, Centro Hospitalar De Trás-Os-Montes E Alto Douro, E.P.E., Vila Real, Portugal; [2]Nefrology Department, Centro Hospitalar De Trás-Os-Montes E Alto Douro, E.P.E., Vila Real, Portugal
Correspondence: D. da Costa Oliveira
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000866

Introduction: Sepsis and septic shock are major healthcare problems, with elevated mortality rates. In addition to the conventional use of continuous renal replacement therapy (CRRT) in acute kidney injury, CRRT can be a useful tool for immune response modulation in sepsis—influencing circulating levels of inflammatory mediators like cytokines and chemokines, the complement system, as well as factors of the coagulation cascade.
Objectives: We aimed to study the local epidemiological and clinical outcomes of patients with septic shock submitted to CRRT in our intensive care unit (ICU).
Methods: Our sample included patients hospitalized in a level two–three care district hospital ICU from January 2014 to May 2019. Patients with septic shock were defined according to the international consensus definitions at the hospitalization time. These patients were then divided into two groups – those submitted to CRRT versus those not submitted to CRRT during the ICU stay. We evaluated patients' demographics, length of ICU and hospital stay, rate of mortality, and previous medical history of renal disease.
Results: The prevalence of septic shock in our ICU population during the selected period (n = 3253) was 27.4% (n = 890), with a median age of 70 years of age. Of these 890 patients, 166 (18.7%) were submitted to CRRT. The median time of ICU stay in patients that survived was 2 days longer in the CRRT group (9 days) when compared to the control group (7 days), but with no statistically significant difference between them. This was also verified when taking into account the total in-hospital stay, accounting for a difference of 3 more days in the CRRT group, with a median of 24 days versus 21 days in the control group. The CRRT group accounted for a statistically significantly higher mortality rate than the control group ($p < 0.001$), with a mortality rate of 48.2% and 27.3% respectively. In our sample, patients with septic shock and previous medical history of chronic kidney disease (CKD) had a statistically significantly higher mortality rate than those without CKD, with a mortality rate of 34.8% and 29.9% respectively ($p < 0.001$). In patients submitted to CRRT, those with a history of CKD, did not present with a higher mortality rate when compared to those without a history of CKD.
Conclusions: Patients with septic shock submitted to CRRT had a longer ICU and in-hospital stay than the control group, although this difference was not statistically different. A high mortality rate of 48.2% was verified in patients with septic shock who underwent CRRT. From our population, a medical history of CKD did not seem to be an indicator of higher mortality in patients subject to CRRT, but further analysis must be done with CKD stratification.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000868

Introduction: Posterior reversible encephalopathy syndrome (PRES) is a condition of reversible subcortical vasogenic brain edema in patients with critical neurological signs (seizures, encephalopathy, headache, and visual disorders) in the background of renal failure, blood pressure significant variations, autoimmune diseases, and obstetrics complications. Brain imaging usually shows vasogenic edema, mainly concerning the bilateral parieto-occipital areas. The physiopathology of PRES concerns endothelial damage associated with drastic blood pressure transitions or immediate effects of cytokines on the endothelium, which conducts to the breakdown of the blood–brain barrier and successive brain edema. This process is commonly reversible and generally has a good prognosis. The increasing use of brain MRI has led to expanded recognition and characterization of the PRES syndrome. However, the lack of data from prospective studies is nevertheless an enormous issue in the knowledge of this condition.
Objectives: Our objective is to analyze the clinical characteristics of the series of PRES cases admitted to the Intensive Care Unit (ICU) of the Vall d'Hebron University Hospital (HUVH) in Barcelona between 2021 and 2022, as well as the repercussions of said diagnosis, about the therapeutic regimen. We hypothesize that critically ill patients who develop complications with PRES have a worse prognosis, increased hospital stay, and require significant modifications in treating the underlying disease.
Methods: During 2021 and 2022, our team diagnosed 7 cases of PRES in patients admitted to the ICU. Their clinical and demographic variables were prospectively analyzed; we followed up on these patients throughout their hospital admission. The primary variable was the requirement of a significant change in their baseline treatment (change/suspension of immunosuppressive medication, clinical decisions on end-of-life). We also evaluated the number of antiepileptic drugs (AEDs) and sedative dosages required during their admission to the ICU. Quantitative variables were expressed as median and interquartile range as they did not meet normality criteria according to the Kolmogorov–Smirnov test. Qualitative variables were expressed as frequencies and percentages. SPSS v15.0 was used.
Results: Our sample consists of 7 patients, with a median age of 42 (21, 64). 57% were women. The median ICU stay was 12 days (8, 15), and the hospital stay was 20 days (16, 107). The median APACHE-II value was 27 (17, 31). During admission, 28% died. Brain MRI could confirm the diagnosis of PRES in 85%. The baseline diagnoses were: a case of SAH during ECMO support due to COVID-19; in 2 cases, treatment with anticalcineurin inhibitors after a lung transplant; a case of severe preeclampsia; a case of polytrauma; a case of neuro lupus; a case of hypertensive crisis. Up to 57% required a significant change in their treatment plan. Specifically, one of the two post-operative double lung transplant patients had to change immunosuppression to rapamycin. In the case of the hypertensive crisis, it led to a deterioration in the level of consciousness that required reconnection to mechanical ventilation. They received 2 AEDs (1, 4) and two simultaneous sedatives (1, 3).
Conclusions: PRES is a rare but severe complication of critically ill patients with multiple underlying pathologies. In many cases, it implies a change in the therapeutic plan and is related to a more extended hospital stay. Its suspected diagnosis is usually confirmed with MRI.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000871

Introduction: Extracorporeal liver support (ECLS) is used to remove toxins and improve liver function in acute-on-chronic liver failure (ACLF). Plasma exchange (PE) is commonly used but has inconsistent results [1–5]. The ADvanced Organ Support system (ADVOS) is a new albumin dialysis system that regenerates albumin using temperature and pH changes and a small amount of albumin solution [6].
Objectives: This retrospective analysis compares survival and surrogate parameters in patients with ACLF grade 3 according to the CLIF criteria [7], treated at intensive care units (ICU) with standard of care and either ADVOS or PE.
Methods: All ACLF grade 3 patients who received either ADVOS or PE in ICUs of the general surgery or internal medicine department at the University Hospital in Essen from 20/03/2017 to 09/06/2022 were included. Demographics and surrogate markers were analyzed for 7 days after the first treatment. Data on extracorporeal treatments, transfusion units, ICU-LOS and LTx-free 28-day mortality rates were also documented.
Results: PE was administered to 31 patients who received 3 (2, 3) sessions in median, while 34 patients received 4 (1, 6) ADVOS sessions. As shown in Table 1, patients had high CLIF-C ACLF scores with a 28-day predicted mortality of 64% and 80% ($p = 0.079$) for PE and ADVOS, respectively. The need for red blood cell (160 vs. 206 units) or platelet concentrate (32 vs. 68 units) transfusions was comparable during intensive care treatment. Patients in the PE group additionally received 1630 units of FFP. The ICU-LOS (10 vs. 8 days, $p = 0.283$) and 28-day LTx-free mortality rates (90% vs. 85%, $p = 0.294$) were comparable for PE and ADVOS groups, respectively. However, compared to the risk stratification by the CLIF-C ACLF score [8], the actual mortality in the PE group was much higher than predicted.

Table 1 (abstract 000871) Demographics, outcome and surrogate markers. Median (IQR)

Parameter	Time	PE	ADVOS	P groups
Age, [years]	Day 1	45 (36, 54)	54 (43, 60)	0.012*
Male gender	Day 1	61% (n = 19)	50% (n = 17)	0.368°
Listed to LTx	Day 1	61% (n = 19)	53% (n = 18)	0.673°

Parameter	Time	PE	ADVOS	P groups
Dialysis	Day 1	77% (n = 24)	85% (n = 29)	0.386°
CLIF-C ACLF Score	Day 1	62.0 (56.1, 71.7)	66.3 (61.8, 71.0)	0.112*
CLIF-C ACLF predicted 28-day mortality	Day 1	64% (44, 93)	80% (63, 92)	0.079*
Actual mortality rate (%)	Day 14	84% (n = 26)	76% (n = 26)	0.543°
	Day 28	90% (n = 28)	85% (n = 29)	0.711°
AUROC CLIF-C ACLF	Day 28	0.821 (0.676; 0.967)	0.544 (0.320; 0.767)	0.107§
p-value Calibration CLIF-C ACLF	Day 28	0.002#	0.198#	
Creatinine [mg/dl]	Day 1	2.26 (1.37, 3.23)	1.95 (1.45, 2.44)	0.335*
	Day 7	1.82 (1.20, 2.71)	1.24 (0.84, 1.48)	0.023*
Albumin [mg/dl]	Day 1	2.7 (2.4, 3.3)	2.8 (2.2, 3.5)	0.772*
	Day 7	2.9 (2.8, 3.3)	3.4 (2.8, 4.7)	0.881*
Bilirubin [mg/dl]	Day 1	21.5 (15.0, 28.9)	12.3 (7.2, 20.4)	0.010*
	Day 7	17.7 (13.8, 23.6)	18.6 (12.6, 28.4)	0.698*

Conclusions: ECLS and PE had comparable survival rates, but predicted mortality rates are significantly different in the PE group. While PE is commonly considered the best ECLS for ACLF [1, 2, 5], this first comparison of PE versus ADVOS does not support this claim. Baseline characteristics of patients differed between the two groups, limiting the evidence of the data and requiring larger trials in these patients. Further analysis is needed to understand the impact of both ECLS in vulnerable cirrhotic patients. The ADVOS system uses a minimal albumin volume, which contrasts with the large plasma substitutions of PE and their associated risks on inflammation and coagulation pathways.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000872

Introduction: Extracorporeal membrane oxygenation (ECMO) is a support strategy for patients with refractory cardiogenic shock or refractory acute respiratory distress syndrome. Nosocomial infection often appears in ECMO patients, although documented rates differ from the different clinical series, varying between 5% and over 60%. The infectious complication could associate with a worse outcome, specially in-hospital mortality. Nowadays, the most frequently documented nosocomial infections in ECMO patients are ventilator-associated pneumonia and bloodstream infection. There is no clear association between bloodstream infections and ECMO-device-related infections, especially cannula-related infections (CRI). While it appears that (CRI) is frequent, few studies have registered this complication, and no considerable study has assessed the factors and prognosis of CRI in patients supported by ECMO. Currently, there are no guidelines for diagnosing and managing CRI. A better knowledge of the characteristics of CRI in patients supported by ECMO could help reduce the risk factors associated with this infection. It could improve the management of affected patients. This study aimed to assess the incidence, microbiological characteristics, and prognosis of CRI in patients supported by ECMO.

Objectives: Colonization of the cannula during ECMO support is a frequent complication associated with worse outcomes when catheter-related infections appear. We aimed to describe the results of the microbiological culture of the cannula tips once the ECMO support finishes. We analyzed cannula colonization's incidence, risk factors, and clinical outcomes.

Methods: A single-center retrospective study including all veno-venous and venoarterial ECMO patients admitted to the Vall d'Hebron University Hospital (Barcelona, Spain) between January 2016 and July 2022. Cannulation was either percutaneous by the Seldinger procedure or by open dissection under direct vision by our team. The cannulations were executed at our hospital or other facilities, where the ECMO team traveled by ambulance. The cannulae were removed under sterile conditions at the end of ECMO therapy. The distal portion of the catheter (approximately 5 cm) was sent for microbiological examination.We performed a descriptive analysis by calculating frequencies and percentages of qualitative variables. We did a bivariate statistical analysis by performing a chi2-test.

Results: A total of 292 patients received ECMO support during the study period, and in 51% of patients, cannulae were correctly sent and cultivated in our laboratory. Antibiotic prophylaxis from cannulation until ECMO withdrawal with either Vancomycin or Daptomycin was used in 205 patients (70%). The total number of cannulae cultivated was 336, of which 26% were positive. Almost half of the cultures were positive for coagulase-negative Staphylococci (CNS) (47.7%). The

second microorganism more frequently isolated was Candida spp (32%), followed by Klebsiella spp (11.36%), Pseudomonas spp (4.54%), and Enterococcus faecium (3.4%). We did not find statistical significance between the facility of ECMO cannulation or site of cannulation and the incidence of cannula infection. The 28-day survival of patients with at least one cannula infection was 72%, with no statistical difference from the survival of patients with negative cultures.
Conclusions: One in four patients receiving ECMO support may suffer colonization/infection of cannulae, despite antibiotic prophylaxis. This frequency is the same independently of the site of cannulation and the facility where the process was performed. The positivity of cannulae cultures was not associated with higher mortality. Prospective investigations are needed to confirm these findings, and an evidence-based definition of colonization and infection is strongly needed.

Cold-water immersion reduces intestinal injury caused by exertional heat stroke via regulating gut microbiota in rats

Y. X. Zhang[1], L. Xuan[1]
[1]Critical Care Medicine, The Eighth Medical Center of Chinese PLA General Hospital, Beijing, China
Correspondence: Y.X. Zhang
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000873

Introduction: Exertional heat stroke (EHS) is a life-threatening metabolic disorder involving thermoregulatory failure and is typically associated with severe intestinal injury. Growing evidence confirms that dysbiosis of gut microbiota contributes to intestinal injury pathophysiology. Recent studies have indicated that dysbiosis of gut microbiota disrupts the integrity of the intestinal barrier, thereby inducing gut-derived endotoxemia, systemic inflammatory responses, and multiple-organ injury. Thus, intestinal injury caused by dysbiosis of gut microbiota can be considered an important pathological phenotype of EHS progression, and maintaining intestinal homeostasis might prevent EHS onset and subsequent pathology. Cold-water immersion (CWI) is the most effective therapeutic strategy for EHS. Previous studies reveal that CWI exerts the therapeutic effects of EHS by increasing the blood flow to the heart and inhibiting the hypermetabolic state of the organ. However, the effect of CWI on intestinal injury caused by EHS has not been well investigated. Therefore, it is of great significance to study the role of CWI in intestinal injury caused by EHS. This study focuses on clarifying the specific molecular mechanism of EHS intestinal injury and providing new EHS therapeutic targets.
Objectives: To investigate the protective effects of CWI on EHS-inducing intestinal injury, and further determine if CWI achieves its therapeutic effect by modulating gut microbiome.
Methods: The Rat EHS model was established by a previous protocol. The animals were placed in the artificial climate chamber (Temperature: 39.5 °C; relative humidity: 65%). After 40 min, rats were quickly placed on the running wheel for EHS induction. Rats were divided into three groups: control group (CTRL group), EHS group (EHS), and CWI group (EHS + CWI treatment). The pathological changes of the ileum and colon were observed by naked eyes and hematoxylin–eosin (H&E) staining. The composition of gut microbiota was examined by rat fecal gene sequencing. Metabolomics analysis was performed to characterize the metabolic profile differences between the CTRL group, EHS group, and CWI group.
Results: The morphology and H&E staining of the ileum showed that the intestinal injury in the EHS group was more serious, while in the CWI group was significantly less than that in the EHS group. The results of rat fecal microbial analysis exhibited that CWI alleviates EHS-inducing dysbiosis of gut microbiota, in particular, CWI promoted the abundance of probiotics, including *Prevotella, Allisonella, Megamonas, and Succinispira*, while CWI reduced the abundance of pathogenic bacteria, including *Desulfampius*, *Desulfococus*, and *Desulfovibrio*. Further metabolomic analysis shows CWI attenuated the alteration of metabolic profiles induced by EHS. Moreover, we identified a total of 42 different metabolites between the EHS and CWI groups. And the levels of potential biomarkers, including Inosine, Guanosine, Hypoxanthine, Arabinosylhypoxanthine, Taurine, and Anserine showed significant correlations with gut microbiota.
Conclusions: CWI treatment mitigates the intestinal injury caused by EHS by enhancing the strain ratio of probiotics, while reducing the abundance of pathogenic bacteria, which in turn to improve the energy metabolic state of the intestinal epithelium and enhances small intestinal mucosal repair in EHS rats. The co-regulatory effect of CWI on microbial-metabolites is expected to provide a new basis for the treatment of EHS.

Introduction: Pelvic fractures are a relatively rare occurrence in traumatized patients: their prevalence is about 3% of all the skeletal fractures and rises up to 25% in polytraumatized patients.1–2 However, their occurrence is characterized by a significant mortality rate, ranging from 10 to 50%0.3 In particular, fractures of the pelvic girdle with a pubic symphysis diastasis > 2–2,5 cm are associated with an increase of pelvic volume, thus facilitating the occurrence of life- threatening retroperitoneal haemorrhages.4–6.
CT scan currently represents the gold standard for detection of pelvic fractures, however its use can be limited in particular situations, such as in haemodynamically unstable patients. X-ray has a low sensitivity (67%)5. US is routinely used in the primary survey in major trauma, however E- FAST cannot detect retroperitoneal haemorrhage.
Objectives: The objective of the present study is to compare CT scan and US measurement of pubic symphysis (PS) diastasis, in order to determine whether sonography allows to perform an accurate early diagnosis of symphyseal diastasis in open book pelvic injuries.
Methods: This is a multicenter, prospective, cohort study, performed on patients admitted to SpedaliCivili of Brescia, Ospedale Careggi of Florence and Ospedale di Circolo e Fondazione Macchi of Varese between December 2020 and July 2022. Total body CT scan symphysis measurements were performed by a radiologist; US symphysis measurements (Fig 1) by an experienced operator who used predefined criteria. According to the local protocol, one centre did not report precise symphysis measurement but only recorded data as presence or absence of diastasis (2,5 cm cut-off).
Results: A total of 208 patients were included in the study. In 102 only the presence or absence of diastasis (according to a cut-off of 2,5 cm) was measured, while in the remaining group complete assessment was available. US and CT scan detected PS widening in six patients (2,9%), while 198 (95%) were negative for diastasis after both tests. Discordant results were found in2 patients (0,9%): in the first case, US did not detect the diastasis but an experienced operator was not available. In the second one, US overestimated symphyseal diastasis, however the patient was haemodynamically unstable and underwent surgery for a diastasis of posterior sacroiliac joint. Using the Bland- Altman plot, we found an excellent agreement between the two diagnostic tests (r: 0.849, Fig. 2).
Conclusions: US evaluation of pubic symphysis appears to be a rapid, reliable, bed-side method to allow early identification of symphyseal diastasis in open book injuries, which is associated with a high risk of haemorrhages. Our data suggest that US may overestimate the pubic symphysis measurements in comparison with CT scan, however this difference appears to be minimal below 5 cm of diastasis. This discordance is not relevant above 5 cm, since it does not affect the clinical management of patients. US evaluation can also be performed in prehospital settings, thus allowing a better management of the patients and their transfer to the most appropriate hospital and an alternative evaluation tool in hospitals where CT scan and X –ray are not immediately available.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000875

Introduction: Increased cell-free plasma DNA (cfpDNA) levels in critical illness are indicative of cell destruction and associate with endothelial damage, multiorgan failure, metabolomic alterations, pro-inflammatory signaling and mortality predicting in sepsis (1–4). Independently on causative or associative link of diminishing cfpDNA and/or course and outcome prediction, cfpDNA level represents a valuable biomarker indicative of successfulness of a care strategy in a particular patient.

Objectives: The aim of the study was to determine if the extracorporeal multimodal hemoperfusion (EMH) with Efferon LPS extracorporeal adsorber that binds LPS and proinflammatory mediators [5–7] is capable to rapidly abrogate cfpDNA levels.

Methods: Adult patients with septic shock (Sepsis-3) [8] (n = 58) within first 12 h since the start of vasopressors infusion and within 24 h after surgical intervention, were included in the study. Patients undergoing extracorporeal hemoperfusion (ECH, n = 36) received two treatments, 24 h apart, and two patients received only one treatment. Control group (CG, n = 20) underwent no ECH, conventional therapy only. ECH was performed using Efferon LPS adsorbers containing mesoporous polymeric scaffold armed with the LPS-selective ligand to sequester both proinflammatory molecules and LPS [5]. Severity of the disease was assessed using clinical scales, hemodynamic parameters, vasopressor use, and oxygenation index. The platelet, leukocyte, lymphocyte, neutrophil counts, levels of C-reactive protein (CRP), procalcitonin (PCT), interleukin-6 (IL-6) and lactate were determined at the baseline and 72 h after inclusion in the study. Endotoxin levels were determined using the kinetic chromogenic LAL test. DNA was purified from quickly-freezed, one-time defrosted plasma samples using organic solvents. DNA concentration was determined by fluorimetry using SYBR green dye. STATA 16.0 (StataCorp, USA) and Excel 2019 with XLStat 2019 add-in (Addinsoft) were employed for statistical analysis.

Results: The median duration of hemoperfusion was 300 (300; 360) minutes for the first treatment and 300 (250; 300) minutes for the second treatment. No differences in clinical and laboratory parameters found between ECH and CG groups at a baseline. There were several clinical benefits in patients underwent ECH: (a) increasing the cumulative hospital survival: sHR = 2.2 (1.1–4.3, p = 0.029, Grey test); (b) significant decreasing multiorgan failure including SOFA scores values in 72 h after the start of ECH from 7 (7;9) to 3(2;7), p = 0.012; (c) the duration of septic shock in the survived patient cohorts significantly differed dependent on the mode of treatment: median time to blood pressure normalization was 57 (37; 80) hours in the ECH group versus 101 (58; 197) hours in the control (sHR = 2.20; 95% CI: 1.11–4.34; p = 0.029); (d) significant increasing the PaO2/FiO2 index in ECH vs CG patients (p < 0.001); (e) significant decreasing proinflammatory biomarkers PCT, CRP, IL-6, and reduction of bacterial LPS concentration (Fig. 1, A-D); (f) significant decreasing the leukocytes and neutrophils count in ECH vs CG patients (p < 0.01). To describe DNA elimination, we used the following regression model: cfpDNA72h = cfpDNA 0 h × (1-E) + G*, where E was the proportion of eliminated cfpDNA in 72 h, G—generation of cfpDNA in 72 h. At R2 = 0.32, the following estimates of model parameters were obtained: elimination of cfpDNA (E) was 17% and 84%, in CG and ECH group patients, respectively (p = 0.003), demonstrating significantly increased elimination of cfpDNA in ECH, but not in CG patients. The concentration of cfpDNA in the CG and ECH groups was not significantly different: G = 17 and 63 ng/mL, respectively, p = 0.082. Extracorporeal removal of cfpDNA can be estimated as the difference in elimination of cfpDNA with and without ECH, thus the removal of cfpDNA by the Efferon LPS adsorber after two ECH cycles was 67% (95% CI: 22–89). The increased cfpDNA levels in patients possessing the cfpDNA values within the upper quartile before ECH significantly decreased post-ECH (Fig. 1,E). Significant trend in diminishing the cfpDNA levels associated with ESH treatment became more evident when day 0 and day 3 cfpDNA levels from both groups were plotted (Fig. 1, F, p < 0.003).

Conclusions: Treatment the septic shock patients with Efferon LPS resulted in decreasing the increased cfpDNA levels associated with significant clinical improvements.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000876

Introduction: VA ECMO has emerged as an effective rescue intervention in patients with cardiogenic shock refractory to standard treatment protocols and its use is rising worldwide in the last decade (1). It is also used as a salvage intervention in patients who are undergoing cardiac surgery and cannot be separated from cardiopulmonary bypass despite inotropic, vasopressor and intra-aortic balloon pump counter pulsation (IABP) support. The latter condition known as post cardiotomy shock (PCS) occurs in 0.5% to 1.5% of all cardiac surgeries (2). Although experience and availability is growing, outcomes in surgical subjects remain poor (3), partially due to support of older and more complex critically ill patients. There is a need for more robust evidence in order to ameliorate clinical practice and improve outcomes.
Objectives: The study purpose is to examine VA ECMO application at our tertiary care center and compare outcomes between patients who were supported with central versus peripheral configuration.
Methods: We retrospectively reviewed the electronic records of 97 consecutive patients who were supported with VA ECMO at our institution between January 2015 and August 2022. We recorded basic demographic data, clinical indication for support, length of hospitalization and survival outcome. Data were statistically analyzed by SPSS programme. We divided patients according to central or peripheral ECMO configuration.
Results: 97 patients, with a median age of 59 years, were supported with VA ECMO. Central configuration was applied in 62% of the cases and peripheral in 38%. Indication for support was post cardiotomy shock (PCS) in 58%, primary graft dysfunction (PGD) in 11%, acute myocarditis in 10%, dilated cardiomyopathy (DCM) in 7%, electric storm in 7%, acute coronary syndrome (ACS) in 3% and cardiopulmonary resuscitation (ECPR) in 2% of the cases. Median length of hospitalization was 15 days and overall survival to discharge was 30%.
Patients supported with Central VA ECMO were older (66 vs 44 years median age) and had shorter length of hospitalization (11 vs 44 days median) than those supported with Peripheral VA ECMO. The indication for support was predominantly PCS (image 1) and their survival outcome was strikingly worse (image 2).
Conclusions: Patients supported with VA ECMO for PCS bare a dismal prognosis (4). We should reconsider patient selection and timing of deployment, although this remains a debatable topic in the literature (5). There is some evidence that peripheral cannulation strategy may favorably affect patient outcomes, but existing data are mainly retrospective (6, 7). Finally, there may be an implication for utilizing shorter life oxygenators, rationalizing this way, the cost of ECMO support in the PCS patient population.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000877

Introduction: Traumatic brain injury (TBI) is one of the main causes of disability, especially in young people. It is a pathology with great heterogeneity, which makes it difficult to determine its prognosis. Traumatic subarachnoid hemorrhage (tSAH) is a frequent finding in brain injuries. Understanding the impact it may have on the outcomes of patients with TBI can help define therapeutic strategies.
Objectives: To evaluate the impact of tSAH on outcomes of patients with TBI.
Methods: A cohort of patients with TBI requiring neurocritical care over a 3-year period was analyzed. The cohort was categorized according to the presence or absence of tSAH on initial computed tomography. Demographic variables, mechanism of injury, severity, evolution and outcome were evaluated. Some variables were analyzed, including demographic characteristics, injury mechanism, severity, evolution, and outcomes. Categorical variables are expressed as counts and percentages and were compared using the $\chi 2$ test; continuous variables are expressed as means and standard deviation and were compared using Mann–Whitney U test. A two-sided level of significance of 5% was used. Data analysis was performed using STATA version 13 ® (StataCorp LCC).
Results: A total of 145 patients were admitted with TBI, of which 43% presented tSAH. A 77.9% (113) were men, and the mean age was higher in patients in the tSAH group (56.8 ± 18.2 vs 45.8 ± 18 years old; $p < 0.001$). In the tSAH group, the main mechanism of injury was an accidental fall (61.9% vs 25.5%; $p < 0.001$), and in the non tSAH group, it was a traffic accident (45% vs 27%; $p < 0.001$). Patients with tSAH had higher head Abbreviated Injury Scale (AIS) scores (3.7 ± 1.0 vs 1.4 ± 1.9; $p < 0.0001$) and higher Injury Severity Scores (ISS) (25.1 ± 14.3 vs 20.4 ± 12.3; $p = 0.038$), with a similar distribution of the Marshall classification ($p = 0.184$). There was no difference in the need for neurosurgery or blood products in the first 24 h. During the evolution in the ICU, patients with tSAH developed more frequent episodes of intracranial hypertension (24.2% vs 6.2%; $p = 0.02$) with a greater need for osmotic treatment (30.2% vs 11%; $p = 0.004$) and decompressive craniectomy (7.9% vs 1.2%; $p = 0.044$). Functional outcome at 6 months and at 1 year showed no difference in the Glasgow Outcome Scale Extended (GOSE). ICU mortality was higher in the tSAH group (23.8% vs 7.3%; $p = 0.018$).
Conclusions: Patients with TBI and initial tSAH did not present different management in the first 24hI; however, they more frequently developed episodes of intracranial hypertension and had a greater need for decompressive craniectomy. ICU mortality was higher in patients with tSAH. The optimal management of these patients remains uncertain and represents a challenge for neurocritical care.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000879

Introduction: Noradrenaline is the recommended first-line vasopressor, although largely effective in reestablishing minimally acceptable mean arterial pressures to maintain organ perfusion, catecholamines have important adverse effects and may even increase mortality rates. Since a relative vasopressin deficiency in septic shock was described, there has been growing interest in the use of vasopressin as an adjunctive agent. Shock characteristics at vasopressin initiation could impact clinical outcomes, being time since shock onset, severity of hypoperfusion, and catecholamine dose requirements particularly interesting.
Objectives: To analyze mortality related factors in septic shock patients, after vasopressin treatment as a second vasopressor associated with noradrenaline.
Methods: Retrospective observational study, carried out after the implementation of vasopressin as a secondary vasopressor treatment protocol (when NAD > 0.2 2 ug/Kg/min). We collected data from all septic shock patients attended at the Intensive Care Unit of Gregorio Marañon Hospital between March and December 2022. Epidemiological data, comorbidities, severity, clinical features, invasive support, complications and outcomes were collected.
Descriptive analyses were expressed as means (standard deviation) for normally distributed quantitative variables, medians (interquartile range) for non-normally distributed variables, and as percentages for categorical data. Univariant analysis was performed using Chi-squared (relative risk) for qualitative variables, and T-student (median comparation) for quantitative ones. Multiple logistic regression was used to determine independent mortality related factors, including significative variables or clinically relevant variables.
Results: Seventy patients were included, 53% were male, mean age 61 ± 16. 50% had respiratory infection, 33% abdominal. Charlson Index 3 (2–4). To evaluate severity of illness we used APACHE II 26 ± 7, SOFA 10 ± 3. 80% required invasive mechanical ventilation for 4 days (1–15 days), and 50% extrarenal depuration.
Time between septic shock diagnose and NAD initiation was 3h (1-5h), time between septic shock diagnose and VAP initiation, 8 h (5-15h). NAD dose when VAP was initiated was 0.6 ± 0.4 µg/Kg/min.
ICU mortality was 49% and hospital mortality was also 49% as all the decesead patients died in the ICU. ICU stay 9 days (3–22), and hospital stay 18 days (3–32).
Mortality related factors adjusted to severity of illness were: age (66 ± 14 vs 56 ± 16, $p = 0.01$), APACHE II (23 + /6 vs 29 ± 8, $p < 0.01$), and NAD dose when VAP was initiated (0.42 ± 0.26 vs 0.85 ± 0.44, $p < 0.01$).
Lactate and NAD dose when VAP was initiated were found to be ndependent mortality factors: lactate (OR 1.57; CI 95% 1.16–2.10) and NAD dose when VAP was iniciated (OR 29.70; CI 95% 1.54–570.82).
Conclusions: In our series, lactate levels and Noradrenaline dose when initiating vasopressin were independent mortality risk factors.

Introduction: Management of traumatic brain injury (TBI) patients focusses on identification, prevention and treatment of secondary insults of brain injury. A major cause for secondary brain injury is increased intracranial pressure (ICP), also referred to as intracranial hypertension (IH). With increasing intracranial volume, compliance of the brain decreases, resulting in alterations in ICP wave morphology. IH is often difficult to foresee and treatment is started reactively when ICP exceeds threshold values. During the time needed to restore ICP to lower values, IH results in secondary brain injury. Therefore, a proactive approach is desired to limit the impact of IH. Mean ICP and changes in ICP wave morphology may be predictors of upcoming episodes of IH.
Objectives: In this study, we investigated if a deep learning model based on ICP waveform and statistical summaries of ICP and ABP is able to predict IH.
Methods: We performed a retrospective study in adult TBI patients that experienced IH during ICU stay. Data was collected from two Dutch academic hospitals and the CENTER-TBI (high resolution) dataset [1]. Patients with decompressive craniectomy were excluded. IH was identified as > 10 consecutive minutes of ICP > 30 mmHg. Target data was selected from the hour prior to IH (pre-IH) and divided in six prediction windows of 10 min. Control segments were isolated two hours from IH and pre-IH segments. After preprocessing, all single ICP waves were extracted and series of 120 consecutive waves were stacked to match the input dimensions of a ResNet50 model. In addition, per input segment, the average ICP waveform of the previous control and IH episode was added. Last, numerical data containing ICU length of stay, time to previous IH event, the number of previous IH events and the mean, median, standard deviation and variance of the 2-h segment of ICP and ABP and per non-overlapping 10 min windows within that segment were added. To artificially increase the training set, 50% and 95% overlap was applied for control and pre-IH input data respectively. Training of the model was done using leave-one-patient-out cross validation and performance of all models was examined with F1 score, sensitivity, specificity and area under the receiving operating characteristic curve (AUC).
Results: 67 patients were included and a total of 201,488 control and 50,193 segments per pre-IH window were extracted as input for the model. Performance of the model was best 0–10 min prior to IH with a median F1 score of 78.6 [IQR 67.2–93.9], sensitivity of 81.9 [IQR 59.1–97.6], specificity of 96.2 [IQR 85.2–99.1] and an AUC of 95.9 [IQR 86.5–99.5]. As prediction windows are further away from IH performance decreases, as can be seen in Figure 1.
Conclusions: In this study we showed a deep learning model is able to predict IH in patients with TBI that experienced IH during ICU stay, using ICP waveform morphology within a clinically relevant time window.

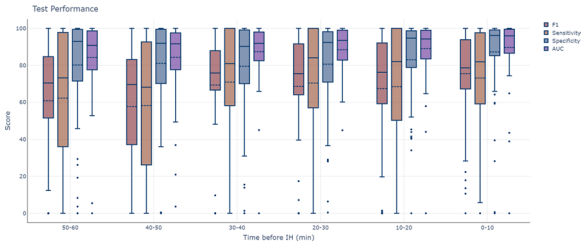

Figure 1 (abstract 000880) Test performance of the model for all prediction windows prior to intracranial hypertension

Introduction: Ventilator-Associated Lower Respiratory Tract Infections (VA-LRTI) increases morbidity and mortality in Intensive Care Unit (ICU) patients (1,2). High incidences of secondary VA-LRTI have been reported among ICU-patients with COVID-19 needing invasive mechanical ventilation (3).
Objectives: To describe the clinical characteristics, incidence, microbiology, risk factors and outcome of patients who developed VA-LTRI, as compared to patients who did not, in a population cohort of Swedish ICU patients with severe COVID-19.
Methods: A multicenter, retrospective cohort study of all ICU-patients with COVID-19 requiring invasive mechanical ventilation for at least 48 h between 1 March 2020 and 31 May 2021 from the ICUs serving the Southeast region in Sweden (a population of approximately 1

million). The primary outcome was the first episode of culture verified VA-LRTI. Patient characteristics together with ventilatory support, clinical course, organ support, antibiotics and immunomodulatory medications, microbiological findings, complications and 30-, 60- and 90-day mortality were registered. Logistic regression analysis was conducted to determine factors associated with increased risk for first VA-LRTI.

Results: Of a total of 536 included patients, 153 (28.5%) developed VA-LRTI. Incidence of first VA-LRTI was 20.8 per 1000 days of invasive mechanical ventilation, increasing from 14.5 to 25.8 from the first to the third pandemic wave. Comparing patients with VA-LRTI to those without revealed no difference in age, sex or number of comorbidities. Additionally, no differences were seen in 30- 60- or 90-day mortality. Patients with VA-LRTI had fewer ventilator-free days, longer ICU and hospital stay, were more frequently in prone position ventilation, received more corticosteroids and had more often antibiotic treatments upon intubation. Logistic regression analysis revealed increased odds for first VA-LRTI in patients treated with corticosteroids during hospital stay (OR 2.64 [95% CI 1.31–5.74]), antibiotics upon intubation (OR 2.01 95% CI [1.14–3.66]) and days of invasive mechanical ventilation (OR 1.05 per day of IMV, 95% CI [1.03–1.07]), adjusted for sex, neuromuscular relaxation, BMI, age, number of comorbidities, days to intubation and prone position (Figure 1). In all VA-LRTI cultures, the proportion of gram-positive pathogens were 31.2%, gram-negative 60.7% and fungal/unspecified 8.1% and a total of 1.9% multidrug-resistant bacteria were found.

Conclusions: There was a high incidence of VA-LRTI in this large cohort of critically ill COVID-19 patients, exceeding VA-LRTI incidence found in Swedish non-COVID patients (4), but still lower than found in other international studies (3,5) VA-LRTI increased morbidity but not 30-, 60- or 90-day mortality. Corticosteroid treatment and antibiotics upon intubation were associated with increased OR of first VA-LRTI, further validating earlier studies with similar results regarding corticosteroids in intubated COVID-19 patients.

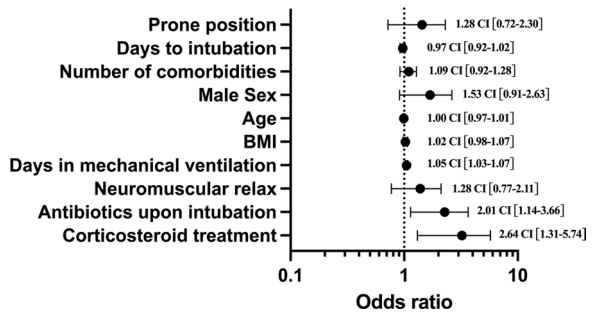

Figure 1 (abstract 000881) Multiple logistic regression analysis with first VA-LRTI as outcome. Data presented as OR [95% CI]

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000882

Introduction: To date, little attention has been paid to the applicability of cardiac arrest care in low resource. Guidelines for resuscitation during cardiac arrest are predominantly based upon evidence from well-resourced, tertiary referral centres.

Objectives: To determine challenges in managing out of hospital cardiac arrest (OHCA) in low-resource settings and to identify key factors preventing optimal resuscitative measures. We consider possible solutions and suggest future avenues of research.

Methods: This was a multicenter retrospective cohort study in a middle sized urban city (estimated population 390,000) served by a single Emergency Medical Services (EMS) system. All records of OHCA above 18 years were reviewed from the Cardiac Arrest Registry from 2015 to 2022. Among data collected were etiology of cardiac arrest, initial cardiac rhythm, time of initiation of cardiopulmonary resuscitation (CPR) and adrenaline administration by EMS team, geographical distances, access to tertiary centre and relevant expertise. Outcomes of interest included return of spontaneous circulation (ROSC) and survival to hospital discharge (STHD).

Results: From the 7-year study period, a total of 889 adults (mean age of 65.3 ± 11.6 yrs) had OHCA with an average mortality of 68.19% [Figure 1]. Of the 889 patients, 488 patients (54.89%) achieved ROSC but only 298 (33.52%) survived to hospital discharge. We observed the further a person lives from a cardiac arrest resuscitation facility, the greater their risk of poor outcome and death [Figure 2]. A rural/urban differences in the management of cardiac arrest and post cardiac arrest were identified with multiple issues that are related to access, transport and transport distances, access to diagnostic testing and treatment in an appropriate facility. Transport of patients to a cardiac centre capable of performing PCI exceeded 90 min in 68.9% of total documented ST elevation myocardial infarct (STEMI) OHCA (OR 42.7; [95% CI], 39.3–48.7; $P < 0.005$). We identified deficiencies in workforce expertise, complex patterns of comorbid health conditions and infrastructure limitations resulted in patients with Killip Class 3 and 4 having a mortality of 62.8%.

Conclusions: Outcomes from OHCA remained poor. We believe mortality reduction may be driven by adopting a faster reperfusion strategy, more efficient referral or access pathways, improving local workforce capabilities and facilities. Adherence to guideline based management and development of effective resuscitation protocols for low-resource settings should be considered in collaboration with local care teams and the EMS.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000883

Introduction: COVID-19 is an ongoing pandemic with varying rates among countries. Renal dysfunction is often recorded with devasting outcomes and health resources consequences.
Objectives: To assess the incidence and risk factors for developing new-onset acute kidney injury (AKI) in critically ill COVID-19 patients admitted to our ICU from the broader area of central Macedonia.
Methods: Single-center, retrospective cohort study in a Greek tertiary-care ICU (March 2020-April 2022). We included all critically ill adult patients who suffered from moderate/severe ARDS caused by PCR-confirmed active SARS-CoV-2 infection. All were treated uniformly according to the national protocol, while none were fully vaccinated. We excluded patients: with underlying Chronic Kidney Disease or on Renal Replacement Therapy (RRT), with a history of nephrectomy or renal transplantation, with readmissions, those with ICU stay ≤ 1 day and immunocompromised. Demographics, medical history, severity scoring, length of ICU stay (LOS), mortality, parameters of invasive mechanical ventilation, administration of nephrotoxic agents, serum creatinine (sCr), estimated glomerular filtration rate (eGFR), vasoactive drugs in high doses (norepinephrine >0.5 mcg/kg/min), and markers of systemic inflammation (NLR, PCT, D-Dimers,IL-6) at ICU admission were recorded. AKI was defined based on sCr KDIGO criteria. All patients were assigned to two groups (AKI, non-AKI) and were followed for the entire ICU stay. We used Chi-square and Mann–Whitney rank sum tests to assess between-group differences. We performed univariate and multivariate analyses to test potential predictors of AKI. The significance level was set at 0.05. All analyses were performed using the R statistical package.
Results: 163 patients were recorded, predominantly male (67.5%) with a median age of 64 (IQR: 56.5 to 71) years. The non-renal SOFA score was 6 (IQR: 4 to 8), the median APACHE II score was 15 (IQR: 13 to 18), and the mortality rate reached 46%. In our cohort, 57.7% had AKI, (28.7% Stage I, 18,1% Stage II, 53.2% Stage III), whereas 44.6% needed RRT. AKI patients were older, had a longer LOS, and increased mortality ($p<0.05$). They had a lower admission eGFR and more frequently received high-dose vasoactive substances or nephrotoxic agents/drugs ($p<0.05$). They also had significantly increased admission values of PCT and IL-6 ($p<0.05$). No differences in medical history were recorded. Multivariate analysis showed that eGFR (OR = 0.98, 95%CI: 0.97 to 0.99, $p<0.001$), use of high-dose vasoactive drugs (OR = 10.84, 95%CI: 5.28 to 23.52, $p<0.001$) and IL-6 (OR = 1.01, 95%CI: 1.01 to 1.02, $p=0.001$) independently predicted AKI.
Conclusions: AKI was a frequent complication in our cohort. ICU admission eGFR and IL-6 levels, and the need for high-dose vasoactive drugs, were independent predictors of AKI development. Early recognition and mitigation of these factors could help reduce the risk or severity of renal dysfunction.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000885

Introduction: Diaphragmatic TDI has recently gained interest as a tool allowing real-time measurement of the diaphragmatic muscle speed40635_2023_546 of contraction and relaxation as well as the rate of diaphragmatic relaxation. Very little is known about the changes of the diaphragmatic TDI pattern when the diaphragm does not return to FRC at the end of a passive expiration. The aim of our study was to assess the diaphragmatic TDI pattern when changes at the passive FRC were induced by two different levels of positive end-expiratory pressure (PEEP).
Methods: In twelve healthy volunteers, lung distension above the passive FRC was induced by two levels of PEEP, 6 and 12 cm H2O. In each subject and during the three conditions (Zero PEEP (ZEEP), PEEP of 6

and 12 cmH2O), the following parameters were measured: tidal volume (Vt), respiratory rate (RR), minute ventilation (MV), diaphragmatic excursion, diaphragmatic thickness, thickness ratio, TDI peak contraction velocity (PCV), peak relaxation velocity (PRV), slope of diaphragmatic relaxation and the increase in lung volume above passive FRC.
Results: The increase in lung volume induced by PEEP was 556.27 ± 150.98 ml at PEEP 6 and 1218.67 ± 383.06 ml at PEEP 12 ($p < 0{,}001$). Diaphragmatic excursion, Vt, RR and MV did not change significantly during the three conditions ($p > 0.05$). Thickness ratio increased, with the increase in lung volume, from 28.24 ± 14.90% at ZEEP, to 37.22 ± 20.51% at PEEP 6 cmH2O and to 47.96 ± 38.61% at PEEP 12cmH2O ($p = 0.21$), with the increase in thickness during inspiration becoming significant ($p = 0.006$). TDI parameters also increased with PEEP; PCV from 2.20 ± 0.49 cm/s to 2.49 ± 0.61 cm/s, and to 2.72 ± 0.68 cm/s, PRV from 1.99 ± 0.54 cm/s to 2.57 ± 0.77 cm/s and to 2.51 ± 0.89 cm/s, and the slope of the diaphragmatic relaxation from 3.86 ± 2.92 cm/s2 to 5.57 ± 3.25 cm/s2 and to 6.01 ± 3.48 cm/s2. All measurements showed a trend towards statistical significance.
Conclusions: Breathing above passive FRC (lung overdistension) induces an increase in the PCV, PRV and in the speed of the diaphragmatic relaxation. Furthermore, the increase in thickness ratio demonstrates that the energy cost of breathing for the same minute ventilation increases.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000886

Introduction: Cardiogenic Shock (CS) is a complex and heterogeneous pathological syndrome that occurs when cardiac output is insufficient to ensure adequate perfusion to remote organs. The most frequent cause of CS is acute myocardial infarction (AMI) and every year more than 200,000 people suffer from CS in Europe and the US, with a death rate between 40 and 60% despite progress made in clinical care solutions. Due to the heterogeneity of aetiologies and conditions of CS patients, treatment decisions must be carefully considered, to account for each patient's specific characteristics, comorbidities, and hemodynamic status.
Objectives: We introduce preliminary clinical validation results for an innovative and proprietary ICU information system for decision support that relies on a digital twin technology to provide personalised disease management strategies to CS patients.
Methods: We developed a digital twin software that relies on predictive, multi-scale mathematical models of the whole human physiology and medical treatments, as well as on machine learning algorithms that allow rapid and effective calibration of these models on the patients' specific health status starting from their available clinical measurements. This model's capabilities of 1) automatically creating accurate virtual twins and 2) providing insights on patients' health status and response to treatments were validated using a collection of snapshots of real clinical cases consisting of systematic collections of anonymous data from cardiac intensive care units.
Results: In Figure 1 are shown the results of the twinning process performed on a patient treated with a combination of vasopressors, inotropes, diuretics and mechanical ventilation after AMI. The software successfully calibrated the underlying computational models allowing for a faithful creation of the patient's digital twin throughout the entire ICU recovery phases. The values of the obtained virtual hemodynamic variables faithfully matched variations of the clinical measurements induced by escalation and/or weaning of the various treatments both in terms of mean values and associated uncertainty. Moreover, the twinning process also produced reliable insights on the trends of non measured variables throughout the entire period of care.
Conclusions: The digital twin model efficiently reproduced the health statuses associated with a wide variety of aetiologies, therapies and parameters availability for multiple patients (data not shown). The versatility and accuracy of this technology in producing a digital copy of a patient could provide a reliable basis for clinicians to: 1) obtain a complete understanding of patients' pathophysiological conditions and evolution, also leveraging the availability of insights on non measured or non measurable clinical variables and 2) test different treatment strategies, predictively assessing patients' response to treatments. These functionalities represent a decisive support to facilitate the adoption of a personalised disease management approach that could result in beneficial impact for CS patients. Further developments are ongoing to extend the validation activities to whole body physiology dynamics and treatment predictions.

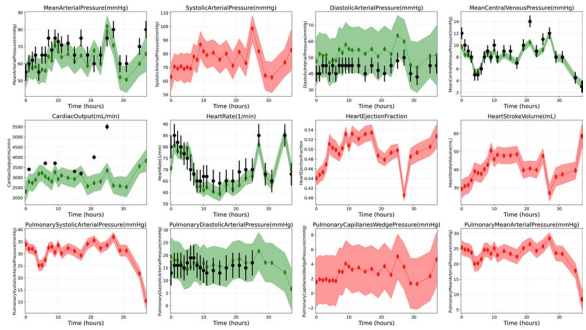

Figure 1 (abstract 000886) Results of the preliminary clinical validation of patient twinning on hemodynamic variables of a patient with mitral and aortic regurgitation admitted in ICU after experiencing AMI. Real clinical measurements are represented with **black dots** while the black lines indicate measurement uncertainty. The **green lines** are the in-silico predictions based on the available measurements, while the surrounding coloured bands represent the range of computational uncertainties. The **red lines** and surrounding coloured bands represent the in-silico predictions and uncertainties for variables with clinical measurements not available. Assessment of the effects of tidal volume and respiratory rate on the velocity characteristics of diaphragmatic motion using Tissue Doppler Imaging (TDI)

E. Soilemezi[1], S. C. Kotoulas[1], P. Pisanidou[1], D. Papanikolaou[1], E. Tsiranidou[1], D. Matamis[1]
[1]ICU, Papageorgiou General Hospital, Thessaloniki, Greece
Correspondence: E. Soilemezi
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000888

Introduction: Tissue Doppler Imaging (TDI) is an echocardiographic technique which uses Doppler to quantify the velocity of tissue rather than blood. Since it directly estimates the velocity of moving tissue, it has been recently applied to assess the velocity of the moving diaphragm. However, the factors that influence the characteristics of the diaphragmatic velocity pattern remain largely unknown. In this study we applied the diaphragmatic TDI technique to determine the distinctive role of the tidal volume and respiratory frequency in the velocity pattern of diaphragmatic tissue motion.
Methods: Diaphragmatic TDI was recorded in 21 healthy adults, who were breathing through a ventilator tubing system (PSV mode with 0 cmH2O of pressure support and 0 cmH2O of PEEP) with a nose clip

to avoid leaks and to measure precisely all ventilatory parameters required. In all recordings the following TDI-derived parameters were measured: diaphragmatic peak contraction and peak relaxation velocity, and the slope of the initial steepest part of the velocity waveform during relaxation, ie, the TDI-derived maximal relaxation rate. The pneumotachographic parameters of the corresponding breaths measured included: tidal volume, inspiratory and expiratory times, and duration of each whole breathing cycle, allowing minute ventilation also to be estimated. The study protocol consisted of three phases; i) subjects were instructed to breathe adopting a ventilatory pattern they found comfortable; ii) subjects were instructed to double the tidal volume they adopted during phase i, while maintaining the same respiratory rate; iii) subjects were instructed to double the respiratory rate they adopted during phase i, while maintaining the same tidal volume. The latter two phases were applied randomly in order.

Results: We found significant increases in the diaphragmatic contraction and relaxation velocity and in the maximal diaphragmatic relaxation rate in both high tidal volume phase (+45.72%, +48.56%, +74.22% respectively, $p < 0.001$ for all measurements), and high respiratory rate phase (+72.47%, +77.19%, +319.42% respectively, $p < 0.001$ for all measurements) compared to normal breathing. Diaphragmatic velocities and velocity's rate of change were strongly related to minute ventilation in all stages of the protocol ($R2 > 0.45$, $p < 0.001$), while the rate of velocity change negatively correlated to expiratory time ($R2 = 0.63$, $p < 0.001$).

Conclusions: Conclusively, in this study we describe that both increasing the depth and frequency of breathing bears major increases in the diaphragmatic contraction and relaxation velocities and diaphragmatic relaxation rate. These outstandingly high values of velocities, especially in the high frequency phase and its association to respiratory times, clearly reflect the diaphragm's intense effort to rapidly regain a resting position as close to FRC as possible, ensuring a mechanical advantage for an efficient next inspiratory effort.

Topic: Acute respiratory failure and mechanical ventilation.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000889

Introduction: Delirium during intensive care unit (ICU) stay is frequent and associated with significant morbidity, mortality and healthcare related costs (1). International guidelines suggest its prevention. However, curative treatment remains unclearly established to date (2). Despite a non-unequivocal literature, haloperidol is the first line used neuroleptic (3). Dexmedetomidine, an alpha2-adrenergic receptors agonist has shown its efficiency in the treatment of delirium in intubated patients but also in its prevention. Dexmedetomidine represents a widely used alternative to haloperidol. Only few studies have compared the efficacy of dexmedetomidine in non-intubated ICU patients as a first line curative treatment of agitated delirium (4).

Objectives: Main objective of 4D trial is to demonstrate that dexmedetomidine decreases agitated delirium duration and the requirement of intubation compared to placebo.

Methods: The 4D trial is an investigator-initiated, prospective, multicenter, randomized, double-blinded, two-arm trial, randomizing 300 non-intubated ICU patients with diagnosis of agitated delirium to receive dexmedetomidine or placebo as a cure (5). The primary outcome measure is a composite of duration of agitation and delirium and the use of intubation with deep sedation and mechanical ventilation. Secondary outcomes include mortalities at 7 and 28 days, ICU length of stay and occurrence of adverse effects. One year quality of life has been investigated with SF-36 score. The sample size will allow the detection of a 50% decrease of agitation duration ($RASS > 0$; 120 min), of an absolute reduction of delirium duration (CAM-ICU positive; 1 day) and of a 50% relative decrease of intubation and mechanical ventilation, with a type 1 error rate of 1.8% (error risk inflation due to components of composite) and power of 90%, assuming a 15% incidence of intubation and mechanical ventilation requirements, an agitation duration of 240 min and a delirium duration of 3 days. One hundred and 10 patients by group will be needed. An intermediate analysis is scheduled and requires the inclusion of 150 patients. 4D ClinicalTrials.gov Identifier NCT03317067.

Results: A total of 151 patients underwent randomization—76 were assigned to the dexmedetomidine group and 74 to the placebo group. A significant effect was observed (-0.49 (-0.81; -0.17), $p < 0.0001$) on main composite outcome in favour of dexemdetomidine group compared to placebo. Items of composite outcome were as follows. Positive RASS score duration (1 [1; 2] vs 2 [1; 7] hours, $p = 0.001$) and CAM-ICU positive (20.0 [12.0; 31.0] vs 23.5 [12.0; 41.0] hours, $p = 0.38$) decreased in dexmedetomidine group. No difference on intubation requirement was observed (2 (2.6%) vs 3 (4.1%), $p = 0.68$), between dexmedetomidine and placeb groups respectivelly. Due to strong statistical significance and enrollment rate decline related to non-inclusion criteria (administration ofdexmedetomidine during previous 72 h and wider use during COVID-19 era), steering committee decided to stop 4D trial after pre-planned intermediate analysis.

Conclusions: Curative dexmedetomidine is effective at reducing a composite of delirium duration, agitation duration and requirement of intubation and mechanical ventilation. Outcome difference were driven by effective control of agitation.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000891

Introduction: Portal hypertension is the most feared complication of cirrhosis, due to the higher morbidity and mortality that its appearance entails and that entails complications such as ascites, encephalopathy and variceal hemorrhage. Among them, the most serious complication is hemorrhage, since it is associated with high mortality. In recent decades there have been important advances in the management of variceal bleeding and one of them has been the introduction of TIPS.
Objectives: To describe the clinical and demographic characteristics, as well as the complications of patients who received transjugular intrahepatic portosystemic shunt (TIPS) for gastrointestinal bleeding.
Methods: This is a retrospective descriptive analysis of patients admitted to our intensive care unit due to gastrointestinal bleeding between September 2020 and December 2022.
Results: During this period, TIPS was performed on 26 patients, 21 of whom were male (80.7%), with a mean age of 61 years. Nine of them had active alcoholism at the time of admission. Alcoholic cirrhosis was the leading cause of liver cirrhosis, accounting for 61.5%, while cryptogenic cirrhosis was the second most frequent cause, accounting for 30.7%. 54.1% of the patients had a Child–Pugh B, and the average MELD score was 17 points, with two patients on the waitlist for liver transplantation.
A decrease in portosystemic pressure gradient of 12 mmHg was achieved in 92% of the patients, with an average gradient of 7.19 mmHg. Therefore, the procedure was considered effective in almost all patients.
No hemorrhagic or arrhythmic complications were reported during the procedure.
The main complication after TIPS placement was hepatic encephalopathy, which occurred in 34.6% of the patients (9), with 6 of them in grades I/II and 3 in grades III/IV. Two patients with grades III/IV required TIPS removal.
The second complication was post-TIPS liver dysfunction, which occurred in 15.38% of the patients (4), with a bilirubin elevation of up to 3 times its previous value. One of them eventually required liver transplantation.
No cardiac, infectious, or shunt dysfunction complications were reported after TIPS placement.
Finally, 9 patients (34.6% mortality) died, 6 of them due to gastrointestinal bleeding, 1 due to coagulopathy and bleeding at other levels, and 2 due to multiorgan failure.
Conclusions: Transjugular intrahepatic portosystemic shunt appears to be a useful therapeutic option in patients with portal hypertension and gastrointestinal bleeding requiring rescue treatment. According to our cohort, it is a safe procedure with few complications, with post-TIPS encephalopathy being the most frequent complication and the only one that can result in procedure reversal. The effectiveness of this therapy will need to be evaluated in larger subsequent studies.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000892

Introduction: Sepsis, defined as life-threatening organ dysfunction caused by a dysregulated host response to infection, is an enormous challenge in intensive care units (ICUs). It may lead to septic shock, multiorgan dysfunction or failure, and death, especially if not identified early and treated appropriately. Septic shock, characterized by severe hemodynamic failure, has a high mortality rate of over 40%. Surviving Sepsis Campaign (SSC) Hour-1 sepsis bundle highlights lactate level, blood cultures, broad-spectrum antibiotics, rapid fluid resuscitation, and vasopressors support as a standard strategy for sepsis management. To obtain a targeted mean arterial pressure (MAP) ($\geq$ 65 mmHg) to ensure tissue perfusion, norepinephrine (NE) is currently recommended as the first-line vasoactive drug when fluid resuscitation fails. If MAP is still inadequate, the SSC guideline proposes to start a second-line vasopressor.
Objectives: To describe ICU admitted patients characteristics at a tertiary hospital, who received vasopressin according to the protocol established, from March to December 2022.
Methods: Observational, prospective study, on septic patients admitted to the ICU from March to December 2022. Epidemiological data, comorbidities, clinical features, invasive support, complications, severity scales and outcome were collected. Descriptive analyses were expressed as means (standard deviation) for normally distributed quantitative variables, medians (interquartile range) for non-normally distributed variables, and as percentages for categorical data.
Results: Data from seventy patients were collected, 53% were male, 92% admitted to ICU for medical pathology. Source of infection: 50% respiratory, 3% abdominal, 17% other sources **Comorbidity**: Charlson 3 (2–4). **Severity scales**: APACHE II at admission 26 $\pm$ 7. SOFA at admission 10 $\pm$ 3, maximum SOFA 12 $\pm$ 3. Time from septic shock diagnose to the start of NAD perfussion was 3 h (1–6); NAD dose when initiating VAP 0,6 $\pm$ 0,4; time from sepsis diagnosis to VAP initiation 8 h (5–16). Time from NAD initiation to VAP initiation 4 h (2–10); positive response to VAP 63%, total time of VAP perfussion 24 h (16–39); NAD was suspended 12 h after VAP therapy interruption (9–24). **Hemodynamic monitoring:** 60% transthoracic echocardiography, 26% thermodilution, 14% pulse wave analysis. **Cardiac dysfunction:** none 73%, mild 22%, moderate 3%, severe 13%. **Volume expansion:** volume administered in Emergency room (ER) 2000 ml (1500-3000 ml). Volume administered in the first 6 h from ICU admission, 2000 ml (1500-3000 ml).

Volume administered in the first 24 h, 5000 ml (4000-6000 ml). **Diuresis**: median diuresis in the first 24 h: 1100 ml (500-1500 ml); in the first 24 and 48 h the hydric balance was positive 98% and 75% respectively. **Preload optimization**: Inferior vena cava 2 cm (1, 4–2, 4), Velocity Time Integral (VTI) 15 ± 4, cardiac index 3, 2 ± 1,4, dynamic variables (stroke volumen variation / pulse contour) 14 (10–17). Preload was optimized in 72% of patients. **Perfusion**: ER lactate 5 mmol/L (2–8 mmol/L), ICU admission lactate 6 mmol/L (4–8 mmol/L), 6 h ICU Lactate 5 mmol/L (3–12 mmol/L).
Invasive mechanical ventilation: 80%. Total days on mechanical ventilation 4 days (1–15). **Renal replacement treatment (RRT) required** in 50% of our cohort. **Complications:** 8% of patients suffered complications: 7% atrial fibrillation and 3% ischemic events.
ICU stay: 9 days (3–22). **ICU mortality**: 49%.
Conclusions: In our cohort, patients clinical situation was highly severe at admission, leading to high mortality. Despite of it; we have observed a vasopressin favorable response.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000895

Introduction: Outcomes of patients with haematological malignancy (HM) have improved rapidly due to advances in diagnosis and new emerging therapies [1]. Historically, mortality of patients with HM in critical care has been very high (up to 90%) but more recent reports have demonstrated improved outcomes [2]. However, a number of these patients require admission to an intensive care unit (ICU), where mortality, especially after acute respiratory failure (ARF), remains significant [3]. Our aim was to assess the impact of patient demographics and disease-related factors on short- and long-term outcomes of patients with HM admitted to ICU.
Methods: Retrospective observational cohort study of patients with HM, requiring admission to ICU between December 2018-December 2020. Uni- and multi-variate logistic regression analyses were conducted to assess the impact of patient and disease factors on ICU / hospital and 1-year mortality, as well as on treatment escalation discussions.
Results: We analysed 238 patients with HM admitted to ICU. Patient demographics and disease characteristics are shown in Table 1. The most common haematological malignancy was non-Hodgkin lymphoma 75/238 (32.8%), 65/238 patients were on a first line treatment, while 125/238 (53.4%) had two or more comorbidities. End-of-life decisions were made in 86 patients (36.9%). Out of 238 patients, 156 (65.5%) were alive at time of ICU discharge, 131 (56.5%) were alive at time of hospital discharge and 104/238 (45.4%) were alive at one year.
Having a diagnosis of lymphoma (OR 2.56; 95%CI 1.21–5.43; p = 0.01) was associated with increased ICU and 1-year mortality (OR 2.58; 95%CI 1.22–5.48; p = 0.01). Admitted in ICU with a diagnosis of myeloma was also strongly associated with increased risk for 1-year mortality (OR 2.3; 95%CI 1.08–4.93; p = 0.03). Disease and transplant status on ICU admission were not independent risk factors, whereas the age of admitted patients significantly affected hospital and 1-year mortality (OR 1.04/year; 95%CI 1.01–1.06; p = 0.003). Isolating a pathogen for ARF was significantly associated with lower ICU (OR 0.39; 95%CI 0.2–0.72; p = 0.003) and hospital (OR 0.43; 95%CI 0.29–0.82; p = 0.01) mortality. Documented discussions around treatment goals occurred almost three times more often when the ARF diagnosis was known (OR 2.97; 95%CI 1.56- 5.65; p = 0.001) but no other association was found.
Conclusions: In this retrospective, single cohort study, only haematological diagnosis on ICU admission and an established diagnosis for ARF were statistically significantly associated with ICU/hospital and 1-year mortality. The known association between undiagnosed AFR and mortality was also demonstrated by these data. However, association between less treatment escalation discussions and unknown ARF aetiology has not been previously reported. Whether this represents physicians' reluctance to limit therapy when a diagnosis is lacking or is a random effect requires further investigation.

Table 1: Patient demographics and disease characteristics.

Total Number n(%)	238 (100%)
Gender: n(%)	
Male	115 (63.4%)
Female	123 (52.6%)
Age: m (SD)	57.3 (13.5)
Co-morbidities: n(%)	
No co-morbidities	60 (25.4%)
One co-morbidity	50 (21.2%)
Two or more co-morbidities	125 (53.4%)
Missing	3 (1%)
Type of Malignancy: n(%)

Metformin-associated lactic acidosis—5-year retrospective study in an Intensive Care Unit

D. da Costa Oliveira[1], P. Reis Pereira[2], D. Bento[1], M. Sousa[1], P. Pinto[1], A. Santos[1], F. Esteves[1]
[1]Intensive Care Unit, Centro Hospitalar De Trás-Os-Montes E Alto Douro, E.P.E., Vila Real, Portugal; [2]Nefrology Department, Centro Hospitalar De Trás-Os-Montes E Alto Douro, E.P.E., Vila Real, Portugal
Correspondence: D. da Costa Oliveira
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000896

Introduction: Metformin is generally regarded as a safe drug. However, one of its rarest but most feared adverse effects is metformin-associated lactic acidosis (MALA), with an associated mortality rate between 30 and 50%. Metformin is frequently contraindicated in patients with advanced stages of renal and hepatic insufficiency, as well as advanced heart failure, as these are known to be at an increased risk of MALA.
Objectives: The aim of this work was to evaluate the epidemiology and clinical outcomes of MALA, as well as the role of continuous renal replacement therapies for the treatment of MALA in our intensive care unit (ICU).
Methods: We selected all patients admitted for MALA in our ICU between 2014 and 2019. We evaluated patients' demographics, rate of mortality, length of hospital stay, treatment with continuous renal replacement therapy (CRRT), modality of CRRT, and previous medical history of renal, heart, or liver disease.
Results: The prevalence of MALA in our ICU patient population during the study period (n = 3825) was 0.05% (n = 20). The average patient age was 75.6 ± 5.7 years and the percentage of female patients was 60% (n = 12). The mortality rate was 10% (n = 2) and the average hospital length of stay was 16 ± 8 days. Twelve patients (60%) were submitted to CRRT; from these, 11 patients were treated with continuous venovenous hemodiafiltration (CVVHD), and 1 patient was treated with sustained low efficient daily diafiltration. In this patient population, chronic kidney disease was present in 75% of the population (n = 15); chronic heart failure in 95% (n = 19) and chronic liver disease in 15% (n = 3) of the population. Average lactate on hospital admission was 13.1 ± 2.8 mmol/L and the average percentage of lactate reduction in the first 24 h of ICU stay was 75 ± 21%. Hospital admission lactate levels and percentage of lactate reduction did not correlate with the length of hospital stay or need for CRRT.
Conclusions: The majority of patients with MALA admitted to ICU had chronic kidney disease or chronic heart failure. CRRT was used to treat a significant proportion of patients. The mortality rate in the ICU environment was lower than overall reported mortality rates for MALA in previous studies.

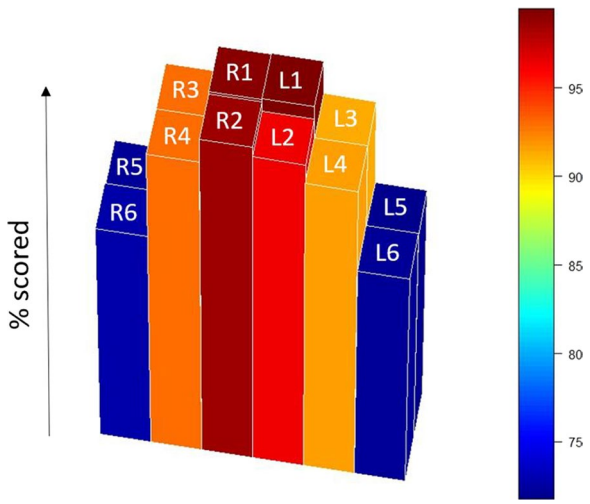
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000897

Introduction: Lung ultrasound (LUS) can be used for daily practice to monitor pulmonary pathologies and clinical decision making in critically ill patients (2). However, there is an ongoing debate concerning the optimal number of regions that should be scanned for an accurate assessment of lung pathology in critically ill patients (3). The 12-region LUS protocol is used most often (4). Nonetheless, the feasibility of a 12-region LUS protocol for daily monitoring of critically ill patients is not known.
Objectives: Primary aim of this study is to assess the feasibility of a daily 12-region LUS protocol in critically ill patients. Based on previous research and clinical expertise, we hypothesized that at least 85% of regions could be scanned (5). The secondary aim is to report factors of influence for missing regions.
Methods: This is a prospective multicentre observational cohort study that was performed as part of the 'Effect of lung ultrasound-guided fluid deresuscitation on duration of ventilation in intensive care unit patients' (CONFIDENCE). The CONFIDENCE protocol has been published previously (2). Patients received daily LUS after hemodynamic stabilisation. LUS examinations were performed by trained healthcare professionals. A 12-region LUS protocol was used: six points per hemithorax. For each region, the operator scored the lung according to the LUS aeration score (6). If a region could not be assessed the option 'not assessable' could be selected.
Results: A total of 393 lung ultrasound examinations in 69 unique patients were analysed. 4137 (88%) of the 4716 lung regions were scored. The figure shows percentages of successful scored LUS examination per region. The anterior regions had the highest percentage of scored examinations. Regions R1, R2 and L1 were scored in 99% of examinations. L2 was scored less frequently with 96% scored. Mostly, due to the presence of the heart which impedes the assessment of lung tissue. The posterior regions (R5, R6, L5 and L6) were scored least often (72%). Reported factors influencing assessment included (in descending order of occurrence) high diaphragm position, thoracic drains or bandages in situ, lateral positioning of the patients in bed, habitus and discomfort or agitation of the patient.
Conclusions: More than 85% of lung regions can be examined in a 12-region LUS protocol in daily practice for critically ill patients. High diaphragm position, thoracic drains or bandages in situ, lateral positioning of the patients in bed, habitus and discomfort or agitation of the patient were reported as factors of influence for missing regions.



Percentage of successfully scored examinations per region. Each hemithorax is divided in to six regions: upper and lower parts of the

posterior (R5,R6, L5 and L6), lateral (R3, R4, L3 and L4) and anterior (R1, R2, L1 and L2) chest wall.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000899

Introduction: Fluid overload is associated with worse outcomes in patients admitted to the intensive care unit (ICU).(1) Venous congestion has been suggested as possible explanation for these worse outcomes.(2) The Venous Excess Ultrasound (VExUS) score has been used to assess venous congestion.(3) However, the incidence of abnormal VExUS-score in the ICU is largely unknown.
Objectives: The aim of this preliminary report is to assess the incidence of abnormal VExUS scores and its components in critically ill patients.
Methods: This is a single-center prospective cohort study in adult ICU patients expected to be admitted for more than 24 h to a tertiary ICU. Within 48 h of ICU admission, VExUS was performed with an interval of 1–2 days, with a maximum of three times. The most abnormal ultrasound measurement was included in our analysis. Primary outcome was incidence of abnormal VExUS scores, defined as a score of 1 or more, and its individual components. Secondary outcome were any associations between patient characteristics and VExUS score.
Results: From January to April 2023 34 patients were included. 62% if the cohort was male, the mean age was 64.5(± 14.0) and 41% of patients were admitted due to sepsis. Of the 34 included patients 56% had an abnormal VExUS score and 3 (9%) patients had a VExUS score of ≥ 2. Incidence of abnormal interlobular renal vein waveforms was highest (53%) followed by abnormal portal vein waveforms (44%) and hepatic vein waveforms (35%) (Table 1). No significant associations between patient characteristics and VExUS scores were found. ($p > 0.05$ for all). All patients ($n = 2$), with a VExUS score of 3 died.

Table 1 (abstract 000899) VExUS score and individual parameters

Inferior vena cava diameter (cm), mean(± SD)	**2.0(± 0.46)**		
Inferior vena cava collapsibility %, median [IQR]	**17.8 [6–28]**		
Individual waveforms n (%)	**Portal vein**	**Hepatic vein**	**Interlobular renal vein**
Normal	19(56)	22(65)	13(38)
Mildly abnormal	10(29)	10(29)	17(50)
Severely abnormal	5(15)	2(6)	1(3)
Failed	0(0)	0(0)	3(9)
VExUS score, n (%)			
0	15(44)		
1	16(47)		
2	1(3)		

Conclusions: In this general critically ill population the incidence of an abnormal VExUS score was 56%. A score of ≥ 2 was found in 9%. No associations between patient characteristics and abnormal VExUS score were found. This is a preliminary report and the study will continue until the sample size of 136 patients is reached.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000901

Introduction: The recent advancements in artificial intelligence (AI) technologies have led to the development of prediction models for clinical decision-making in the intensive care unit (ICU) [1]. However, the availability of high-quality ICU data is fundamental for the development and implementation of these models [2]. While a significant amount of ICU data, such as vital signs or laboratory test results, are automatically collected and easily analyzed, other data, such as clinical complications, still require manual entry through additional checklists, resulting in poor data quality and an enormous administrative burden for ICU professionals [3].
Objectives: This study aimed to determine whether text analytics could reduce administrative burden and improve data quality for registering pressure ulcers in the ICU.
Methods: This study included adult patients (age > 17 years) admitted to the Erasmus University Medical Center ICU between January 1, 2022 and December 31, 2022. Pressure ulcer checklists and nursing reports were automatically extracted from the electronic health record. Natural language processing (NLP) techniques were utilized to extract pressure ulcers from unstructured nursing reports. Pressure ulcer rates were compared between structured checklists and unstructured nursing reports.
Results: The study analyzed a total of 2,524 ICU admissions and 2,286 unique patients, with 216,000 nursing reports and 9,586 checklists analyzed. The combined pressure ulcer rate was 13.6% (343 out of 2,524 admissions); 47/2,524 were identified from checklists and 296/2,524 from nursing reports. The use of NLP techniques improved pressure ulcer detection by 650% (from 1.8% to 11.7%; $p < 0.001$).
Conclusions: Text analytics can successfully be used to extract data from nursing reports and has the ability to improve data quality and to decrease administration fatigue in the ICU. Further research is necessary to explore the impact on ICU professionals' workflow.

Incorporating muscle ultrasound in mNUTRIC score as an added tool for nutritional assessment in critically ill patients: a prospective observational study from a tertiary care center

V. Sundarsingh[1], P. Rodrigues[1], M. Kumar[1], N. Baliga.[1]
[1]Critical Care Medicine, Father Muller Medical College, Mangaluru, India
Correspondence: V. Sundarsingh
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000902

Introduction: Loss of muscle mass impairs the physical recovery of critically ill individuals, increasing morbidity and mortality. Catabolism caused by inadequate diet and stress is a significant factor (1). It would be more important to identify at-risk patients early. The modified nutrition risk (mNUTRIC) score, a screening instrument to evaluate nutritional status in critically sick patients, has been proven to be accurate at predicting 28th day mortality (1).Muscle ultrasound (MUS), a nutritional evaluation technique, can be used to screen for sarcopenia to enhance the effectiveness of interventions for people at risk (3). In instances of muscle loss, the quadriceps muscle layer thickness (QMLT) is easy to define and assess, and ultrasonography of the quadriceps muscle also exhibits strong intra- and inter-observer reliability (2).
Objectives: •1) To determine whether adding QMLT to mNUTRIC will increase its capacity for prediction.
2) Finding an association between the mNUTRIC score and the Neutrophil–Lymphocyte ratio (NLR).
3) To determine whether mNUTRIC and ICU outcomes such as ICU length of stay (LOS),
Mechanical Ventilation (MV) free days at 28 days, renal Replacement Therapy (RRT) free days at 28 days and duration of antibiotics are correlated.
Methods: All patients with age > 18 years admitted in intensive care unit were included in this study. Only the first ICU admission during a hospital stay were included. Patients with amputated limb, surgery, neurological, or rheumatological problems involving the lower limbs, patients with skin lacerations or wounds in the areas selected for ultrasound evaluation, patients readmitted to the ICU during the same hospital admission and patients transferred to other ICU/hospitals were excluded from the analysis. At admission all patients were scored with mNUTRIC score. They will also be subjected for Quadriceps muscle layer thickness (QMLT). Then mNUTRIC score will be modified with addition of muscle ultrasound(MUS),which will be referred to as mNUTRIC-MUS score. When Quadriceps muscle length ultrasound (QMLT) is used, QMLT > 1.72 cm was given 0 point & QMLT < 1.72 cm was given 1 point. Patients were classified as having a high mNUTRIC score if the sum is (5–9) and low score if the mNUTRIC score is (0–4).
Results: The study population consisted of 50 critically ill patients, with median age of 61 (54–73) years, among whom 37 (74%) were men. The median mNutric of 4 (3–6), and QMLT of 21.08 (16.90–25.54) mm. Secondary outcomes such as mechanical ventilator free days, vasopressor free days, need for RRT were not significantly different between those at high and low risk of malnutrtion according to mNUTRIC. ICU length of stay (4 vs 7 days, $p = 0.016$) and NLR ((8.82 vs 17.61, $p = 0.03$) were significantly different between the groups at high and low risk of malnutrition. Receiver operating characteristic curves (ROC) with areas under the curve (AUC) for mNUTRIC AND mNUTRIC-MUS were similar and are described in the table below.
Conclusions: The addition of muscle ultrasonography to the mNUTRIC score had no effect on its predictive ability. In patients at high risk of malnutrition, the neutrophil–lymphocyte ratio was found to be considerably greater. As a result, in future studies, NLR can be explored for nutritional assessment of the critically ill patients.

TABLE-1:BASELINE CHARACTERISTICS OF STUDY POPULATION

CHARACTERISTICS(n=50)	VALUES
MEDIAN AGE	61(54-73)
NO OF MALE	37(74%)
MEDIAN LOS (ICU)	4 days (3-7)
MEDIAN LOS (HOSPITAL)	9 days (6-12)
MORTALITY	14/50 (28%)
MEDIAN APACHE 2	16 (11-20)
MEDIAN SOFA	5 (3-6)
NO OF PATIENTS AT HIGH RISK FOR MALNUTRITION	12/50 (24%)
MEDIAN mNUTRIC	4(3-6)
MEDIAN QMLT mm	21.08(16.9-25.54)
MEDIAN NLR	7.84(4.24-18.02)

TABLE – 2: COMPARISON BETWEEN LOW mNUTRIC AND HIGH mNUTRIC SCORE

PARAMETER	LOW mNUTRIC (<5)	HIGH mNUTRIC (5-9)	P value
Age	59(53-72)	61(54-73)	0.453
Length of stay (ICU)	4(3-5)	7(3.25-30)	0.016
Mortality	4/36	10/14	<0.001
QMLT (mm)	21.25(16.90-25.57)	21.02(16.10-25.02)	0.768

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000903

Introduction: Early identification of critically ill neonates with risk of severe sepsis can optimize therapeutic strategies, guide empiric antibiotic use and avoid unnecessary broad-spectrum antibiotics. We aimed to examine whether machine learning (ML) methods can help clinicians toward more appropriate decision of empiric antibiotics for neonatal intensive care unit (NICU) patients on intubation due to respiratory failure.
Methods: A total of 1734 neonates with respiratory failure were randomly divided into training (70%, n = 1214) and test (30%, n = 520) sets. The primary outcome was occurrence of severe sepsis and/or septic shock. The area under the receiver operating characteristic curves (AUCs) of several ML algorithms were compared with that of the conventional neonatal illness severity scoring systems including the NTISS and SNAPPE-II.
Results: For prediction of severe sepsis, the random forest (RF) model showed the highest AUC (0.930 [0.905–0.956]) for neonates on mechanical intubation with respiratory failure, and the bagged classification and regression tree model demonstrated the next best results (0.892 [0.859–0.924]). The ML methods are better than traditional methods to predict severe sepsis and/or septic shock. The superior performances and net benefit of the RF model were confirmed by the best accuracy (0.908), F1 score (0.714) and better calibration, and the decision curve analysis, respectively. In addition, Shapley additive explanation (SHAP) values were utilized to explain the RF prediction model.
Conclusions: Machine learning methods is applicable with good predictive accuracy to predict severe sepsis and/or septic shock in the NICU, which can help clinicians' decision regarding the choices of empiric antibiotics for critically ill neonates. Future prospective trials are warranted to document its clinical usefulness and benefits on reducing medical resources.

Pharmacokinetics of minocycline in critically-ill patients with difficult to treat Acinetobacter baumannii ventilator-associated pneumonia; a preliminary report

Z. Athanassa[1], S. Manioudaki[1], A. Dimoula[1], I. Petsa[1], V. Charizopoulou[1], A. Dokoumetzidis[2], V. Koumaki[3], A. Sakagianni[1], G. Valsami[2], A. Tsakris[3]
[1]ICU, Sismanogleio General Hospital, Marousi, Greece; [2]Department of Pharmacy, National and Kapodistrian University of Athens, Athens, Greece; [3]Microbiology Department, National and Kapodistrian University of Athens, Athens, Greece
Correspondence: A. Sakagianni
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000905

Introduction: The prevalence of multidrug resistant (MDR) *Acinetobacter baumanni* (*A. baumannii*) infections is increasing while available treatment options are limited. The lack of new effective antimicrobial agents has led to reintroduction of old antibiotics like minocycline for the treatment of MDR *A.baumannii.*
Objectives: The aim of this study is to assess minocycline pharmacokinetic properties after enteral administration in patients with extensively drug (XDR) and pandrug (PDR) resistant *A.baumannii* ventilator-associated pneumonia (VAP).
Methods: We conducted a prospective study of ICU patients between January 2022 and July 2022. Patients with a diagnosis of VAP due to XDR or PDR *A.baumannii* received minocycline as combination therapy. The diagnosis of VAP was based on observation of purulent secretions, deterioration of blood gas exchange, new infiltrates of chest computed tomography and isolation of XDR or PDR *A.baumannii* heavy growth at semiquantitative endotracheal aspirate (ETAS) cultures. The minimum inhibitory concentration (MIC) of minocycline was determined using broth microdilution. According to CLSI breakpoints, *A.baumannii* susceptibility to minocycline was defined as MIC $\leq$ 4 μg/ml, while an MIC up to 8 μg/ml was considered as intermediate susceptibility. Eligible patients received minocycline via nasogastric tube in a loading dose of 200 mg followed by 100 mg every 12 h. Blood samples were drawn at 1, 2, 6 and 11.5 h after loading dose. In addition blood samples were received on day 3 at 1, 4, and 8 h after administration of sixth maintenance dose (steady state). Minocycline serum concentration was determined by high performance liquid chromatography (HPLC). Demographics, co-morbidities and duration of treatment with minocycline were recorded. In addition, clinical and laboratory data (fever, haemodynamic instability, PaO2/FIO2 ratio, WBC count, CRP, procalcitonin) and cultures of endotracheal suction aspirates (ETSA) were assessed at the onset and end of treatment. End-point outcomes were clinical improvement defined as recession of clinical signs, increase of PaO2/FIO2 ratio, and microbiological response defined as no, rare or light bacterial growth in ETSA.

Results: Sixteen patients were included (13 men) with a mean age of 66.6 years. Most patients (15) had documented severe COVID-19 infection on ICU admission. Seven isolates were susceptible (MIC < 4 µg/ml) and 9 were intermediately susceptible (MIC 8 µg/ml) to minocycline. The mean duration of treatment with minocycline was 9 days. Minocycline was co-administered with other antimicrobials mainly meropenem and/or colistin. At the end of treatment a favorable clinical response was observed in 12 out of 16 patients (75%), while a favorable microbiological response in 11 patients (69%). Median (IQR) minocycline serum concentrations at 1, 2, 6 and 12 h after administration of loading dose were 0.5 (0.41–1.08) µg/ml, 0.88 (0.46–2.16) µg/ml, 0.75 (0.24–1.08) µg/ml and 0.37 (0.06–0.89) µg/ml respectively. At steady state median (IQR) minocycline serum concentrations were 2.1 (0.95–4.1) µg/ml, 1.82 (0.71–3.6) µg/ml and 0.68 (0.31–1.14) µg/ml respectively at 1, 4 and 8 h after the sixth dose. Minocycline concentrations varied among patients at all sampling periods.
Conclusions: Minocycline serum concentrations peaked at 2 h after enteral administration of 200 mg bolus dose. At steady state, the highest serum concentrations were observed at 1 h after administration. However, even at steady state, minocycline serum concentrations were low compared with *A. baumannii* susceptibility breakpoints to minocycline. The observed variation in minocycline serum concentrations might be attributed to differences in drug absorption and patients' characteristics. Since currently minocycline is available only in enteral formulation in Europe further studies evaluating pharmacokinetics after administration of higher doses are needed.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000907

Introduction: Critically ill patients with shock are often exposed to a significant degree of untreated relative hypotension during vasopressor support. (1) Such relative hypotension, quantified as 'mean arterial pressure (MAP) deficit', is independently associated with adverse clinical outcomes. (1) Whether minimizing such MAP-deficit during vasopressor therapy for shock may reduce the risk of adverse clinical outcomes in ICU needs to be tested in a definitive RCT. However, before embarking on a large RCT, we need to conduct a pilot phase to assess feasibility of this protocol.
Objectives: In this pilot RCT, we assessed feasibility of individualizing MAP targets based on patients' own pre-illness MAP, compared to standard care, during vasopressor support for shock in ICU.
Methods: Eligible patients were adults, aged 40 years or older, who were receiving vasopressor support for a non-hemorrhagic shock state in ICU. Thirty-seven eligible patients were randomly allocated to the standard care group or the intervention group at two tertiary-level academic ICUs in Australia and Ireland. The feasibility endpoint was time-weighted average MAP-deficit during vasopressor therapy. MAP-deficit was derived as the percentage difference between patients' pre-illness MAP and ICU achieved-MAP whilst on vasopressors. Preliminary efficacy outcomes were major adverse kidney events within 14 days (MAKE-14) and 14-day mortality. MAKE was defined as a composite measure of death, new renal replacement therapy, or doubling of serum creatinine level from pre-illness level at day 14.
Results: The cohort comprised of 37 patients (mean age, 65 years; 57% males). Baseline characteristics were overall well matched. The median time-weighted average MAP-deficit in the control group versus intervention group was 17%, [interquartile range [IQR]: 10–21] *vs.* 9%, [IQR: 5–14], p = 0.026) as shown in Figure 1. The median time-weighted average noradrenaline-equivalent dose in the control group versus intervention group was 0.06 mcg/kg/min [IQR: 0.03–0.11] *vs.* 0.11 mcg/kg/min [IQR: 0.06–0.15], p = 0.015). Clinical outcomes and adverse events were similar across both groups (Table 1).

Table 1 (abstract 000907) Outcomes

	Standard (n = 20)	Individualised (n = 17)	*P* value
Day 14 all-cause mortality, n (%)	3 (15%)	1 (6%)	0.37
Major Adverse Kidney Event within 14 days, n (%)	4 (20%)	2 (12%)	0.50
Day 90 all-cause mortality, n (%)	4 (24%)	2 (13%)	0.41
Adverse events post-randomisation			
Atrial arrhythmia	3 (15%)	4 (24%)	0.51
Ventricular arrhythmia	3 (15%)	2 (12%)	0.77
Mesenteric or myocardial ischemia	0 (0%)	0 (0%)	-
Takotsubo cardiomyopathy	0 (0%)	1 (6%)	-
Bilateral digital ischemia	0 (0%)	1 (6%)	-
Ischemic stroke	1 (5%)	0 (0%)	-

IQR: Interquartile range; MAP: Mean Arterial Pressure, mmHg;
Conclusions: An individualized blood pressure target strategy during vasopressor therapy in ICU was feasible and safe in this pilot RCT. Adequate level of treatment separation was achieved in-between the two groups.
Study registration: ACTRN12618000571279.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000909

Introduction: Cardiopulmonary function parameters are critical in understanding ventilation-perfusion matching and guiding individual patient care. Pulmonary Blood Flow (PBF), Physiological Dead Space (VD), and Functional Residual Capacity (FRC) are currently measured using time-consuming and invasive methods. PBF is typically measured using thermodilution via a pulmonary catheter minus shunt fraction, VD via volumetric capnography coupled with blood-gas measurements and FRC via nitrogen washout. To overcome the limitations of these traditional methods, the non-invasive, semi-continuous VQm Pulmonary Health Monitor (PHM)™ has been developed to optimize therapy while providing near-real time data.
Objectives: The aim of this study was to evaluate the performance of the VQm PHM™, a non-invasive cardio-pulmonary health monitor, in measuring PBF, VD, and FRC in mechanically ventilated surgical patients in comparison to established gold standard measurements.
Methods: PBF was estimated using a modified differential Fick equation and compared to the thermodilution cardiac output (TDCO). Shunt fraction was estimated from central venous and arterial blood gases measurements using the Berggren equation and the result was subtracted from TDCO to calculate the reference PBF1. VD was obtained using volumetric capnography and arterial blood gas values, similar to the reference measurement obtained using the GE Healthcare ventilator. FRC was compared to nitrogen washout methods also using the GE Healthcare CARESCAPE™ ventilator. Agreement was evaluated using Bland–Altman analysis and concordance was characterized using four-quadrant plot analysis.
Results: 42 patients, mean age 66.7 ± 13.1 years, were included in this analysis. For PBF, 19 patients (17 males) produced 70 measurements. The mean difference between paired PBF values was 0.2 L/min, the 95% limits of agreement were 1.3 and -1.0 L/min (Fig. 1A) with a concordance of 93% (no exclusion zone) (Fig. 1B).
For VD, 19 patients (14 males) produced 89 paired measurements. The mean difference between paired VD values was − 1%, the 95% limits of agreement were − 13% to 10% (Fig. 2) with a concordance of 77% (2.5% exclusion zone).
For FRC, 23 patients (17 males) produced 98 paired measurements. The mean difference between the paired FRC values was − 0.8L, the 95% limits of agreement were 0.4L to − 2.1L with a concordance of 85% (2.5% exclusion zone) (Fig. 3).
Conclusions: Our results indicate good agreement and trending for PBF and VD and good trending for FRC measured using VQm and our reference values.

Experiences of patient violence in Swedish intensive care units

F. Sjöberg[1], M. Salzmann-Erikson[2], E. Joelsson-Alm[3], A. Schandl[3]
[1]Department of Anesthesia and Intensive Care, KI Södersjukhuset, Stockholm, Sweden; [2]Department of Caring Sciences, Faculty of Health an Occupational Studies, University of Gävle, Gävle, Sweden; [3]Department of clinical science and education, Karolinska Institutet, Södersjukhuset, Stockholm, Sweden
Correspondence: F. Sjöberg
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000911

Introduction: In the intensive care unit (ICU), every second patient develops acute brain dysfunction and delirium, because of severe illness and/or medical treatment (1). ICU patients may have delusions and even believe that the healthcare personnel try to inflict harm upon them (2). This belief in combination with psychomotor agitation may lead to violent incidents in intense resistance (3). Except for debilitating consequences for patients, violent incidents are major problems in healthcare causing physical and psychological harm to healthcare workers (4–6). However, systematic approaches to describe healthcare workers' experiences and management of aggressive ICU patients are needed.
Objectives: To explore ICU healthcare workers' experiences and perceptions of violent behaviors in patients with acute brain dysfunction.
Methods: A qualitative descriptive design including focus group interviews with 36 ICU healthcare workers (physicians, nurses, nurse assistants and physiotherapists) in 4 Swedish ICUs who had experience of managing aggressive patients with acute brain dysfunction. A six-step reflective thematic analysis was used to analyse data.
Results: Nurses and assistant nurses were perceived to be at an increased risk of being exposed to violence, while physicians were mostly exposed to verbal assaults and threats from relatives. Delusions were perceived to be associated with a higher risk of violence in bedside work. The healthcare workers stated that incidents were under-reported, where only serious threats or physical assaults were reported. Most violent situations were experienced as unavoidable due to the patients' illness.
Conclusions: This study contributes an understanding of workplace violence in the ICU and may serve as a basis for development of violence prevention strategies useful in care and treatment of delirious patients.

Impact of CCL-14 on fluid management and hemodynamic monitoring of patients with severe AKI

I. Palmares[1], T. Vilaça[1], A. Curto[2], P. T. Freitas[1], S. Coelho[1]
[1]Intensive Care Department, Hospital Fernando Fonseca, Amadora, Portugal; [2]Nephrology Department, Hospital Fernando Fonseca, Amadora, Portugal
Correspondence: I. Palmares
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000912.

Introduction: Severe AKI is a common complication of critically ill patients, frequently observed in the context of multi-organ damage. Fluid management and hemodynamic monitoring can be particularly challenging in these patients. We aim to evaluate the impact of CCL-14, a biomarker of persistent severe AKI, in clinical practice.
Methods: A single-center, prospective, observational study of critically ill patients with AKI stage 2 or 3 by KDIGO criteria on ICU admission was performed. CCL-14 was measured by immunoassay on fresh urine samples within 48 h of admission and repeated after 48 h using the NEPHROCLEAR™ CCL14 Test on the Astute140® Meter (Astute Medical, San Diego, CA). We excluded patients with stage 5D chronic kidney disease; expected length of ICU stay < 48 h, renal replacement therapy (RRT) in the week prior to ICU admission; and patients with a clinical decision to start RRT prior to study inclusion. The assisting physician answered a questionnaire before and after CCL-14 determination.
Results: A total of 50 patients were included, median 71-year-old, 64% male, 88% caucasian, median APACHE 23.5. During ICU stay, 12% needed RRT, 82% vasopressors, 80% mechanical ventilation and 78% had septic shock. Diagnosis of AKI by KDIGO was performed by serum creatinine criteria in 54%, urine output in 28% and by both criteria in 14%. 42% had severe persistent AKI.
Before knowing the CCL-14 result, the assisting physician thought the fluid balance (FB) target should be positive in 46%, neutral 40% and negative 14% (CCL14 values were 1.95, 1.28 and 1.33 ng/ml, respectively). All clinicians answered they wouldn't change the current hemodynamic monitoring.
After knowing the CCL-14 result, the assisting physician thought the FB target should be positive in 38%, neutral 46% and negative 16% (CCL14 values were 0.80, 1.55 and 1.35 ng/ml). A positive FB (versus neutral or negative FB) was considered a target by a lower number of clinicians (Wilcoxon test p-value 0.046). Only 2% of clinicians (n = 1) answered they would change the current hemodynamic monitoring.
Conclusions: CCL-14, by predicting persistent severe AKI, may be an additional tool to help clinicians decide the target FB of their patients. In our study, higher CCL-14 values were associated with a less probable choice of a positive FB. There was no difference in the choice of hemodynamic monitoring according to the CCL-14 value.

Impact of early versus late tracheostomy in critically ill COVID-19 patients: experience of a single-center in Greece

M. Sileli[1]; E. Kerezidou[1]; M. Kamaterou[1]; G. Katsikaki[1]; D. Ntantos[1]; G. Gogos[1]; N. Kapravelos[1]; C. Iasonidou[1]

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000913

Introduction: In anticipated prolonged invasive mechanical ventilation, elective tracheostomy is indicated in critically ill COVID-19 patients. However, the optimal time to perform a tracheostomy in these patients is still debated.
Objectives: The primary endpoint was to assess the effect of tracheostomy timing on mortality in critically ill COVID-19 patients. The secondary endpoints were to evaluate its impact on invasive mechanical ventilation time (MV), ventilation-associated pneumonia (VAP), secondary infection, and length of ICU stay (LOS).
Methods: We conducted a retrospective, single-center study in a Greek tertiary-care ICU from March 2020 to April 2022. We included all adult patients with moderate to severe ARDS due to PCR-confirmed COVID-19 disease who underwent percutaneous tracheostomy. We recorded demographic data (age, gender, BMI), comorbidities quantified by the Charlson's Comorbidity Index (CCI), severity scoring (APACHE II, SOFA score), pO2/FiO2 ratio, days until tracheostomy, MV days, VAP, secondary infections, LOS, and ICU mortality. VAP was defined as clinical suspicion with concomitant positive cultures of tracheal aspirates. All patients were uniformly treated according to the national recommendations. None of them were fully vaccinated. We allocated patients into early and late tracheostomy groups (early $\leq$ 10 days, late > 10 days) and followed them until discharge or death in the ICU. The chi-square, student t-test, and Wilcoxon-Mann-Witney U tests were used as appropriate. The p-value was set at 0.05. Statistical analysis was performed using the R statistical package.
Results: We analyzed data from 72 patients who underwent percutaneous tracheostomy with a mean age of 63,9 $\pm$ 9,4 years; 65,3% were males. The median Charlson Comorbidity index was 2 (IQR: 2 to 3,2), the mean APACHE II was 15,3 $\pm$ 3,3, and the median SOFA was 7 (IQR: 4 to 8). 58,3% of patients met the criteria for severe ARDS. The median LOS was 23 days (IQR:19 to 33.2), with a mortality rate of 47,2%. None of the ICU healthcare workers was infected by Covid-19 due to the intervention. Twenty tracheostomies (27,8%) were performed early, and the rest late. No differences were observed regarding demographics, comorbidities, severity scores, and ARDS categories between groups ($p > 0.05$). There was no significant association between early tracheostomy and MV days, the incidence of secondary infections, the overall LOS, and the mortality rate ($p > 0.05$). Notably, VAP was significantly lower in the early tracheostomy group ($p = 0.002$) in our patients.
Conclusions: Early tracheostomy was associated with a reduced incidence of VAP in our cohort. However, it had no impact on mortality, duration of MV, the incidence of secondary infections, and faster discharge. These results extend the current observations. Further studies on the optimal time to perform a tracheostomy on COVID-19 patients are mandatory.

Vassopresin impact on the need of renal replacement therapies in septic shock patients

J. Cui[1], G. Castañeda[1], J. Cedeño Mora[1], P. García Olivares[1], C. Ramirez[1], C. Alvarez[1], R. Ruiz Cacho[1], N. Cango[1], A. Rodriguez[1], M. Artabe[1]
[1]Intensive care unit, H.G.U Gregorio Marañón, Madrid, Spain
Correspondence: G. Castañeda
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000914

Introduction: Vasopressor therapy is used in septic shock to increase vascular resistance, raise mean arterial pressure and maintain perfusion of critical body tissues and organ systems. The Vasopressin and Septic Shock Trial (VASST) was the first large randomised comparison of vasopressin with Noradrenaline. Subsequent post hoc analyses and other studies suggested a potential reduction in renal dysfunction with higher dose vasopressin as well as a potentially synergistic interaction with corticosteroid treatment.
Objectives: To analyse the association between vasopressin (VAP) and noradrenaline (NAD) use with the need of Renal Replacement Therapies (RRT) in septic shock patients.
Methods: Observational, prospective study on septic shock patients admitted at Gregorio Marañón Intensive Care Unit (ICU) between March and December 2022, to assess the impact of vasopressin and noradrenaline use in the need of RRT in septic shock patients. Epidemiological data, comorbidities, severity, clinical features, invasive support, complications and outcomes were collected.
Descriptive analyses were expressed as means (standard deviation) for normally distributed quantitative variables, medians (interquartile range) for non-normally distributed variables, and as percentages for categorical data. Univariant analysis was performed using Chi-squared (relative risk) for qualitative variables, and simple logistic regression for quantitative variables. Severity adjusted multiple logistic regression was used to determine independent mortality related factors.
Results: 70 patients were included, 53% male. Mean age 61 $\pm$ 16 years. Charlson Index 3 (2–4).
Severity scales: APACHE II 26 $\pm$ 7, SOFA score at admission 10 $\pm$ 3, maximum SOFA score 12 $\pm$ 3.
Organic support: need of invasive mechanical ventilation 80%, mean duration of ventilation therapy 4 days (1–15).
Renal replacement therapy: in 50% of our cohort.
Initial volume expansion: In the ER 2000ml (1500–3000), first 6h at ICU 2000ml (1500-3000ml), first 24h at ICU 5000ml (4000–6000). 98% of patients had positive fluid balance after 24h at ICU. 32% of patients had negative or neutral fluid balance after 48h at ICU.
Effective lactate clearance during the first 24h since ICU admission was achieved in 54% of patients, patients had optimal preload in 72% of cases, and NAD dose at VAP initiation was 0.6 $\pm$ 0.4 ug/Kg/min.
Global ICU and in-hospital mortality: 49%
Univariate analysis: there was significant difference between the APACHE II score in patients needing RRT and those who did not need it (27 $\pm$ 8; 24 $\pm$ 7) $p = 0,04$, as well as SOFA score (9 $\pm$ 3; 12 $\pm$ 3), $p = 0,01$ and in lactate levels (5 $\pm$ 3; 12 $\pm$ 3) $p = 0,03$. The differences between the rest of the variables compared (Age, Charlson Index, time from shock to the initiation of VAP or NAD, time between NAD and VAP initiation and the NA dose at the moment of VAP initiation) were not statistically significant.

Conclusions: In our series, septic shock patients receiving NAD, using VAP as a second vasopressor, did not reduce the need of RRT.

Variable	Significance
Age	OR 0,67 (0,92 – 1,05)
Charlson Index	OR 0,57 (0,76 – 1,16)
APACHE II	OR 0,99 (0,91 – 1,10)
Lactate	OR 0,53 (0,99 – 1,47)
SOFA score on ICU admission UCI	OR 0,72 (0,98 – 1,68)
Time from hemodynamic shock to NAD initiation	OR 0,74 (0,74 – 1,01)
Time from hemodynamic shock to VAP initiation	OR 0,11 (0,98 – 1,17)
NAD dose at the moment of VAP initiation	OR 0,51 (0,29 – 11,94)

ICU acquired weakness incidence and outcome after cardiac surgery

T. Soulele[1], K. Kolovou[1], M. Antonopoulos[1], M. Panoutsopoulou[1], E. Tzatzaki[1], M. Chronaki[1], E. Spiropoulou[1], C. Kindi[1], N. Rouvali[1], M. Georgopoulou[1], S. Dimopoulos[1]
[1]Icu, Onassis Cardiac Surgery Center, Kallithea, Greece
Correspondence: T. Soulele
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000915

Introduction: ICU acquired muscle weakness (ICUAW) is associated with frailty, morbidity, prolonged hospital length and poor quality of life in patients post-critical illness.
Objectives: Aim of this study is to assess incidence of ICUAW in patients admitted in Cardiac Surgery ICU immediately after cardiac surgery and its association with clinical outcome.
Methods: 189 consecutive patients admitted to ICU after cardiac surgery participated in this study. Demographic and clinical characteristics were recorded and ICUAW was evaluated daily using MRC scale until 7th ICU stay or ICU discharge. ICUAW was defined as MRC scale < 48.
Results: 17 patients (9.5%, 67 ± 15 years) developed ICUAW after ICU admittance. These patients had higher EUROSCORE (7 ± 10 vs 2 ± 3, %, $p < 0.001$) longer cardio-pulmonary bypass (CPB) time (163 ± 65 vs 116 ± 49 min, $p = 0.001$) and aortic cross-clamp time (112 ± 40 vs 84 ± 41, min, $p = 0.01$), were more sedated (2139 ± 2131 vs 686 ± 437, min, $p < 0.001$), received more vasopressors (71 vs 26, %, $p = < 0.001$ and inotropes (82 vs 59, % $p = 0.05$), presented more delirium (71 vs 23, %, $p < 0.001$) and had more acute kidney injury (53 vs 22, %, $p = 0.01$). ICUAW was associated with longer duration of mechanical ventilation support [73 ± 97 vs 15 ± 10 h, $p < 0.001$) and ICU stay (129 ± 43 vs 39 ± 28 h, $p < 0.001$).
Conclusions: Patients post cardiac-surgery admitted in ICU present frequently with ICUAW. ICUAW is associated with adverse outcome and prolonged ICU stay.

Topic: Nursing care and physiotherapy

Service evaluation of compliance with newly implemented ABCDEF bundle

H. Goudie[1], S. Norman[1]
[1]Center for Medical Education, School of Medicine, Cardiff University, Cardiff, United Kingdom
Correspondence: H. Goudie
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000916

Introduction: In response to the increased recognition of long term consequences of surviving critical illness, The Society of Critical Care Medicine's (SCCM) (1) introduced the ABCDEF bundle (Assess, prevent, and manage pain[A]; Both Spontaneous Awakening Trial [SAT] and Spontaneous Breathing Trial [SBT] [B]; Choice of analgesia and sedation [C]; Delirium: assess, prevent, and manage[D]; Early mobility and exercise [E]; Family engagement and empowerment [F]) to incorporate preventative measures of care to reduce the risk of ICU patients developing delirium. The ABCDEF bundle aims to use a multicomponent strategy in preventing delirium and acknowledges the large number of predisposing factors that contribute to delirium in the critically ill patient. The ABCDEF bundle was implemented in the Researcher's unit in January 2022.
Objectives: To undertake a service evaluation to assess the Author's ICU compliance with the ABCDEF bundle to identify its effectiveness in reducing delirium.
Methods: We performed an in-depth literature review to help inform our service evaluation. We then conducted a single centre, retrospective service evaluation (SE) using all consecutive patient data collected from electronic health records to evaluate compliance with the ABCDEF bundle. All patient data was included with the exclusion of end of life (EOL) patients and patients that have been admitted to ICU for < 24 h. Data was collected from four ICUs within a single centre teaching hospital in England. Researcher 1 manually collected the data from electronic patient records during the dates 18/07/22 to 25/07/22, six months post ABCDEF bundle implementation. Each section of the ABCDEF bundle was extracted into a data collection question aimed to assess how compliant the ICU unit was with the bundle. If there is no compliance with a section of the bundle, the Researcher 1 investigated the patients' notes to identify why. This helped us draw conclusions about how to improve compliance with the bundle. Data was collected for each patient over one 24-h period.
Results: A total of 30 patient records met the inclusion criteria and their data was included in this service evaluation. All the patients ($n = 30$) were assessed for pain using the CPOT score, and of those patients assessed $n = 5$ was scored as having pain. Eighty-two percent of patients of patients receiving continuous sedation did not receive a sedation hold. Of 82% of patients that did not receive a sedation hold, 34% were too unstable for the sedation hold, 33% were too agitated for the sedation hold, 22% were not prescribed a sedation hold by the ICU doctors and 11% were having a transfer or procedure, therefore a sedation hold was not performed. The majority of patients that were mechanical ventilated received a SBT (69%). Of the patients that did not receive a SBT, 75% were deemed too unstable and 25% because the nurses had not carried out the SBT. The majority of RASS scores (97%) were in line with the correct RASS score prescribed for the patient.The majority of patients did not receive daily CAM-ICU scores (93%). Sixty five percent of patients were not mobilised. Staff not initiating mobilisation was the most common reason why patients were not mobilised (38%), followed by patient refusal (31%), patient instability (15%), nurses not being confident to mobilise the patient without the physiotherapist (8%) or physiotherapist assessing the patient as being too unstable to mobilise. Most patients

had family involvement (73%). Of the 27% percent of patients who did not receive family involvement, 63% of families were unable to visit, 13% refused to visit,12% were not permitted to visit due to COVID-19 restriction and 12% had no relatives.

Conclusions: This service evaluation found that there were varying levels of compliance with each element of the bundle, with some elements having much better compliance than others. We found that the 'A' 'C' and 'F' elements of the bundle had good compliance, which refuted evidence identified in our review of the literature, where compliance was found to be variable (2, 3). However, the 'B' 'D' and 'E' sections of the bundle had poor compliance, due to several barriers to implementation; this was supported by the literature (2,3,4). We found that further improvement in compliance is needed for the ABCDEF bundle to be effective in reducing delirium in our organisation.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**0009017

Introduction: Both Out of (OHCA) and In Hospital (IHCA) pediatric cardiac arrest has traditionally been considered a futile medical condition with dismal outcomes. This is further magnified by resuscitation protocols are typically articulated from the perspective of an ideal resource environment without much consideration of applicability in district hospitals or non-tertiary centre.

Objectives: To determine clinical outcomes from both paediatric OHCA and IHCA in low-resource settings, to identify shortcomings in relation to resuscitation in these areas, possible solutions and to suggest future research priorities.

Methods: This was a multicenter retrospective study in a middle sized urban city (estimated population 390,000) served by a single Emergency Medical Services (EMS) system. All records of OHPCA under 16 years old were reviewed from the Cardiac Arrest Registry from 2017 to 2022. Data collected included demographic profiles, etiology of cardiac arrest, initial cardiac rhythm, time of initiation of cardiopulmonary resuscitation (CPR) and adrenaline administration by EMS team and duration of CPR. Outcomes of interest included return of spontaneous circulation (ROSC) and survival to hospital discharge (STHD).

Results: From the 5-year study period, 68 children (mean age of 5.8 ± 1.2 years) were included in this study. 22 (32.4%) were infants (< 1 year old) and 7 (10.3%) were neonates (< 28 days old). Of those 68 cases, total mortality was observed at 63.23% (n = 43). Return of spontaneous circulation (ROSC) was achieved in 9 (13.23%) of patients and 10.29% survived to hospital discharge. OHCA was witnessed in 72 (75.8%) children from total 95 OHCA cases and bystander CPR was delivered only in 19 (20.0%) cases while all IHCA were witnessed. Asystole was recognized as most common (n = 35) initial rhythm at scene [Table 1]. A delay in initiating cardiopulmonary resuscitation (CPR) and adrenaline administration were observed in 49 cases of OHCA and 1 in IHCA. The median time from emergency call to CPR and from CPR to first adrenaline administration was 20.4 ± 1.4 min and 2.2 ± 1.8 min for OHCA and 0.7 ± 0.2 min and 1.8 ± 0.7 min for IHCA. Longer time to CPR and adrenaline administration was associated with lower chance of achieving ROSC and STHD. Using multivariate analyses, fewer adrenaline doses ($p < 0.05$), witnessed cardiac arrest ($p = 0.001$), initial rhythm of ventricular fibrillation ($p < 0.05$) and shorter CPR duration ($p = 0.007$) were good prognostic factors for ROSC and STHD.

Conclusions: Outcomes from OHPCA in low resource settings are poor. Unwitnessed OHCA, delays in the initiation of CPR and adrenaline administration were each associated with lower survival. Recognition and timely identification of at-risk patients as well as delivery of high-quality CPR and post–cardiac arrest care are imperative to maximize the chances of achieving favorable outcomes. Effective resuscitation protocols and for low-resource settings should be developed collaboratively involving local experts and the EMS team.

Table 1: Child's demographic and associations with outcome

	All (n=98)	Return to Spontaneous Circulation		Survival to Hospital Discharge	
		YES	NO	YES	NO
Witnessed OHCA	52	22	30	10	42
Bystander CPR	19	12	7	8	11
Time to CPR by EMS (min) [Mean±SD]	20.9±1.2	18.8±1.2	20.7±1.5	18.9±1.3	20.8±1.7
Total CPR period (min) [Mean±SD]		19.3±3.3	31.2±7.7	19.4±4.7	23.8±2.2
Time to 1st Adrenaline from CPR [Mean±SD]	2.9±1.3	2.9±1.7	3.1±1.9	1.9±2.7	2.1±1.8
Witnessed IHCA	6	6	0	5	1
Time to CPR (min) [Mean±SD]	0.4±0.2	0.4±0.1	0.6±0.1	0.4±0.1	0.6±0.2
Total CPR period (min) [Mean±SD]		11.3±2.2	27.5±2.7	9.9±1.7	26.2±3.7
Time to 1st Adrenaline (min) from CPR [Mean±SD]	1.5±0.7	1.5±0.3	2.1±0.3	1.5±0.5	2.0±1.6

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000918

Introduction: Extra ICU Nurses report emotional distress and feelings of inadequacy with the complexity of intensive care procedures. The main reported challenge has been the lack of proper training in curative and palliative management.
Objectives: This study aimed to examine healthcare professionals' attainment after target learning of extra ICU nurses.
Methods: This was a cross-sectional pre and post intervention among healthcare professionals of the physical medicine and rehabilitation department of Zaghouan Regional Hospital (Tunisia). The participants answered a 5-item survey evaluating management of different ICU situation and stress level based on the scale EPSS (Educational Practices in Simulation Scale). It was used to assess improvement in knowledge, skills and stress degree before and after special learning.
Results: Twenty four responses were compiled. Median age of participants was 32 years [25–45] with a gender-ratio of 0.84 and a median work of experience of five years [4–18].The results of the simulated clinical immersions showed significantly improvement in self-efficacy scores ($p=0.02$). A one tailed paired t-test presented a significant increase from pre-test scores ($M=18.5$, standard deviation (SD) $=5.9$) to post-test scores ($M=33.5$, $SD=3.7$); ($p<0.001$). On another hand, our study showed positive differences between pre- and post simulation, indicating that learning outcomes were attained through simulation. We noted a decrease in the sensation of difficulty to practice some acts demonstrated through the simulation and the stress face some situation ($p=0,04$ and $p=0,02$ respectively). However, the confidence of their skills was decreased after the simulation ($p=0,02$). Finally, we don't found difference in the sensation of irritation and nervosity in pre and post-test ($p=0,1$).
Conclusions: Our study showed that simulated training had a positive impact on the healthcare professionals' acquisition of palliative care. We demonstrated that simulation training was an efficient tool for implementing new protocols, thus bringing benefits to healthcare systems, professionals and patients.

Reducing unnecessary blood testing in intensive care—a quality improvement project

A. Batista[1], O. Jundi[1]
[1]Anaesthesia and Critical Care Department, Bradford Royal Infirmary, Bradford, United Kingdom
Correspondence: A. Batista
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000919

Introduction: Patients in intensive care units are critically unwell and require close monitoring of physiological and analytical parameters. This has been shown to lead to high volume of blood testing with associated blood loss, anaemia and increased need for red blood cell transfusions (Chant C, 2006). A recent QI study published in the British Medical Journal where they obtained a significant decrease of about 1.4 tubes of blood drawn per patient-day showed a statistically significant decrease in the number of red blood cell transfusions (Bodley T, 2023). Reducing unnecessary blood tests is not only a cost-saving measure, it also prevents patient harm.
Objectives: With this quality improvement project we aimed to audit phebotomy volume and design an intervention aimed at reducing unnecessary blood testing.
Methods: Retrospective audit of all patients admitted to our 16-bed district general hospital intensive care unit in the month of September 2022 and number of blood tests collected. A structured approach was used to first identify main factors leading to unnecessary blood test ordering and then design specific interventions to address these. A post-intervention audit is planned to evaluate intervention effect and consider next steps.
Results: During the month of September of 2022 there were a total of 80 patients admitted to the intensive care unit, comprising a total of 373 patient-day episodes. There were an average of 2.67 tubes of blood collected per patient-day and 337 full blood count (FBC) tests done (average of 0.9 per patient-day), 330 coagulation screens (average of 0.88 per patient-day), 333 urea and electrolytes (U&Es) tests (average of 0.89 per patient-day) and 324 liver function tests (LFTs), bicarbonate, chloride, calcium, phosphate and magnesium (average of 0.87 per patient-day). Without taking into account the significant volume of blood taken for blood gas analysis (average of 3.9 per patient-day and other small volume tests done, this constitutes an average of 9.4 mL of blood per patient per day, increased significantly if we could account for the blood discarded as waste when drawing from arterial of central lines. Looking at a randomly selected date 67% of liver function tests and 60% of coagulation screens were likely unnecessary—within physiological range on that date and previous date and not needed for clinical decision making.
Main factor identified as causative is that daily blood tests are requested and collected by the night nursing team before handover and requests are based on electronic order sets. Secondary factors included knowledge gap regarding potential harm and absence of a mechanism to evaluate frequency of blood testing in ward rounds.
We are currently working to change the electronic order sets to a daily profile with only FBC, U&Es and extended electrolytes and an extended order set that includes LFTs and coagulation screen. We are also working to create a night ward round proforma on our electronic system that includes a review of blood test requests and their frequency. Finally, once these are implemented we will start an educational and awareness campaign and audit results over another month to consider how effective this was and next steps.
Conclusions: Unnecessary blood testing is a very relevant issue in current medical practice given the accessibility and ease of request and it is especially important in intensive care units with the acuity of patients and the presence of sampling lines. Education about the potential harms and understanding of the precipitating factors is vital to improve patient care.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000921

Introduction: The optimal management of mechanical ventilation after lung transplantation (LUTX) is currently based on expert opinion. Particularly, the distribution of ventilation (V̇) and perfusion (Q) after LUXT and the effect of Positive End-Expiratory Pressure (PEEP) upon it has not been described, except with pulmonary scintigraphy (REF), which use is limited by invasiveness and availability.
Objectives: To non-invasively evaluate the regional distribution of V̇ and Q (by electrical impedance tomography (EIT) – Enlight, Timpel, BRA) alongside gas exchange, partitioned lung mechanics, at three PEEP levels in the postoperative period of LUTX recipients.
Methods: Consecutive patients who had undergone bilateral LUTX were studied within 24 h after graft reperfusion. Three PEEP levels (14–10-6 cmH2O) were tested throughout a decremental PEEP trial, preceded by a recruitment maneuver. While paralyzed and ventilated (tidal volume: 6 mL/kg donor predicted body weight), V̇ and Q regional distribution, regional lung collapse and hyperdistention were calculated while regional lung Q was assessed by hypertonic saline bolus, according to EIT. In addition, partitioned lung mechanics, gas exchange, and hemodynamics were collected.
Results: Six patients (Table 1) were enrolled from January 1st to April 10th, 2023.

Table 1 (abstract 000921) Patient characteristics at enlistment and at postoperative baseline

		Enlistment				Postoperative baseline				
Patient	Gender	Age yr	Disease	LAS score	LS dx %	PEEP cmH2O	Crs, mL/cmH2O	PaO2/FiO2 mmHg	Vd tot/VT, %	Qs/Qt %
1	M	59	IPF	39	44	8	56	334	68	4
2	M	37	CF	36	93	10	54	250	60	13
3	M	66	COPD	37	65	10	64	390	59	4
4	M	55	IPF	40	51	10	55	309	56	7
5	M	59	Systemic sclerosis	43	45	10	56	309	59	7
6	M	37	Sarcoidosis	37	54	10	48	230	48	13

M, male; LAS, lung allocation score; LS, lung scintigraphy; PEEP, positive end-expiratory pressure; Crs, compliance of the respiratory system; PaO2/FiO2 arterial pressure of O2 / fraction of inspired O2; Vd tot/VT respiratory dead space / tidal volume; Qs/Qt pulmonary shunt fraction.

EIT at all PEEP levels – documented: 1/similar distributions of V̇ between left and right grafts (absence of bronchial anastomosis strictures), 2/re-establishment of Q distribution between grafts (adequate functioning of vascular anastomosis). The Intermediate PEEP resulted in the highest respiratory system compliance (best balance between collapse and hyperdistention) (Figure 1). No difference in shunt level or dead space fraction was observed. A minimal effect of the PEEP level was observed on ventral to dorsal lung perfusion distribution, while the High PEEP level caused a reduction of ventral ventilation (Figure 2).
Conclusions: In the immediate post-LUTX period, EIT is a feasible option to monitor ventilation and perfusion distribution. Intermediate PEEP levels guarantee optimal graft ventilatory mechanical properties and gas exchange without affecting lung perfusion distribution.

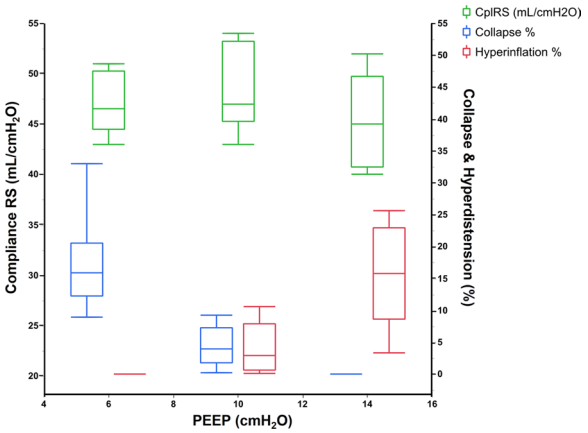

Figure 1 (abstract 000921) Distribution of Crs, collapse and hyperinflation at different PEEP levels. CplRS: respiratory system compliance

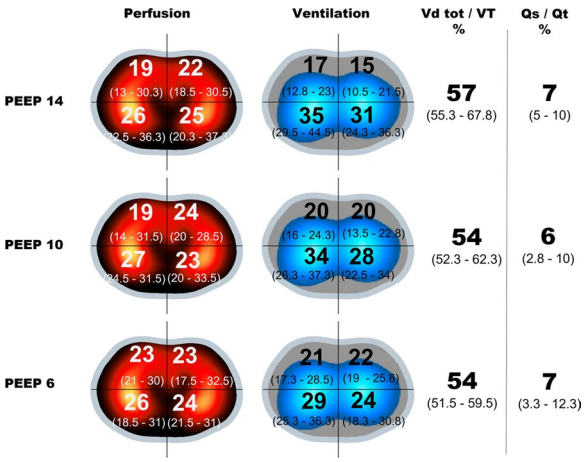

Figure 2 (abstract 000921) Regional distribution of ventilation, perfusion, dead space and shunt at different PEEP levels. Vd tot/VT respiratory dead space/tidal volume; Qs/Qt pulmonary shunt fraction

Introduction: Extracorporeal organ support (EOS) is a radical but necessary solution for severely decompensated physiology, requiring expert knowledge and experience. However, depending on the practicing environments, clinicians might not be granted with sufficient exposure to such unique techniques. This gap between the technique's necessity and providers' preparedness is suspected to be a possible explanation for considerably variable outcomes following the technique's application. A recent devastating pandemic, coronavirus disease 2019 (COVID-19), has led to spiking incidence of multiple organ failures, and the need for EOS accordingly rose. Amid this disaster, our understanding of EOS might have chance to be improved.
Objectives: This study examined the relationship between patient mortality outcome and the indicators of each institution's familiarity with EOS to deduce reasons for variability in its efficacies.
Methods: Data is pulled from ongoing, prospectively collected multicenter registry-based database containing demographic and clinical information of patients treated for severe acute respiratory syndrome coronavirus 2 (SARS-CoV2) infection at participating institutions. For each institution, the ratio of cases where EOS was utilized to the number of entire cases was calculated. EOS modalities of interest included mechanical ventilation (MV), extracorporeal membranous oxygenation (ECMO), and continuous renal replacement therapy (CRRT). For each modality, institutions were ranked based on the respective ratio and classified into either more or less experienced depending on whether it belonged to the upper or lower half ranks. Then, the association between mortality and experience status was analyzed by calculating adjusted odds ratios (AOR).
Results: In total, 1,114 patients from 26 hospitals were included in the analysis. 294 (26%) patients died while admitted, and the mortality rates ranged from 15 to 50%. The extent of experience varied significantly among hospitals. For MV, ECMO, and CRRT, the proportion of EOS utilization respectively ranged from 14.8% to 100%; from 0% to 31.7%; and from 0% to 31.7%. Utilization of every EOS modality was significantly associated with mortality (AOR: MV 4.24 [95% CI: 2.28-8.06]; ECMO 5.0 [95% CI: 2.37–10.8]; CRRT 10.5 [95% CI: 4.83–24.4]). However, the experience status did not show significant associations with mortality (AOR: MV 1.46 [95% CI: 0.82–2.63]; ECMO 1.19 [95% CI:0.7–2.03]; CRRT 0.76 [95% CI: 0.44–1.32]).
Conclusions: Relative familiarity with each EOS modality did not show associations with mortality outcomes. This futility might reflect our yet incomplete understanding of reasons behind variable EOS efficacies and suggests further investigation.

Introduction: Intermediate care units are increasingly used for their potential to optimize hospital throughput, reduce the pressure on intensive care unit (ICU) beds and reduce ICU mortality [1] However, the diversity in formats of these units is remarkable. Several groups of patients may benefit from admission to these units. Patients whose admission to a full ICU is considered futile represent an important cohort in these units, because despite the patient's frailty, implementation of some support therapies may be beneficial [2].
Objectives: The main objective of this study is to describe demographic, baseline characteristics and outcomes of patients admitted to our Intermediate Care Unit in whom ICU admission was considered futile. As secondary objectives, we intend to record life support therapies required by these patients.
Methods: We performed a retrospective observational study during an 8-month period. All patients admitted to our Intermediate Care Unit in whom ICU admission was considered futile were included. In our Intermediate Care Unit, continuous monitoring, vasoactive drug infusion, high flow nasal cannula, non-invasive ventilation, and hemodialysis are available. Nurse to patient ratio is 1:4.
Results: Quantitive variables are expressed as median and interquartile range (IQR). Qualitative variables are expressed as proportions. Statistical analysis was performed with R 4.2.2 for Windows.
During the study period, 43 patients were included. 63% were male; Median of age was78 years old (69–81). 6-month survival was 83%. APACHE II and Charlson Comorbiditylindex were respectively 18 (15–25) and 7 (5–8). Median length of stay was 4 days (2–6). Septic shock was the most common principal diagnosis at the moment of admission (57%), followed by respiratory failure (18%).
Norepinephrine infusion was required in 54% of patients. Need for high oxygen nasal cannula and non invasive mechanical ventilation were respectively 32 and 27%. In 5% of patients hemodialysis was indicated.
Conclusions: Admission to an Intermediate Care unit of selected patients in whom ICU admission was considered futile may be associated with a high 6 month-survival.
The most frequently life support measures required were norepinephrine infusion and high flow oxygen.

Introduction: Background: Hypertriglyceridemic pancreatitis (HTGP) is a rare entity with significant morbidity and mortality. It is thought that high triglyceride levels are directly toxi to the pancreas and management typically involves efforts at rapid lowering of serum triglycerides (TG). Both plasmapheresis (PL) and intravenous (IV) insulin infusions are often used clini40635_2023_546cally for this purpose but have not been compared or studies in large cohorts. Furthermore, the role of IV insulin in patients with HTGP without concurrent diabetes remains unclear. We aimed to investigate these questions in a cohort of patients hospitalized for HTGP at a tertiary care center over a 20-year period.
Methods: A retrospective chart review of patients hospitalized for acute HTGP between January 1, 2002, and December 31, 2022, was performed. Patients were stratified into 4 groups according to treatment modality received: intravenous (IV) insulin infusion alone; plasmapheresis alone; IV insulin followed by plasmapheresis and conservative management. Efficacy of these modalities in lowering sreum triglycerides, development of pancreatitis and other organ complications as well as hospital LOS (length of stay), ICU admissions, ICU LOS and mortality were compared between the groups.
Results: A total of 136 patients hospitalized with hypertriglyceridemic pancreatitis (HTGP) were identified over this 20-year time period from Jan 2002 to Dec 2022 with a mean age of 49 (range 21–79) years with 67% being male. Diabetes was noted in 102 (75%) of patients, current alcohol use in 15 (11%), coronary artery disease in 11 (8%) and chronic kidney disease in 8 (6%) of patients. Three patients (6.7% of females) were pregnant at the time of HTGP admission. Mean hospital length of stay (LOS) was 7.8 (range 1–103) days. ICU admission occurred in 38% of the patients with HTGP with a mean ICU LOS of 6 (range 1–43) days. Treatments included either insulin alone (n = 90, 66%), conservative treatment methods (n-30, 22%), insulin followed by plasmapheresis (n = 12, 9%) and plasmapheresis alone (n = 3, 2%). A total of 15/34 (44%) of the non-diabetic patients were treated with IV insulin and 2/34 (6%) were treated with insulin followed by plasmapheresis. Median presenting triglyceride level was 3810 mg/dl (range 1157 to 24,712 mg/dl). Multiple sessions of plasmapheresis were utilized in 2 patients with the other 13 patients undergoing a single session of plasmapheresis. We observed 0% mortality during the admission for HTGP. Pancreatic necrosis was noted in 14 patients (10.3%) and peripancreatic fluid collections in 27 (20%). Renal replacement therapy (dialysis) was needed in 11 (8%) and end stage renal disease (ESRD) developed in 7 (5%) of patients. Repeat admissions for HTGP occurred in 31% of patients post index admission for HTGP.
Conclusions: HTGP is a serious condition occuring mostly in males (67% of our cohort) and in those with pre-existing diabetes (75% of the cohort). The majority of patients were treated with IV insulin alone (66%) and this included 44% of non-diabetics who were also treated with IV insulin. About 12% of patients were treated with plasmapheresis. No patient died during the index HTGP admission. However, about 38% of patients required ICU admission with 10% developing pancreatic necrosis, 8% requiring dialysis and 5% developing end stage renal disease (ESRD).

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000927

Introduction: The process of resuscitation in septic shock hinges on the detection of tissue hypoxia, and the subsequent performance of interventions aimed at increasing cardiac output to reverse it. However, there is still an open debate on the choice of the parameter(s) that inform us of tissue hypoxia. The latest Surviving Sepsis Campaign (SSC) guidelines recommend only the use of lactate as a metabolic guide to resuscitation, ignoring the fact that in situations of dysoxia, with defects in oxygen utilization, lactate can be elevated without being due to insufficient cardiac output. Therefore, in these situations, the hemodynamic interventions that would result would not be linked to a benefit for the patient, but rather to the deleterious effects of positive fluid balance.
The present study aims to analyse the value of the integration of different metabolic markers in the evaluation of the response to volume administration in the process of hemodynamic resuscitation of patients in septic shock.
Methods: Retrospective observational study, in a 30-bed general ICU. Adult patients with septic shock in the first 24 h of admission, with a cardiac output monitoring system, and in whom their medical team indicated volume loading (intervention) due to suspected persistent tissue hypoperfusion were included. Hemodynamic and metabolic variables [lactate, central venous saturation (SvcO2), veno-arterial CO2 difference (PcvaCO2) and estimated respiratory quotient (PcvaCO2/CavO2)] were collected pre-intervention and at the end of the intervention. A two-stage cluster analysis was performed to group patients according to a metabolic profile, including the pre-intervention metabolic variables. Comparative analysis was performed on the evolution of cardiac output and metabolic parameters, as well as Pearson correlations of the changes in these variables, as a function of the metabolic cluster.
Results: A total of 77 interventions were studied in 55 patients. 62% were male, with a mean age of 62 ± 16 years, baseline lactate was 50 ± 40 mg/dl, 96% required noradrenaline perfusion, and 91% were receiving mechanical ventilation. The reason for volume loading was persistently high lactate (81%) and/or the presence of low SvcO2 values (42%). The best cluster model was obtained with the inclusion of SvcO2, PcvaCO2 and PcvaCO2/CavO2, classifying patients into two profiles, and with SvcO2 as the variable with the greatest weight in the model. Cluster 1 presented lower SvcO2 values (61 ± 6 vs 77 ± 5%, p < 0.001), higher PcvaCO2 (8 ± 2 vs 6.2 ± 2.2 mmHg, p < 0.001) and lower PcvaCO2/CavO2 (1.5 ± 0.4 vs 2.2 ± 0.7, p < 0.001), with no differences in lactate values. When the response to volume administration was analysed, 65% of patients increased their cardiac output value (75% of cluster 1 and 60% of cluster 2, p ns). Increase in cardiac output was only associated with decrease in lactate in cluster 1 patients (r 0.4, p 0.04; Figure 1). No isolated pre-intervention metabolic variable was associated with lactate evolution.
Conclusions: The integration of the different metabolic variables improves the detection of situations of tissue hypoxia and, therefore, the capacity to detect those patients who may benefit from receiving interventions that increase cardiac output. The use of lactate as the only metabolic marker, although currently recommended by the SSC, could be clearly insufficient, and even misleading, in decision making in the process of resuscitation in septic shock.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000932

Introduction: SpO2/FiO2 may be used for ARDS classification1. It is known that skin pigmentation may induce bias in SpO2- SaO2 bias, and it was recently showed that oximeter brand influences the SpO2 measurements2.
Objectives: To evaluate the impact of the SpO2 bias on ARDS misclassification when using SpO2/FiO2.
Methods: We performed a retrospective analysis of the OXYGAP study2 using 211 pairs of SpO2 values with Nonin-OEM and Philips-FAST pulse oximeters and related PaO2. We compared the classification provided by PaO2/FiO2 and SpO2/FiO2 with Nonin and Philips. The usual PaO2/FiO2 thresholds were used (300-200-100) and thresholds based on Rice's equation were used for SpO2/FiO2 (315-235-150). A theoretical set of SpO2/FiO2 values were obtained with SaO2 values going from 88 to 96% and FiO2 going from 25 to 80% with steps of 5%, for Nonin and Philips oximeters (SpO2 bias of −3 and +1%), and for light and dark skinned (SpO2 bias 0 and +3%).
ARDS classifications were compared within the different conditions.
Results: FiO2 were available in patients on invasive mechanical ventilation (n=22), high flow nasal canula (n=15), in patients without respiratory support (n=84, FiO2=21%), or in patients under conventional oxygen therapy (estimated FiO2 based on oxygen flow, n=83). SpO2 were missing for one of the evaluated oximeters in 7 patients. Classification of ARDS based on the different pulse oximeters did not differ much (differences below 3% between groups, Figure), however there were differences in comparison with PaO2/estimated FiO2 and SpO2/FiO2 classifications.
In the theoretical set of values, 108 SpO2/FiO2 values were obtained for several conditions (Nonin and Philips oximeters, light and dark skin). ARDS misclassifications were below 5% for Nonin vs. Philips and light vs. dark skin pigmentation. With Nonin and Philips oximeters the classification as No, mild, moderate and severe ARDS were 8, 17, 37, 38% and 11, 17, 38, 34% respectively. With light and dark skin pigmentation, the classification as No, mild, moderate and severe ARDS were 10, 17, 37, 36% and 13, 17, 39, 31% respectively.

Table (abstract 000932) ARDS classification based on theoretical 432 values of SpO2/FiO2 with Nonin, Philips pulse oximeters and with light and dark skin pigmentation

	Nonin	Philips	Light Skin	Dark Skin
No ARDS	8%	11%	10%	13%
Mild	17%	17%	17%	17%
Moderate	37%	38%	37%	39%
Severe	38%	34%	36%	31%

Conclusions: Utilization of SpO2/FiO2 to classify the severity of ARDS is feasible with low number of misclassifications when comparing SpO2/FiO2 with different pulse oximeters or with discrepancies related to skin pigmentation. In the cohort of patients, classifications differed when comparing PaO2/estimated FiO2 and SpO2/estimated FiO2 for No ARDS and mild ARDS categories.

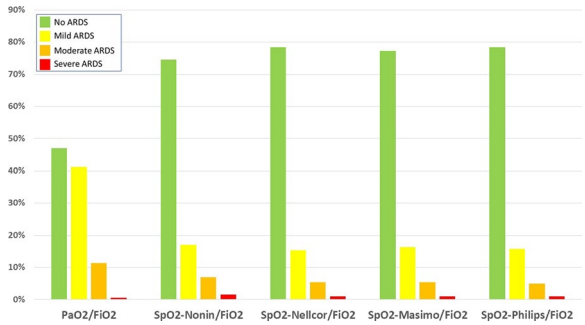

Figure (abstract 000932) ARDS classification based on PaO2/estimated FiO2 or SpO2/estimated FiO2 with different pulse oximeters (Nonin, Nellcor, Masimo, Philips) in the secondary analysis of the Oxygap study and 211 pairs of SpO2 with four pulse oximeters and PaO2

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000933

Introduction: Devices allowing efficient expiratory filtration are required to avoid contamination of the air in ICU rooms of patients under invasive mechanical ventilation. Usual filtration tests are conducted for large particles (3000 nm), while smaller particles may carry several viruses. SARS-CoV-2 virus size is about 100 nm and may be carried with particles of any size, including particles smaller than 1000 nm. The impact of gas humidity to evaluate the filtration efficiency for different particle size is unknown.
Methods: On a test bench simulating dispersion of aerosols with particles ranging from 29 to 5000 nm, we evaluated the filtration efficiency of several devices: an HMEF (heat and moisture exchanger filter) and an HEPA filter (High-Efficiency Particulate Absorbing filter): DAR Hygrobac S (352–5877) and Draeger Twinstar HEPA (MP01801). Filters were placed one at the time in the test bench. Aerosols were generated from a buffer suspension containing two model viruses: φX174 and MS2. Viral aerosols passed through the filter at an air flow rate of 60L/min, with experiments conducted with dry and humid air. Particle counters and air samplers were placed upwind and downwind of the filter. The absolute humidity of dry and humid

gases were respectively approximately 7 and 30 mgH2O/L. Particles were counted and infectious viruses were quantified upwind and downwind to calculate the filtration efficiency for both particles and viruses. The maximal filtration efficiency sensitivity in this test bench is 99.99%.

Results: Main preliminary results are shown on the figure. For HMEF, the filtration efficiency is reduced for small particles below 1000 nm. With dry gases, filtration is reduced for particles below 1000 nm, while with humid gases, filtration is reduced for particles below 500 nm. For particles of 300 nm, filtration efficiency is below 95%. The filtration efficiency is significantly higher with HEPA filter in comparison with HMEF. The HEPA filter filtration was 99.99%/99.99% with dry air and humid air, while the HMEF filtration was 99.09%/98.87% with dry air and 99.48%/99.56% with humid air for PhiX174 and MS2 respectively.

Conclusions: Gas humidity has an impact on filtration efficiency. Particles under 300 nm are not entirely filtered with the tested HMEF. However, the infectious viruses are present in smaller quantities reflecting that many unfiltered particles do not contain viruses. However, with HMEF, the filtration efficiency based on cultivable viruses do not attain expected results (above 99.999%). The clinical impact of this reduced filtration is unknown.

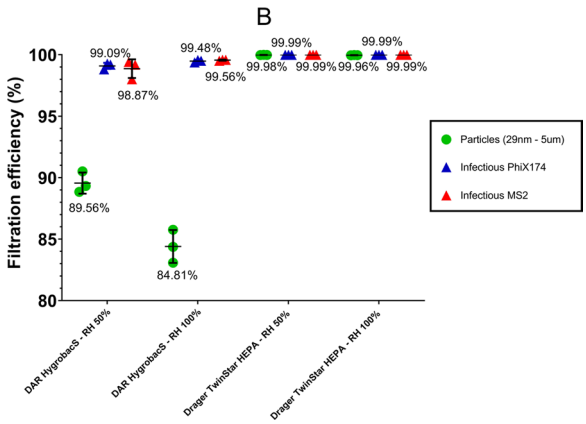

Figure B (abstract 000933) Shows the filtration efficiency for infectious viruses and for particles ranging from 29 to 5000nm. Filtration efficiency means are shown for each triplicate

.

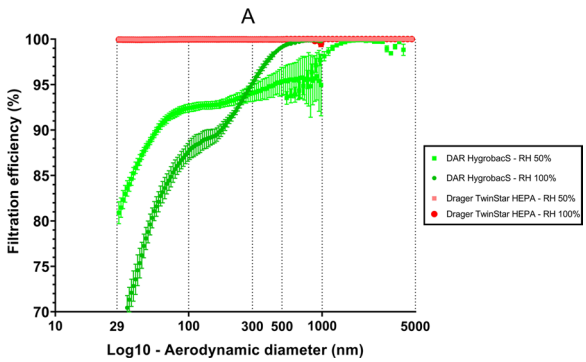

Figure A (abstract 000933) Shows the filtration efficiency regarding the size distribution of particles at different relative humidity. This graph shows particles only

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000934

Introduction: According to the Berlin definition of acute respiratory distress syndrome (ARDS), bilateral infiltrates can be diagnosed using chest X-ray or computed tomography (CT)-scan. However, the interindividual agreement for the diagnostic of lung infiltrates on chest X-ray is poor and may explain the low rate of ARDS recognition by clinicians. Indeed, as compared to CT-scan, the accuracy of chest X-ray interpreted by a radiologist to identify ARDS was limited. However in daily practice, chest X-rays are interpreted at the bedside by intensivists, not radiologists. We hypothesized that the agreement between chest X-ray interpreted by intensivists and CT-scan interpreted by a radiologist, as reference standard for ARDS diagnosis, was poor.

Methods: From January 2015 to December 2021, we included all CT-scan performed in patients invasively ventilated with PaO_2/FiO_2 ratio $\leq$ 300 mmHg with positive end-expiratory pressure $\geq$ 5 cmH_2O on the day of the CT-scan and a chest X-ray performed within the 24 h around the CT-scan. Patients whom hypoxemia was related to cardiogenic pulmonary edema were excluded. CT-scans and chest X-rays were interpreted semi-quantitatively by a senior radiologist and by two senior intensivists (with > 20 years and < 10 years of experience), respectively. The primary outcome was the agreement between chest X-ray and CT-scan for ARDS diagnosis using Cohen's kappa. Secondary outcomes were the sensitivity of chest X-ray for ARDS diagnosis in the overall population, and in the subgroup of focal ARDS, defined as infiltrates in the lower lobes on CT-scan.

Results: Among the 1015 CT-scan performed during the study period, 332 were included in the analysis. Mean age of patients was 62, 74% were males, and 29% were immunocompromised. In-ICU mortality was 41%. CT-scans were performed 3 [1–11] days from intubation. The day of the CT-scan, mean PaO_2/FiO_2 ratio was 165 mmHg. The prevalence of ARDS on CT-scan was 82%. Consolidations were mostly found in inferior lobes whereas ground glass was found evenly in all lobes.
The agreement between chest X-ray and CT-scan for ARDS diagnosis was moderate (Cohen's kappa 0.41 [95% confidence interval 0.30–0.51]) with the most experienced intensivist and was fair with the less experienced one (Cohen's kappa 0.29 [95% confidence interval 0.18–0.41]). Sensitivity of chest X-ray for ARDS diagnosis in the overall population was 77% (95%CI 71–82) and 80% (95%CI 75–84) according to each intensivist. In the subgroup of focal ARDS, it was 54% (95%CI 40–67) and 67% (95%CI 53–79), respectively.

Conclusions: Chest X-ray interpreted by intensivists and CT-scan interpreted by a radiologist had fair to moderate agreement for ARDS diagnosis. The performance of chest X-ray was particularly poor in focal ARDS. Systematic CT-scan assessment in hypoxemic patients may improve the likelihood of ARDS diagnosis.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000937

Introduction: Acute-on-chronic liver failure (ACLF) is a critical syndrome occurring in individuals with acutely decompensated cirrhosis, characterised by high short-term mortality and multiorgan failure. Accurate prognostic scores are essential to support ICU treatment and outcomes. Socioeconomic status (SES) is a known, independent contributor to ill health and mortality. This study aims to determine if incorporating SES into the CLIF-C ACLF score, a prognostic tool for ACLF outcomes, adds value in predicting in-hospital mortality in patients with ACLF.
Methods: Data from consecutive patients admitted to the Royal Free London ICU with a complication of cirrhosis, between 2016 and 2017, were obtained from the Royal Free NHS Trust database. CLIF-C ACLF scores were calculated at day 0 and 2 of ICU admission and in-hospital survival was assessed. SES was determined using the English Indices of Deprivation, a validated government tool that utilises individual postcodes to infer a deprivation decile. A higher decile indicates a higher SES and vice versa. Multiple logistic regression was used to examine the joint association between both CLIF-C ACLF and SES upon in-hospital mortality.

Table 1 (abstract 000937) Multiple analyses comparing in-hospital mortality groups

	In-Hospital Mortality					
	Dead		Alive			
	n	Mean ± SD	n	Mean ± SD	Test used	p-value
Age	48	55.8 ± 12.3	83	53.3 ± 15.0	Independent T-Test	0.317
Deprivation Decile	48	4.54 ± 2.90	83	5.30 ± 2.57	Mann–Whitney U Test	0.054
CLIF-C ACLF D0	48	59.9 ± 11.2	83	50.1 ± 9.74	Independent T-Test	< 0.001
CLIF-C ACLF D2	32	64.9 ± 10.2	55	50.5 ± 11.3	Independent T-Test	< 0.001
Delta (D0 to 2)	32	0.125 ± 9.36	55	-2.49 ± 7.61	Independent T-Test	0.163
	n	**Male/ Female**	**n**	**Male/ Female**	**Test used**	**p-value**
Sex	48	27/21	83	54/29	Chi-Squared Test	0.317

Table 2 (abstract 000937) Effect of adding SES to CLIF-C ACLF score on in-hospital mortality prediction at days 0 and 2 of ICU admission: results of binary logistic regression analysis

Day	n	p-value	Odds Ratio	95% CI
0	131	0.048	0.847	(0.718 to 0.999)
2	87	0.041	0.821	(0.664 to 0.992)

Results: The cohort comprised of 851 patients, of which 131 patients have been analysed thus far. There is no significant difference in age or sex between mortality groups *(Table 1).* SES proved a statistically significant improvement to the CLIF-C ACLF score in predicting in-hospital mortality at day 0 and 2 of ICU admission *(Table 2).*To add, the odds ratios demonstrate a significant inverse relationship between SES and in-hospital mortality.
Conclusions: Our findings suggest SES can add predictive value to the CLIF-C ACLF score with regards to in-patient mortality, allowing acute care clinicians to more accurately risk stratify patients in ICU. These findings may also have implications for public health strategies for targeting primary and secondary prevention schemes. Validation in larger cohorts is justified.

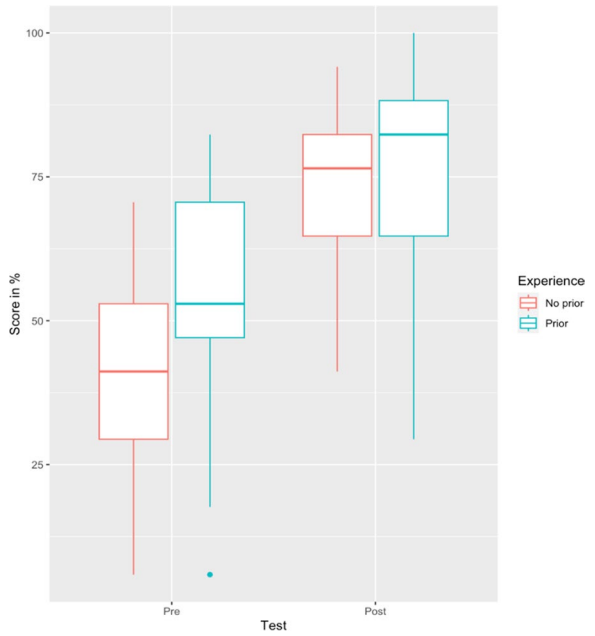
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000938

Introduction: Lung ultrasound (LUS) has become an essential skill in critical care as part of point of care ultrasonography (1). LUS may be perceived as to require significantly less training compared to more advanced ultrasound (1,2). However, the quality of the acquired image is operator dependent and subjective to interpretive error. Therefore, adequate education and training is indispensable for effective clinical use. As of yet, few studies have been published that specifically study the training effectiveness for interpreting LUS images.
Objectives: The aim of this study was to study the effectiveness of a two-hour training program to learn and understand the basics of LUS. We hypothesized that 80% of the subjects will be able correctly identify 80% of LUS images after a two-hour training program.
Methods: A prospective observational cohort study of intensive care unit (ICU) physicians, both intensivists and residents, and medical students, from different hospitals in the Netherlands. Subjects participated voluntarily. Subjects received a two-hour training program. A test was performed where subjects were asked to correctly interpret

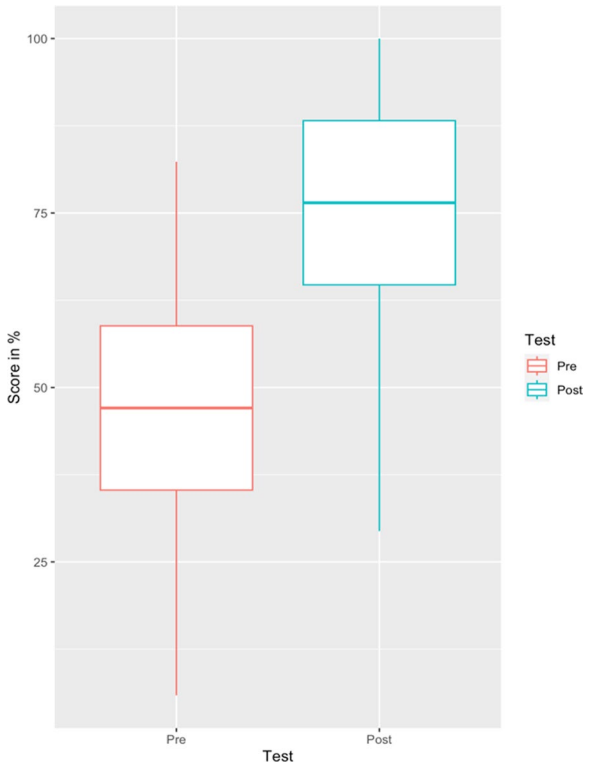
fifteen LUS images with five multiple choice options (A-, B1-, B2- and C-profile and pleural effusion). The test was taken before and after the two-hour training to correct for prior knowledge. Primary outcome was defined as the percentage of subjects who scored 80% or higher in the posttest score. In addition, the learning curve of subjects defined as the increase of percentage points between pre- and posttest was assessed. Lastly, the performance between subjects with and without prior ultrasound knowledge before the start of the training program was assessed. The data of both pre- and posttest was nonparametric. The difference between pre- and posttest was assessed with the Wilcoxon signed-rank test.

Results: Forty-seven subjects were included from four different hospitals. Sixteen subjects were certified in lung ultrasonography, seven subjects had prior experience without any training or certifications and twenty-four subjects did not have any prior experience with LUS. After training 46.8% of the subjects had a score of 80% or higher. Mean pretest score was 47.7 ± 18.5. Mean posttest score was 74.8 ± 15.3, Figure 1. There was a significant difference between pretest and posttest score ($p < 0.0001$). The subjects with prior knowledge performed significantly better at the pretest ($p = 0.01$), but scored equally at the posttest compared to the subjects without prior knowledge.

Conclusions: This study shows that after a two-hour training program around 50% of intensivists, ICU residents and medical students reach competence in interpreting LUS images. The hypothesized 80% of subjects who should be able to correctly interpret 80% of LUS images was not reached with the two-hour training program.



Boxplots of performance (Score in %) on pretest (left) and posttest (right) of subjects without (red) and with (blue) prior knowledge



Boxplots of performance (Score in %) on pretest (left) and posttest (right) scores (i.e. before and after the two hour training program).

Implementation of standardised transfer checklists and protocols in a UK District General Hospital

I. Griffiths[1], J. Cadman[1], J. Macallan[2], J. Chittenden[2], A. Myers[3], T. Samuels[4]
[1]Anaesthesia, East Surrey Hospital, Redhill, United Kingdom; [2]Critical Care, East Surrey Hospital, Redhill, United Kingdom; [3]Icu, East Surrey Hospital, Redhill, United Kingdom; [4]Critical care, East Surrey Hospital, Redhill, United Kingdom
Correspondence: I. Griffiths
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000940

Introduction: At least 10,000 patients undergo critical care inter-hospital transfer per year in the UK.1 Both inter- and intra-hospital transfers of these patients are associated with risk. Complications are reported during two thirds of intra-hospital transfers.2 One third of inter-hospital transfer complications result in adverse outcomes.3 Training and careful planning are essential to ensure high levels of patient safety. The Association of Anaesthetists of Great Britain and Ireland (AAGBI) suggests training should include attendance at a transfer course.4 The AAGBI and Intensive Care Society (ICS) suggest that transfers should be standardised across networks.1,4 NICE UK recommend the use of standardised protocols, training, equipment, and checklists.5
Objectives: To assess standardisation of training, checklists and protocols for clinical teams involved in providing transfers for critically ill patients in our UK district general hospital.
Methods: Clinical staff involved in critical care transfers were interviewed regarding their training and familiarity with protocols for the transfer of critically unwell patients. Quantitative and qualitative analysis of the survey was performed. Problems were identified using Ishikawa analysis. Aims, objectives and outcome measures outlined. A 'Plan-Do-Study-Act' (PDSA) cycle was subsequently developed.
Results: Analysis from 66 respondents (22 (33%) doctors, 44 (67%) nurses) demonstrated the following (Table 1):

	Yes	No
Attended transfer course	63 (96%)	3 (4%)
Attended transfer course within last 5 years	43 (68%)	20 (32%)
Felt a refresher course would be useful	35 (55%)	29 (45%)
Facilitated a transfer within last 3 months	42 (65%)	23 (35%)
Used a checklist prior to transfer	45 (73%)	17 (27%)
Felt a checklist would be useful	65 (99%)	1 (1%)
Aware of a checklist for transfer within this hospital	58 (88%)	8 (12%)

Table 1
Results also suggest that a checklist should be available in multiple formats. Qualitative analysis of results suggests a need for additional training sessions on transfers, easily accessible and concise checklists using various modalities, and a separate MRI checklist.
Conclusions: This survey reveals that despite clear national guidance, there remains a lack of standardisation in training and protocol use for the transfer of critically unwell patients in our hospital. Our study highlights the need to ensure that staff have up to date transfer training and checklists available. Since many staff rotate through working in critical care, training must be repeated regularly and protocols must be easily accessible to all. The next phase of this study is to carry out PDSA cycle 1 and implement widespread use of checklists for all transfers, with laminated checklists available in transfer kits. Further cycles will be carried out to ensure implementation of these checklists, with the aim of improved patient safety during transfers.

An audit into compliance with lung protective ventilation strategies in a UK District General Hospital

J. Barry[1], J. Mooney[1], M. Aslam[2]
[1]Foundation doctor, George Eliot Hospital, Nuneaton, United Kingdom; [2]ITU, George Eliot Hospital, Nuneaton, United Kingdom
Correspondence: J. Barry
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000941

Introduction: Ventilator-induced lung injury (VILI) is a complication of mechanical ventilation that can cause acute lung injury due to volutrauma, barotrauma, and harmful inflammatory processes (1). Protective lung ventilation (PLV), involves giving low tidal volumes (6-8 ml/kg) to patients and is a recommended strategy to help prevent VILI, especially in the context of acute respiratory distress syndrome (ARDS) & COVID-19 (2,3). It is therefore the standard of care that patients should receive PLV in Intensive Care Units (ICU).
Objectives: This retrospective study evaluated the compliance with PLV, as a standard of care, in George Eliot Hospital's ICU in Nuneaton, UK from November 2022 to January 2023. Patient data was analysed to determine if there were complications of mechanical ventilation during or after their ITU stay, and whether there is any association between the incidence of these complications, and the administration of PLV.
Methods: Data was collated for 30 patients who received mechanical ventilation during the aforementioned timeframe, analysing the daily range of tidal volumes they received, and assessing the incidence and severity of complications following extubation and further care. Patients were considered to be on PLV for a given day, if the range of tidal volumes was within the PLV parameters for their ideal body weight. PLV was defined as 6-8 ml/kg of ideal body weight.
Results: 54% of the patients received tidal volumes within PLV boundaries on at least one day during their time spent on mechanical ventilation. Of the patients that received PLV, 16% received PLV for over half the time they were mechanically ventilated. Complications were seen in patients who both did and did not receive PLV, and included acute kidney injury, cardiomyopathy, pleural effusion, and delirium, both during and after admission to ICU.
Of the patients that did not receive PLV, 60% of them had chest x-rays in the days following extubation, each of which showed new pathology, including atelectatic changes, bibasal collapse, consolidation, airspace shadowing, and effusion. Of the patients who received PLV, 67% had chest x-rays in the days following extubation, all of which demonstrated new pathology.
Of the patients that didn't receive PLV, 40% were discharged, 40% are still current inpatients, or have been transferred to different hospitals, and 20% are deceased. Of the patients that did receive PLV, on at least one day during the time they were receiving mechanical ventilation, 67% have been discharged, 16.5% are still inpatients or have been transferred to another hospital, and 16.5% are deceased.
Conclusions: Our findings show that most patients received tidal volumes outside the recommended range for PLV, potentially leading to adverse outcomes including lung volume loss, acute kidney injury, cardiomyopathy, and pleural effusion, both during and after admission. These results highlight the importance of adhering to PLV strategies to reduce the risk of VILI and associated complications.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000942

Introduction: The optimisation of the inspiratory and expiratory circuits used with heated humidification is necessary to avoid condensation and related problems, such as auto-triggering, difficulties to trigger the ventilator, or increase in expiratory resistances1.
Objectives: The objective of the study was to compare humidity in several expiratory circuits of different heated wire humidifiers.
Methods: On a bench model simulating humidified expired gas (absolute humidity of 35 mgH2O/L), we have measured hygrometry of expiratory gases at proximal side (corresponding to the Y-piece), and distal side (ventilator inlet) of expiratory circuits. The circuit evaluated were Inspired ref. 51005683 (Vincent medical), FP950 (ref:950A81J, Fisher&Paykel), MR850 (RT210, F&P) and Evaqua2 (RT380, F&P), at different room temperatures (22–24 °C and 28–30 °C).
The ventilator settings were Assist Control, tidal volume 400ml; respiratory rate 25/min; PEEP 5 cmH2O; FiO2 0.21; Flow 60 lpm.
Hygrometry was measured with the psychrometric method and 3 measurements were performed for each condition.
Expiratory Tidal Volumes in each condition were all recorded from the ventilator screen.
Results: Main results are shown on the Figure. The absolute humidity was reduced along the expiratory circuit with the FP950 and the Evaqua circuits (RT380). To avoid condensation in the expiratory limb, the VHB20 increases the temperature along the expiratory limb (leading to a reduction of relative humidity with stable water content). A similar functioning was observed with the MR850/RT210 circuit. No condensation was found along the expiratory limb for the different tested circuits in the bench study conditions. Results at different ambient temperatures were very closes.
Despite high temperatures at the inlet ventilator, the tidal volumes measured by the ventilator were very closes.
Conclusions: Different strategies are used to avoid the occurrence of condensation in the expiratory limb. Two circuits (FP950 and Evaqua2) use "porous" materials allowing a reduction of the humidity along the expiratory line. Two circuits (VHB20 and RT210) use a strategy of increased temperature allowing a reduction of the relative humidity to limit the risk of condensation. However, this strategy may alter the tidal volume measurements (which has not been shown with the ventilator used in the study), and may increase the resistance if HME filters are used instead of filters (with low hygrophobic/hygroscopic properties)1.

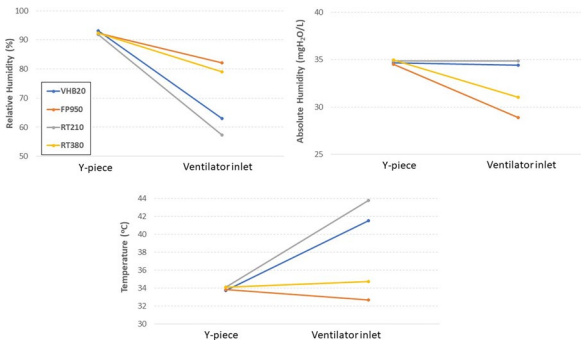

Figure (abstract 000942) Mean Relative Humidity, Absolute Humidity and gas Temperature measured at the Y-piece and at ventilator inlet with different circuits used with VHB20, FP950 and MR850 (RT210 and RT380, Evaqua2) heated humidifiers

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000944

Introduction: Critical illness is associated with significant mortality and morbidity including a risk of long-term disability and functional decline (McPeake 2021, Morgan, 2021). The early identification of patients at risk of critical illness may allow early preventative measures to be instigated to avoid admission and allow individuals to understand the implications of a possible future critical illness. Here we demonstrate that, across the country of Wales, interactions with primary care are significantly different for patients that suffer a critical illness compared to the general population.
Methods: We performed a retrospective observational study using the Secure Anonymised Information Linkage (SAIL) Databank (Ford 2009, Lyons 2009, Jones 2014) which contains billions of linked primary and secondary care, person-based health records and covers over 80% of the population of the country of Wales. We identified all adult patients aged 18–100 in the database for the years 2016–2018 and extracted all dates where at least one data point (e.g., general practice attendance, lab test, prescription, administrative action) was recorded in their primary care electronic healthcare record (EHR). We refer to these dates collectively as General Practice Events (GPEs). Our outcome of interest was emergency ICU admission in the year 2018. For all patients with an emergency ICU admission, we extracted all GPEs up to 24 months prior to their admission. For patients that did not undergo an ICU admission, a random date in 2018 was selected and all GPEs up to 24 months prior were extracted. As such, regardless of outcome, each patient was assigned an *outcome date* and 24 months' worth of preceding GPEs were extracted.

We calculated the total number of GPEs identified for each patient and the median time difference between all sequential GPEs. We report the median and [interquartile range (IQR)], by outcome group, for each of these values. This study was approved by the SAIL independent Information Governance Review Panel (IGRP) (ref 1323).

Results: 1,400,014 individuals met study inclusion criteria. A total of 3268 patients had an emergency ICU admission in the year 2018 (i.e., ICU admission rate of 0.23%). Patients admitted to ICU were slightly older (62 years [23] vs 60 years [27], had more GPEs in the 2 years prior to ICU admission (128 [165] vs 48 events [52]) and a shorter median time interval between GPEs (5 days [3] vs 9.5 [11]). These differences are more pronounced in younger age groups as the number of GPEs (Figure 1) and median time difference between GPEs (Figure 2) tend to converge for those aged over 85.

Conclusions: We have shown that, in the country of Wales, the patterns of primary care interaction are different for 2 years prior to an emergency critical care admission. Patients interacted more frequently with primary care services if they subsequently underwent an emergency ICU admission, compared to the general population. These findings suggest that the trajectory of critical illness may evolve over years, opening the possibility of very early identification of patients at risk of future deterioration from electronic healthcare records.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000945

Introduction: Providing gas humidification greater than 28 mgH2O/L is mandatory for patients with prolonged intubation, with either heat and moisture exchangers (HME) or heated humidifiers (HH). Several studies showed significant differences between independent measurements of the humidity delivered by the HME and manufacturers data1-3.

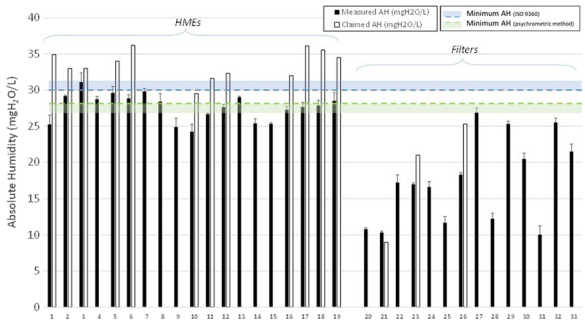
Methods: We tested on a bench, the hygrometric performances of ***19 HMEs*** and ***14 Filters***: We used the psychrometric method to measure hygrometry at steady state, with expiratory humidity of 35 mgH2O/L simulated as previously described2. For each condition, 3 hygrometric measurements were performed with similar conditions for ambient air temperature 25 ± 0.5 °C, and ventilator settings (respiratory rate 20/min, tidal volume 500 ml, FiO2 21%, PEEP 5 cmH2O, square flow 60 l/min).

We compared data obtained on bench with data provided by the manufacturers.

Results: The mean measured absolute humidity in the group of HME and filters were 27.6 and 17.4 mgH2O/L respectively. For HME, mean humidity data provided by the manufacturers was 33.6 mgH2O/L ($P < 0.01$ in comparison with measured humidity). The mean differences between measured humidity and data provided by the manufacturers for HMEs was 5.7 mgH2O/L, with 6/12 (50%) of devices with differences of 5 mgH2O/L or above.

The main results are presented on the Figure 2. These results are preliminary.

Conclusions: Few HMEs provided sufficient gas humidity and important differences were found in terms of humidification performances between HMEs and filters. Data provided by manufacturers obtained with gravimetric method may not be reliable.



Absolute Humidity according to manufacturer's (white bars) and to humidity measurements with the psychrometric method (black bars). The humidity of 28 mgH2O/L (red line) is considered a safe limit for prolonged mechanical ventilation.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000947

Introduction: Sepsis is a life-threatening organ dysfunction caused by a dysregulated host response to infection (1). Altered systolic and diastolic functions are associated with increased mortality, with a variable presentation (2–4). Assessment of systolic function usually uses classical echocardiographic variables, whereas assessment of diastolic function in critically ill patients is challenging, as there is no index to assess simultaneous relaxation, left ventricular stiffness and high filling pressures. The left atrium (LA) plays a crucial role in cardiac haemodynamics by regulating left ventricular (LV) filling through its reservoir function, conduction, and contraction,5 and left atrial strain (LARS) measured by speckle tracking is being investigated as an indicator of diastolic function and left ventricular filling pressures (LVFP) (6,7).
Objectives: to investigate association between the assessment of diastolic dysfunction with left atrial strain (LARS) measured by speckle tracking in patients with sepsis.
Methods: A prospective cohort study in a critical care unit. Inclusion criteria: diagnosis of sepsis or septic shock (Sepsis 3.1), > 18 years of age. Exclusion criteria: previous structural heart disease, ejection fraction (EF) < 50%, types 2, 3 diastolic dysfunction and ultrasound window limitations. Pro-BNP and troponin T were measured as markers of myocardial injury. A transthoracic echocardiogram (TTE) was performed within 24 h of study entry. E/A ratio was recorded by transmitral flowgram, e', using tissue Doppler, E/e' ratio was calculated to assess LV filling pressures, LARS was analyzed in apical four-chamber and two-chamber views, average LA reservoir fraction expressed as percentage. Patients with normal mitral filling pattern or decreased distensibility and E/e' ratio < 8 were classified as normal and those with pseudonormal or restrictive filling pattern with E/e' > 12 were classified as dysfunction type 2 and 3 respectively. GE VIVI IQ model with matrix transducer and atrial strain software was used.
Results: A total of 97 patients were included, 53 (54.64%) with normal diastolic function and normal filling pressures and 44 (45.36%) patients with types 2 and 3 diastolic dysfunction and elevated filling pressures. Mortality in the group with normal diastolic function was 17% versus 54.6% in the dysfunction group, P = 0.000. Mean E/E' values were 7.9 vs. 15.5 in the normal function versus dysfunction groups, respectively, P = 0.000. Mean LARS for the group with normal function was 20.89.1% vs. 16.44.7% in the group with dysfunction, P = 0.0129.

Characteristics	Total group N = 97	No dysfunction n = 52	Disfunction N = 43	P Value
Male, n (%)	58 (59.8)	32 (60.4)	26 (59.1)	0.898
Age, years	67.214.7	62.515.7	72.911.1	0.0004
Apache score	15.16.9	14.36.5	16.07.3	0.2400
SOFA max	6.63.0	6.42.9	6.93.3	0.4737
Heart rate, b/m	95.421.1	93.020.2	98.322.1	0.2199
E/E'	11.44.8	7.91.8	15.54.0	0.0000
Left atrial strain biplane (%)	18.97.8	20.89.1	16.44.7	0.0129
ICU mortality	33 (34.0)	9 (17.0)	24 (54.6)	0.000

Data expressed as number (%) or mean ± SD. EF ejection fraction; E/e´ early transmitral velocity to tissue Doppler mitral annular early diastolic velocity ratio

Conclusions: A LARS value < 18% has been shown to be safe for estimating patients with elevated filling pressures, being outside the normal range in all age groups observed. In the setting of sepsis, utility should continue to be evaluated; in our population it was associated with increased mortality.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000948

Introduction: In patients with persistent critical illness (PerCI), prognosis after day 10 is no longer determined by the initial admission diagnosis, but by a cascade of events resulting in new and persistent organ failure.(1) Acquired immune paralysis, resulting in occult infections or persistent inflammation both play a role in PerCI.(2) [18F]FDG PET/CT can be used as a method to image (low-grade) infection and inflammation.(3,4).
Objectives: To investigate the value of [18F]FDG PET/CT in patients with PerCI.
Methods: Patients ($\geq$ 18 years) admitted to the ICU of the University Medical Center Groningen between 2010 and 2023 by whom a [18F]FDG PET/CT was performed ten days or more after ICU admission were retrospectively included. [18F]FDG PET/CT report was evaluated for infection foci and in combination with clinical records therapy change was scored. Therapy change was defined as any therapeutic decision (e.g. starting, stopping, continuing or restricting) reported to be made directly after the [18F]FDG PET/CT. In addition, we assessed whether presence of infection on the [18F]FDG PET/CT was associated with length of ICU stay and all-cause mortality using Kaplan–Meier with Log-Rank test.
Results: 18 patients were included. Clinical signs of Inflammation or infection was the main reason to perform a [18F]FDG PET/CT scan. In 13 (72%) patients an infectious focus was found. [18F]FDG PET/CT was followed by therapy change in 11 patients (61%). In 9 patients a decision was made regarding antibiotic therapy. Corticosteroids were started in 2. Furthermore, in 2 patients drainage of infected collections was performed and in one patient supportive therapy was limited. Two patients died. Mean ICU admission time was 47 days. No association between presence of infection on [18F]FDG PET/CT and ICU stay and all-cause mortality was observed.
Conclusions: In patients with PerCI and clinical suspicion of inflammation, PET-CT contributes to identification of an infectious or inflammatory focus and results in therapy change. Larger prospective studies are needed to determine the impact of PET/CT on length of stay and mortality in this patient category.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000949

Introduction: Abnormalities in Lung ultrasound (LUS) have been shown to correlate with pulmonary edema and fluid overload.(1) Recently, Lung ultrasound has been used to monitor and guide fluid management in intensive care unit (ICU) patients.(2,3) The Venous Excess Ultrasound (VExUS) score has been proposed for monitoring venous congestion.(4) Both the LUS and VExUS score monitor markers of fluid overload.(5) However, their correlation within ICU patients is unknown. We hypothesise that higher LUS score and VExUS score are positively correlated.
Objectives: The aim of this study is to investigate the correlation between LUS and VExUS score.
Methods: This is a single-center prospective cohort study in adult ICU patients expected to be admitted for more than 24 h to a tertiary mixed ICU. Within 48 h of ICU admission, LUS and VExUS were performed with an interval of 1–2 days, with a maximum of three times. We selected LUS score at time of the most abnormal VExUS for analyses. Our primary outcome was the correlation between LUS score and VExUS score. Secondary outcomes were correlation between cumulative fluid balance and LUS score and cumulative fluid balance and VExUS score. Correlations were tested using Spearman or Pearson statistic when appropriate.

Results: From January to April 2023, 36 patients were included. The mean age of the cohort was 64(± 13.9), 61% was male. The most common reason for ICU admittance was sepsis, n = 14 (39%), followed by cardiac reasons, mostly out of hospital cardiac arrest, n = 9 (25%). The median cumulative fluid balance at time of ultrasound was 1342.7 mL. The median LUS score was 6 and the median VExUS score was 1 (Table 1). No significant correlation between LUS score and VExUS score was found: ρ = 0.10, p = 0.55. No significant correlation between cumulative fluid balance and LUS score or VExUS score was found ρ = -0.004 P = 0.98 and ρ = -0.11 P = 0.49 respectively.

Table 1 (abstract 000949) Ultrasound measurements

Lung Ultrasound (LUS) Score	
Median LUS score [IQR]	6[1.5–11.25]
Venous Excess Ultrasound(VExUS) score n %	
Median VExUS score [IQR]	1[0–1]
0	15(42)
1	17(47)
2	2(6)
3	2(6)

Conclusions: In this cohort of ICU patients no significant correlation between LUS score and VexUS score was found. However, due to a relatively small sample size in a mixed ICU population it is too early to accurately assess this correlation.

Introduction: In mechanically ventilated patients with a level of positive end-expiratory pressure (PEEP) ≥ 10 cmH2O, the PEEP-test, consisting in a transient decrease in PEEP to 5 cmH2O, has been recently suggested to detect volume responsiveness [1]. In this princeps study, its effects have been assessed on cardiac index (CI) measured with an invasive monitoring device. Changes in perfusion index (PI), which quantifies the amplitude of the plethysmographic signal, has been used as a surrogate of CI variations and might be employed to assess the hemodynamic effects of the PEEP-test.

Objectives: We evaluated if changes in PI could detect a positive PEEP-test.

Methods: In a prospective observational study conducted in an intensive care unit, the PI was measured in 28 patients with acute circulatory failure and no cardiac arrhythmias, under mechanical ventilation with a PEEP level ≥ 10 cmH2O. PI and CI (pulse contour analysis, PiCCO2 device) were measured before and during a 1-min PEEP-test. A positive PEEP-test was defined by an increase in CI > 8.6%.

Results: Demographical and clinical characteristics at baseline are presented in Table 1. During the PEEP test, PEEP was decreased by 7 (5–10) cmH2O. In the 14 (50%) patients with a positive PEEP-test, CI and PI increased by 17 (15–20)% and 14 (9–20)%, respectively. These changes were significantly larger than the respective changes in CI and PI in patients with a negative PEEP-test (5 [4–8]% and 0 [0–6]%, respectively) (Figure 1). A significant correlation between maximal changes in CI and PI during the PEEP-test was observed (rho = 0.80 [0.60–0.90], p < 0.0001). An increase in PI > 7% during the PEEP-test reliably detected a positive PEEP-test with an area under the receiver operating characteristic curve of 0.94 (0.78–0.99) (p < 0.0001 vs 0.5), a sensitivity of 93 (66–100)% and a specificity of 86 (57–98)% (Figure 2).

.

Table 1 (abstract 000950) Demographical and clinical characteristics at baseline

Variables	Study population (n = 28)
Age, years	63 (14)
Male sex, n (%)	18 (64)
BMI, kg/m^2	29 (27–32)
SAPS II	40 (35–50)
Norepinephrine, mcg/kg/min	0.16 (0.09–0.6)
Tidal volume, mL/kg	5.9 (0.4)
PEEP, cmH2O	13 (11–15)
Plateau pressure, cmH2O	26 (24–28)
Driving pressure, cmH2O	11 (10–15)
Respiratory system compliance, mL/cmH2O	33 (27–42)

Conclusions: An increase of PI during the PEEP-test > 7% reliably detects a positive response of CI to the PEEP-test. In patients in whom an invasive monitoring of CI is not available, PI may be used as a surrogate for assessing the PEEP-test effects.

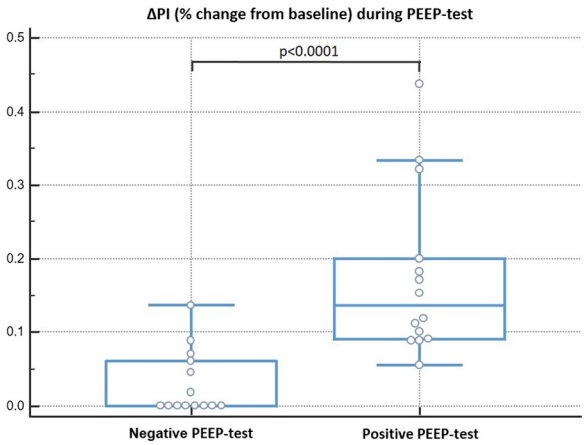

Figure 1 (abstract 000950) Changes in perfusion index (PI) during a PEEP-test according to PEEP-test response

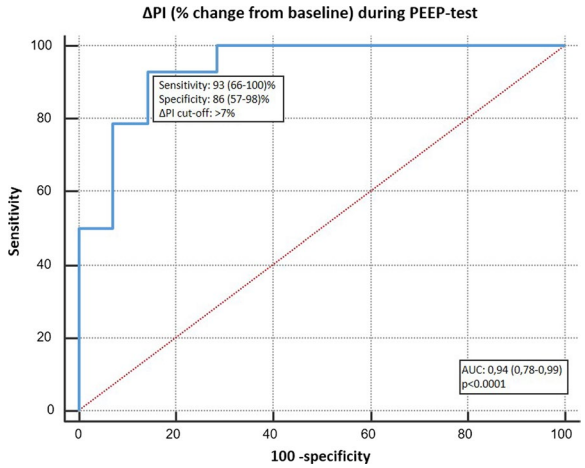

Figure 2 (abstract 000950) Area under the receiver operating characteristic curve generated for the detection of a PEEP-test by the changes in perfusion index (PI)

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000952

Introduction: Reactivation of cytomegalovirus (CMV) occurs in up to one third of critically ill patients (1). Even though its clinical relevance is still under debate, numerous studies have shown an potential increase in mortality (2), duration of hospital stay, days on mechanical ventilation (3) and a greater health system resource utilization (4). Effective anti-viral drugs against CMV are widely available but can have relevant side effects and might be less effective in resistant strains. The hemoperfusion device Seraph 100 Microbind Affinity blood Filter (Seraph-100) can remove certain pathogens, including viruses (5–9). This technology mimics a heparin sulfate rich cell surface, as the pathogens form a nonreversible bind with heparin coated, ultrahigh molecular weight polyethylene beads (9). We have tested the Seraph-100 in a patient with a suspected ganciclovir resistant CMV infection to analyze its adjuvant effectiveness.
Objectives: Explorative analysis to evaluate Seraph-100`s efficacy in reducing CMV viral load by quantitative polymerase chain reaction (PCR) in an immunocompromised patient.
Methods: The general consent to use anonymized data was given by the patient on admission to the University hospital of Zurich. According to our in house standard, the immunocompromised patient received an antiviral treatment with ganciclovir as soon as the elevated CMV viral load was diagnosed, but it increased in the course so that ganciclovir resistance was suspected. Given that the patient was already on a continuous kidney replacement treatment (CKRT) a Seraph-100 was connected in series (post-filter configuration) to the extracorporeal circuit with a blood flow (Q) of 80 ml/min and an ultrafiltration of 250 ml/h. Plasma samples for CMV PCR analysis were taken at start and then hourly over a 4-h course of Seraph-100 treatment both systemically and post-Seraph. CMV clearance rates were calculated as CI = Q x (Csyst – Cpost) / Csyst.
Results: To our surprise, we were not able to detect any reduction in CMV viral load. The initial systemic CMV DNA concentration of 1590 IE/ml went up to 1890 IE/ml at the end of the treatment and post-Seraph viral copies were even higher from the first sample on with 2220 UI/ml and increasing up to 2440 IU/ml. Consequently, negative clearance rates were calculated (t0: − 31 ml/min, t1: − 12 ml/min, t2: − 13 ml/min, t3: − 24 ml/min, t4: -23 ml/min).
Conclusions: In this explorative analysis CMV load was not removed by Seraph-100. We interpreted the viral load increase in post-Seraph samples in the context of hemoconcentration due to ultrafiltration during CKRT.

Comparison of two oxygenation SpO2 targets with two different oximeters – impact on oxygen flow rates and on oxygenation parameters

F. Lellouche[1], P. A. Bouchard[1]
[1]Centre de recherche, Institut Universitaire de Cardiologie et de Pneumologie de Québec-Université Laval, Québec, Canada

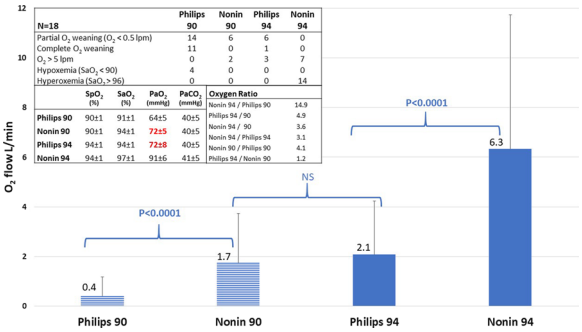
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000953

Introduction: SpO2 target influences oxygen utilization1. It was recently shown that oximeter brand influenced the SpO2 measurements2.
Objectives: To evaluate the impact of the combination of SpO2 target and oximeter brand on oxygen utilization, oxygen weaning, occult hypoxemia and occult hyperoxemia.
Methods: We currently conduct a randomized cross-over study in 20 stable ICU patients requiring oxygen therapy delivered through nasal canula after cardiac surgery. Patients without adequate SpO2 signal are excluded. Four randomized periods of 10 min are conducted in all patients with different SpO2 targets (90 and 94%) and different oximeters (Nonin and Philips). For each period we collect the oxygen flow and oxygen blood gases at the end of the period. We compared the oxygen flow, the rate of occult hypoxemia (SaO2 < 90% with SpO2 ≥ 90%) and occult hyperoxemia (SaO2 ˃ 96% with SpO2 ≤ 96%), oxygen partial weaning (< 0.5L/min) or complete weaning and the rate of high O2 flow requirements (˃ 5L/min).
Results: We present preliminary data based on first 18 patients (mean age 69 ± 9 years, 15 were men, all had light skin pigmentation, none had shock). At baseline, SpO2 was 93.2 ± 1.9% and oxygen flow was 2.0 ± 1.5 L/min. Main results for the oxygen flow and oxygenation parameters in the different study periods are displayed in the figure. Differences in mean oxygen flow during Nonin 90 (1.7 ± 2.0 L/min) and Philips 94 (2.1 ± 2.1 L/min) are not statistically different (P = 0.11). However, all other comparisons of the oxygen flow are statistically different. The rate of complete weaning was 50% in the Philips 90 period and 0% in other periods. Oxygenation parameters (SaO2, PaO2) were similar during Nonin 90 (94 ± 1%, 72 ± 5 mmHg) and Philips 94% (94 ± 1%, 72 ± 8 mmHg). Conversely, there were statistically different oxygenation levels with Nonin 94 (97 ± 1%, 91 ± 6 mmHg) and Philips 90 (91 ± 1%, 64 ± 5 mmHg).
Conclusions: In patients requiring conventional oxygen therapy, the SpO2 target, the oximeter brand and even more the combination of both had major impact on oxygen utilization, oxygen weaning and both occult hypoxemia and hyperoxemia. Patients managed with Nonin 90 and Philips 94 had similar oxygen flow and similar arterial oxygenation parameters. These data underline the necessity to use corrected SpO2 targets rather than universal SpO2 targets to manage oxygen therapy.

N=18					Philips 90	Nonin 90	Philips 94	Nonin 94
Partial O_2 weaning (O_2 < 0.5 lpm)					14	6	6	0
Complete O_2 weaning					11	0	1	0
O_2 > 5 lpm					0	2	3	7
Hypoxemia (SaO_2 < 90)					4	0	0	0
Hyperoxemia (SaO_2 > 96)					0	0	0	14
	SpO_2 (%)	SaO_2 (%)	PaO_2 (mmHg)	$PaCO_2$ (mmHg)	Oxygen Ratio			
Philips 90	90±1	91±1	64±5	40±5	Nonin 94 / Philips 90			14.9
Nonin 90	90±1	94±1	72±5	40±5	Philips 94 / 90			4.9
Philips 94	94±1	94±1	72±8	40±5	Nonin 94 / 90			3.6
Nonin 94	94±1	97±1	91±6	41±5	Nonin 94 / Philips 94			3.1
					Nonin 90 / Philips 90			4.1
					Philips 94 / Nonin 90			1.2



Comparison of oxygen flow utilization in different study conditions: Philips 90, Nonin 90, Philips 94, and Nonin 94) and ratio of oxygen utilization for the different tested conditions.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000954

Introduction: It is known that Covid-19 has, at least initially, a nonspecific clinical course and that up to 17% of patients may require invasive mechanical ventilation (1). Many patients are initially managed with non-invasive mechanical ventilation through a High Flow Nasal Cannula and Bilevel Positive Airway Pressure (2). The patient is intubated in a decision that may involve level of consciousness, respiratory rate, oxygen saturation, fraction of inspired oxygen and breathing pattern (3). Thus, there may be significant differences between physicians with regard to the correct time to intubate a patient, and this possible delay may impact the clinical outcome (3).
Objectives: To analyze the relationship between intubation day and mortality in COVID-19 patients.
Methods: We performed a cohort study considering all COVID-19 patients consecutively admitted between March 2020 and December 2020 requiring supplemental oxygen. The primary outcome was hospital mortality after intubation, and a Cox model adjusted by SAPS-3 was used to evaluate the effect of time from onset of hospital admission to intubation in mortality.
Results: A total of 250 patients were evaluated and 73.6% were intubated. Overall, the median to intubation was 4 (2–7) days after hospital admission. Mortality occurred in 68 (27.2%) patients in which the intubation was done more than 4 (2.0–5.75) days after hospital admission. Adjusted mortality hazard ratio to the patients intubated before than 4 days was 0.68 (95% CI, 0.52 to 0.88), between 5 and 10 days 1.74 (95% CI, 1.06 to 2.87) and those more than 10 days was 2.74 (95% CI,

1.02 to 7.34). Hospital length of stay was different among intubated patients before and after 4 days [28 (18.7–43.2) vs. 36 (25–56) days], difference 7 days (95% CI, 2 to 12) P = 0.01. All sensitivity analyses confirmed the robustness of our findings.
Conclusions: An early approach to invasive mechanical ventilation improved outcomes in this cohort of COVID-19 patients, delaying intubation in the course of symptoms may be associated with higher mortality (Figure 1).

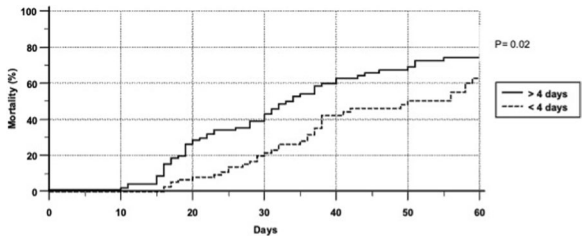

Figure 1 (abstract 000954) Kaplan–Meier curve with estimated mortality in 60 days with intubation performed before and after 4 days

Post-ECMO decannulation ultrasound for identifying inferior vena cava thrombosis

J. Han[1], S. Patel[2], P. Cavaleiro[1], A. Bhaiji[2]; B. Rawal[3]; S. Singh[1]
[1]Adult Intensive Care Unit, Royal Brompton & Harefield NHS Foundation Trust, London, United Kingdom; [2]Department of Medicine, Chelsea and Westminster Hospital, London, United Kingdom; [3]Department of Radiology, Royal Brompton Hospital, London, United Kingdom
Correspondence: J. Han
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000955

Introduction: Extracorporeal membrane oxygenation (ECMO) is a method of providing cardiac or respiratory support. The ECMO circuit increases the chances of developing thromboembolism, and most patients during ECMO are treated with heparin with close anti-Xa monitoring.[1] Despite this, cannula-associated deep vein thrombosis (CaDVT) is a recognised and frequently occuring complication.[1] Due to this, ultrasound (US) of deep veins associated with the ECMO circuit, such as the internal jugular veins and femoral veins, is routinely performed post decannulation.[2] The inferior vena cava (IVC) is not analysed routinely, and the incidence and significance of clots in this area has not been fully elucidated. A pre-COVID pandemic study showed 54.9% patients had a thrombotic event, with 29.3% CaDVT, and 46.2% IVC thrombosis.[3].
Methods: Single-centre, retrospective, observational study. 309 patients who had ECMO treatment at Royal Brompton Hospital between November 2019 to March 2022 were analysed. Patients were excluded if they died on ECMO, if they were repatriated before US, or if the post-decannulation US occurred over one week after decannulation. 213 patients were included.
Results: 213 patients (all VV-ECMO) were included. Cannulation sites were evaluated in 213 patients and IVC was evaluated in 128 patients. A clot is defined as a thrombus or a fibrin sheath. 43% of patients presented with a clot (n = 91, in IVC, iliac, femoral, jugular, or saphenous veins). The incidence of CaDVT was 29.6% (63/213 for femoral or jugular clot), and IVC clot was 28.1% (36/128), of which 61% (22/36) had isolated IVC clot. 14 patients had both CaDVT and IVC clot. Characterising the IVC clots, 14% (5/36) was a thrombus, and 31/36 (86%) was a fibrin sheath/cast.
Conclusions: The incidence of IVC thrombosis is high in the post-COVID ECMO cohort. The IVC clot occurred independently of CaDVT in the majority of cases (61%). The majority of IVC clots were fibrin sheaths/casts. This is comparable to our previous pre-COVID data on IVC clots. Further research should focus on the clinical significance of an isolated IVC thrombus, and contributing factors in the development of an isolated IVC thrombus.

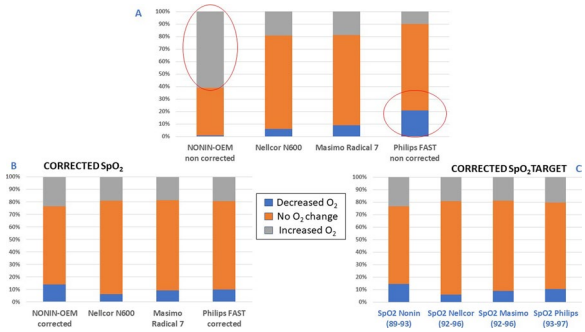
Utilization of corrected SpO2 or corrected SpO2 target to homogenize the practices regarding management of oxygen therapy

F. Lellouche[1], A. Delobel[1], M. A. Blanchet[1], P. A. Bouchard[1]
[1]Centre de recherche, Institut Universitaire de Cardiologie et de Pneumologie de Québec-Université Laval, Québec, Canada
Correspondence: F. Lellouche
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000956

Introduction: SpO2 target influences oxygen utilization with increased by threefold the oxygen flow with 4% difference in SpO2 target1. It was recently showed that oximeter brand influenced the SpO2 measurements2. Combination of the errors on the SpO2 measurement related to the oximeter brand and choice of different target may have major impact on the clinical management of patients in the clinical practice and during research. One solution may be to use a corrected SpO2 target rather than an universal SpO2 target to homogenize the practices. The other solution is to correct the SpO2 values based on the known SpO2-SaO2 biases.
Objectives: The objective of the study was to evaluate if the utilization of a corrected SpO2 target or of corrected SpO2 values could homogenize the O2 management.
Methods: We performed a secondary analysis of the Oxygap study to evaluate the oxygen utilization (Increase, Decrease or No change of O2 support) in the 211 included patients. The oxygen flow was modified based on individual SpO2 values to maintain (i) a non corrected SpO2 target of 92–96%, using the Nonin, Nellcor, Masimo, Philips and (ii) a corrected SpO2 target with same pulse oximeters. The correcting factors were based on the SpO2-SaO2 bias for each oximeters found in the Oxygap study2, respectively −3.1, −0.3, −0.2 and +0.9%. We also evaluated the impact of the utilization of corrected SpO2 values, based on the known SpO2-SaO2 bias.

Results: Based on the values obtained in the Oxygap study with 211 patients, the oxygen management showed significant discrepancies when SpO2 were not corrected or when SpO2 target was not corrected (Figure, panel A). When SpO2 values were corrected (Figure, panel B) or when SpO2 target were corrected (Figure, panel C), the management of oxygen support was homogenize with reduction of discrepancies.
Conclusions: The utilization of corrected SpO2 values or corrected SpO2 target may allow to reduce the large discrepancies in O2 utilization based on confounding factors related to pulse oximetry measurements. Additional corrections based on skin pigmentation will be required when bias will be adequately evaluated.



Management of oxygen support in the cohort of 211 patients of the OXYGAP study to maintain SpO2 within 92–96% with uncorrected SpO2 (Panel A), with corrected SpO2 (Panel B) or with corrected SpO2 target (Panel C)

Unscheduled return to the paediatric emergency department within 72 h: a follow-up with big data

R. Spiegel[1]
[1]Department of Acute Medicine (Surgical IMC Unit, Internal Medicine and Emergency Department), University Hospital Basel, Riehen, Switzerland
Correspondence: R. Spiegel
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000957

Introduction: The reasons for unscheduled return visits to the paediatric emergency department (PED) within 72 h after PED-discharge are subject to debate, e.g. some studies found that they are mainly justified and occasionally lead to direct admission to the paediatric intensive care unit (PICU), [1], while other studies consider most of them avoidable [2].
Objectives: The following analysis is an ongoing project since 2019. It aims to use big data in order to explore the reasons for unscheduled return visits to the PED. It is continuously updated once new data become available, i.e. once new studies have been published. Earlier analyses have been presented at conferences in Switzerland and Germany [3]-[5]. With almost 30 million cases globally, it belongs to the largest analyses in paediatric emergency medicine.
Methods: A PubMed literature search included all studies until 31st of March 2023 (i.e. the month prior to the ESICM LIVES 2023 abstract deadline). It had the search terms "emergency department", "return", "72 h" as well as the two different forms of spelling "pediatric – paediatric." Publications without restriction to location or language were included. 29 publications with over 29.8 million PED visits and 804,422 unscheduled return visits were identified in 4 continents. These were (in alphabetical order): Africa, Asia, Europe, and North America. To evaluate the causes for PED-return, the reasons identified in each study were put in relation to the total number of studies, e.g. in x studies out of the total number of 29 studies, the reason "clinical condition" was the cause for an unscheduled PED-return. This permitted the calculation of a ratio for each reason. For example, the ratio for the reason "clinical condition" was defined as the number of studies x where the clinical condition was identified as the reason for unscheduled PED-returns, divided by 29. Sometimes several reasons were identified per study, for instance the clinical condition as well as young age (e.g. infants with worsening symptoms). After calculating the ratios, 95 percent confidence intervals of these ratios were computed by applying the modified Wald method (GraphPad, San Diego, CA, USA). The ratios and their confidence intervals permitted an overview of the reasons for unscheduled PED returns.
Results: Irrespective of the size of the study or the location, the main reason for unscheduled PED-returns is the clinical condition with worsening symptoms or failed improvement (21 out of 29 studies, ratio 0.72, 95% CI 0.54–0.86), followed by young age (12/29 studies, ratio 0.41, 95% CI 0.25–0.59), organizational aspects (e.g. reachability of a paediatrician or family physician, 7/29 studies, ratio 0.24, 95% CI 0.12–0.42), failed coping attempts by the caregivers (7/29 studies, ratio 0.24, 95% CI 0.12–0.42), gender aspects (5/29 studies, ratio 0.17, 95% CI 0.07–0.35) and cultural aspects (3/29, ratio 0.1, 95% CI 0.03–0.27).
Conclusions: This big data analysis showed similar results in every continent. Unscheduled return visits to the PED are mostly justified, as the main reason is the clinical condition, i.e. worsening symptoms or failed improvement. This sometimes led to direct PICU-admission due to clinical deterioration. Therefore, it is absolutely vital to take unscheduled return visits seriously. When looking at the confidence intervals, all other identified reasons play a minor role compared to the clinical condition. There is no doubt that an unscheduled PED return is not always justified and might also be avoidable. However, when incorporating as many data from as many regions as possible, there is evidence that on a global level, unscheduled PED returns are generally justified. Further evidence stems from the fact that the main two reasons for PED return (clinical condition and young age) are almost the same in every continent. Similar to a prior analysis [5], limitations are that the period "young age" was not defined equally in every study, with a range from birth up to 6.5 years in some studies. In addition, the study sizes varied substantially. North America not only contributed the largest number of studies, but also had studies with the highest number of PED cases, where for example a single study contributed to more than 25 million cases. Nevertheless, the general findings are robust irrespective of the continent or the number of cases per study.

Are sonographic measures of the diaphragm at unit admission linked to ventilation outcome?

J. Kleinsmith[1], A. Lupton-Smith[1], L. Gerber[1], C. Koegelenberg[2], S. Hanekom[1]

Introduction: The duration of mechanical ventilation is associated with increased mortality and the development of post intensive care syndrome. Sonographic measurements of the diaphragm taken at the time of weaning failure have been used as predictors of successful weaning outcome. However, the importance of monitoring the diaphragm from unit admission is increasingly being recognized. Identifying patients at risk of prolonged intubation at the time of unit admission could allow for focused treatment interventions aimed at prevention of ventilator induced diaphragm dysfunction and reducing time on the ventilator.
Objectives: To explore the associations between sonographic measures of the diaphragm within the first three days of unit admission and ventilation time.
Methods: This prospective observational cohort study was conducted in a tertiary hospital from March 2017 to August 2017, and received approval from the Institutional Health Research Ethics Committee (S16/09/173). Sonographic measurements of the diaphragm were initiated within 24 h of intubation, at the zone of apposition using a 5–12 MHz ultrasound transducer. Diaphragm thickness (Tdi) was measured at end-inspiration and end-expiration, and diaphragm thickening fraction (DTF) was calculated as the percent change between thickness at end-inspiration and end-expiration. All measurements were performed by a single researcher. Data was analysed in consultation with a statistician including correlation analysis using Pearson or Spearman's rho test as indicated and between- group differences using Mann–Whitney U test.
Results: Forty-nine mechanically ventilated participants were assessed within 24 h of intubation, with a mean age of 46.69 ± 18.25 years, mean APACHE score of 16.20 ± 8.96, and n = 13 (27%) of patients died in the ICU. The median time on ventilation was 56.5 h (IQR: 20 – 359.5), with the majority of patients (84%, n = 41) being ventilated for less than seven days. Moderate to strong positive correlations were observed between Tdi inspiration and expiration over the first three days and ventilation time. All correlations were significant. A moderate negative correlation was found between DTF and ventilation time. However, this negative correlation was only significant on Day 3 (Table 1). Additionally, there was a significant difference in day 1 DTF (p = 0.016*) between patients who were extubated within 7 days of unit admission and patients who were intubated for longer than 7 days. APACHE II and C-reactive protein (CRP) on unit admission were moderately correlated with time on the ventilator (Table 2).
Conclusions: Sonographic measures of the diaphragm taken within the first three days of unit admission are associated with ventilation outcome. However, APACHE II score and CRP on unit admission may act as potential confounders. The findings from this study will inform the planning of a study aimed to develop a predictive model that incorporates sonographic measures at unit admission, to estimate the probability of extended time on ventilator. Further investigation is warranted to determine the clinical utility of these findings in the context of patient care.

Introduction: Definition of temporal serum proteome profiles after out-of-hospital cardiac arrest may identify biological processes associated with severe hypoxia–ischemia and reperfusion. It may further explore intervention effects for new mechanistic insights, identify candidate prognostic protein biomarkers and potential therapeutic targets.
Objectives: This pilot study aimed to investigate serum proteome profiles from unconscious patients admitted to hospital after out-of-hospital cardiac arrest according to temperature treatment and neurological outcome.
Methods: Serum samples at 24, 48, and 72 h after cardiac arrest at three centres included in the Target Temperature Management after out-of-hospital cardiac arrest trial underwent data-independent acquisition mass spectrometry analysis (DIA-MS) to find changes in serum protein concentrations associated with neurological outcome at 6-month follow-up and targeted temperature management (TTM) at 33 °C as compared to 36 °C. Neurological outcome was defined according to Cerebral Performance Category (CPC) scale as "good" (CPC 1–2, good cerebral performance or moderate disability) or "poor" (CPC 3–5, severe disability, unresponsive wakefulness syndrome or death).
Results: Of 78 included patients [mean age 66 ± 12 years, 62 (80.0%) male], 37 (47.4%) were randomised to TTM at 36 °C. Six-month outcome was poor in 47 (60.3%) patients. The DIA-MS analysis identified and quantified 403 unique human proteins. Differential protein abundance testing comparing poor to good outcome showed 19 elevated proteins in patients with poor outcome (log2 fold change (FC) range 0.28–1.17) and 16 reduced proteins (log2(FC) between -0.22 and -0.68), involved in inflammatory/immune responses and apoptotic signalling pathways for poor outcome and proteolysis for good outcome (Figure 1 a-b). Analysis according to level of TTM showed a significant protein abundance difference for six proteins (five elevated proteins in TTM 36 °C (log2(FC) range 0.33–0.88), one reduced protein (log2(FC) − 0.6)) mainly involved in inflammatory/immune responses only at 48 h after cardiac arrest, with no significant changes during temperature intervention (Figure 1c). In an interaction analysis between neurologic outcome and temperature target, a significant association for the antioxidant extracellular superoxide dismutase was shown. Extracellular superoxide dismutase was elevated in patients with a poor outcome treated at a target temperature of 36 °C.
Conclusions: Serum proteome profiling revealed an increase in inflammatory/immune responses and apoptosis in patients with poor outcome. In patients with good outcome, an increase in proteolysis was observed, whereas TTM-level only had a modest effect on the proteome profiles. Further validation of the differentially abundant proteins in response to neurological outcome is necessary to validate novel biomarker candidates that may predict prognosis after cardiac arrest.

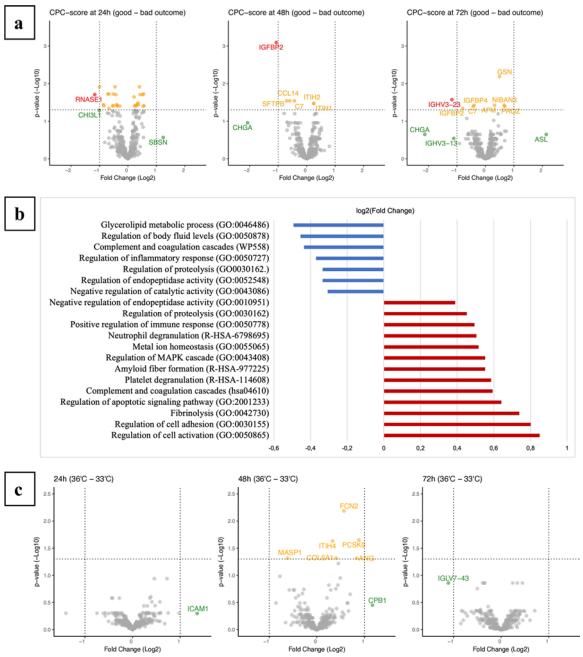

Figure 1 (abstract 000961) Proteomic analysis results for protein abundance according to neurological outcome and temperature treatment. **a)** Volcano plots for the differential abundance of proteins for neurological outcome at 24, 48, and 72 h. Positive log2(FC) indicates good outcome, negative log2(FC) indicates poor outcome. Statistically significant proteins (adjusted p-value ≤ 0.05) and regulated proteins (absolute log2(FC) > 1) are labeled in red. Proteins with a significant adjusted p-value with a log2(FC) between − 1 and 1 are labeled in yellow, and statistically nonsignificant proteins with an absolute log2(FC) < − 1 or > 1 are labeled in green. **b)** Proteins enhanced for neurological outcome were annotated by selected gene ontology terms for biological process. The average log2(FC) for all proteins included in each term is plotted to show the direction of average change for poor outcome (in red) as compared to good outcome (in blue). **c)** Volcano plots for the differential abundance of proteins between temperature treatment of 36 °C to 33 °C at 24, 48, and 72 h. Positive log2(FC) indicates treatment with 36 °C, negative log2(FC) indicates treatment with 33 °C. Proteins with a significant adjusted p-value with a log2(FC) between -1 and 1 are labeled in yellow, and statistically nonsignificant proteins with an absolute log2(FC) < − 1 or > 1 are labeled in green

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000962

Introduction: Common anticoagulation strategies in continuous renal replacement therapy (CRRT) are regional citrate anticoagulation (RCA), unfractionated heparin (UFH), and no anticoagulation. The *KDIGO Clinical Practice Guideline for AKI 2012*(1) recommend using RCA, rather than UFH, as first choice anticoagulation for patients without contraindications to RCA. Citrate toxicity is a major complication of RCA (2). Hyperlactatemia predicts RCA accumulation (3), and therefore, universal RCA prescription for CRRT as per current guidelines, may be inappropriate in patients with severe hypoperfusion states, particularly cardiogenic and septic shock.
Objectives: To assess the effect of anticoagulation strategies (RCA, UFH and Nil) in CRRT on haemodynamic status in critically ill AKI patients with shock.
Methods: A retrospective study was carried out in a single tertiary referral centre ICU in Ireland. Data were collected retrospectively from the ICU Electronic Clinical Information System database (Metavision®). The patient cohort included all patients admitted to ICU who received CRRT in 2021 – 93 patients were identified. Demographics, ICU admission indication (categorised by organ failure support type), the presence of shock on CRRT commencement, CRRT anticoagulation type and patient outcomes (including ICU length of stay, and mortality) were all recorded from the database. Vasopressor requirements were recorded on ICU admission and on CRRT commencement. Peak vasopressor requirements within 24 h of CRRT start were also recorded. A Noradrenaline Equivalence (NAE) was calculated for all three aforementioned times.
Results: 93 patients (mean age, 63 years; 69.9% male) were included in the study, categorised by anticoagulation subgroup:

Table 1 (abstract 000962) Anticoagulation Subgroups and ICU Length of Stay (LOS)

Anticoagulant	Number of patients (%)	ICU LOS (days)
RCA	49 (52.7%)	14.38
Nil anticoagulation	19 (20.4%)	5.95
Heparin anticoagulation	11 (11.8%)	9.22
RCA switch	9 (9.7%)	15.24
Nil to anticoagulation switch	5 (5.4%)	16.32

In-ICU mortality occurred in 12 RCA (24.5%, mean 11.92 days), 3 heparin (27.3%, mean 6.11 days), and 10 Nil anticoagulation patients (52.6%, mean 2.58 days). Vasopressor requirements were present in 67.3% RCA (mean NAE 0.262 mcg/kg/min), 45.5% heparin (mean NAE 0.290 mcg/kg/min) and 79.0% nil anticoagulation (mean NAE 0.330 mcg/kg/min) commencing CRRT, increasing to 77.6%, 63.6%, and 89.5%, respectively, within a 24 h period post-commencement. Peak vasopressor requirements in a 24-h-period post CRRT commencement were lower in the RCA group (mean NAE 0.353 mcg/kg/min) than heparin (mean NAE 0.432 mcg/kg/min) or nil anticoagulation (0.465 mcg/kg/min).
Conclusions: This study is ongoing, however, preliminary findings suggest that in critically ill patients with AKI and shock receiving CRRT, RCA does not exacerbate haemodynamic compromise with respect to heparin or nil anticoagulation.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000963

Introduction: In the last decades, the survival of cancer patients has increased exponentially. Taking this fact into account, more cancer patients are admitted to out intensive care units.
Objectives: The main outcome is to analyze the factors related to in-hospital mortality (ICU and hospital ward less than 1 month after discharge from ICU) of oncohaematological patients in the intensive care unit with an active diagnosis of: solid organ tumor, lung neoplasia or haematological malignancies.
Methods: Retrospective descriptive study of oncohematological patients admitted for medical, surgical or coronary reasons in the intensive care unit in the period 2017–2022.
Sociodemographic, clinical-analytical and mortality parameters are described. In addition, specific scales related to oncohematology were calculated: ECOG (quality of life), and MASCC (infectious complications); as well as the Charlson comorbidity scale and the APACHE II prognostic classification scale.
Differences between survivors and deaths (intra-ICU and/or in the first month after being discharged to the ward) were analyzed using statistical analysis with Pearson's Chi-square test or Fisher's exact test for qualitative variables or t-Student's test and Levene's test for quantitative variables. The required significance threshold was 0.05.
Results: A total of 81 patients were included: solid tumors (n = 31), lung (n = 7) and hematological malignancies (n = 43). A total of 33 patients died during thier stay in the ICU or in less than a month on the hospital ward.

In the qualitative variables analysis, we found a statistical association between the probability of hospital death and the following variables: treatment with antibiotics in the 48 h prior to admission (OR 4.375; 95% CI 1.640–11.673), neutropenia (OR 3.193; 95% CI 1.174–8.688), hypotension on admission (MAP < 60 mmHg) (OR 2.667; 95% CI 1,029–6,912), the connection to MV (OR 2,889; 95% CI 1,051–7,938) and the duration of MV both in the first 24 h of admission (OR 2,875; 95% CI 1,082–7,367) as beyond 24 h (OR 2.917; 95% CI 1.570–7.311), the diagnosis of ARDS (OR 11.556; 95% CI 4,025–33,175), the prone maneuver (OR 5.5; 95% CI 1,570–19,226) and the use of CRRT (OR 3,807; 95% CI 1,315–11,022).

Table 1 (abstract 000954) Statistically significant quantitative variables

VARIABLES	DEATHS	SURVIVORS	DIFFERENCE OF MEANS	CONFIDENCE INTERVAL(95%)	STATISTICAL SIGNIFICANCE
AGE	60,08	65,55	− 5,46	0,43–10,50	0,031
MASCC SCALE	10,46	13,42	− 2,78	0,35–5,20	0,02
RESPIRATORY RATE	27,06	22,08	4,97	1,63–8,31	0,006
HEART RATE	107,42	96,71	10,71	0,58–20,845	0,038
GLASGOW COMA SCORE	14,39	12,73	1,66	0,02–3,30	0,026
PLATELETS (MM3)	86,515,15	176,068,75	− 89,553,59	51,66–127,452,19	0,001
PCR (MG/L)	226,68	103,35	123,32	26,78–70,01	0,001
LDH (U/L)	582,45	402,29	180,16	60,01–300,31	0,004
FIO2	93,27	65,63	27,64	15,14–40,14	0,001

Conclusions: The factors associated with the probability of death in oncohematological patients are diverse, highlighting the use of invasive respiratory support, shock on admission, CRRT and the MASCC scale.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000965

Introduction: Sepsis and its most severe form, septic shock, has a high fatality rate as a consequence of the evolution to multiorgan dysfunction. A possible explanation for the development of organ dysfunction is the persistence of tissue hypoperfusion, even after the restoration of macrohemodynamic parameters. In addition, improved microcirculation in patients with septic shock appears to be associated with lower mortality. Initial experimental and clinical studies with vasodilator drugs like nitroglycerin suggest that it is possible to improve tissue perfusion in shock states (8–12). The rationale for using vasodilators such as nitroglycerin is based on the potential to recruit microcirculation and lead to improved flow in the microcapillary network.
Monitoring peripheral perfusion is a good alternative to assess tissue perfusion and appears to be attractive to assess the effects of nitroglycerin in septic shock after reaching macrohemodynamic resuscitation targets.
Objectives: To assess whether infusion of nitroglycerin in patients with septic shock improves capillary refill time within the first 24 h of shock diagnosis.
Methods: Prospective interventional pilot study in patients with septic shock admitted to the Intensive Care Units of the Hospital Santa Casa de Porto Alegre. Inclusion criteria: patients > 18 years, with septic shock (norepinephrine need after fluid replacement), with mean arterial pressure (MAP) ≥ 65 mmHg, who persist with hyperlactatemia (> 2.0 mmol/l) and capillary refill time (CRT) > 5 s. Informed consent obtained from the legal guardian. Protocol: Initial infusion of 2 mg/h of nitroglycerin (T0), the dose being doubled every 15 min up to a maximum of 16 mg/h in 45 min (T45). Hemodynamic parameters and CRT were evaluated at the same time intervals (T0, T15, T30, T45, T60) and after 30 min of infusion suspension (T90).
Results: 10 patients were included. In one patient NTG was stopped after the start of the infusion and in another patient at increasing the dose from 8 mg/h to 16 mg/h. CRT decreased for nine patients at T60 (T0: 6.5 ± 0.7 s vs. T60: 3.6 ± 0.9 s, p < 0.001). Six patients normalized the CRT (≤ 3 s). The norepinephrine dose (T0:0.52 ± 0.20 mcg/kg/h vs. T60: 0.53 ± 0.23 mcg/kg/h, p = NS) and MAP (T0: 77 ± 6 mmHg vs. T60:69 ± 6 mmHg, p = NS) remained stable.
Conclusions: Nitroglycerin infusion was shown to be effective to improve capillary refill time in patients with septic shock.

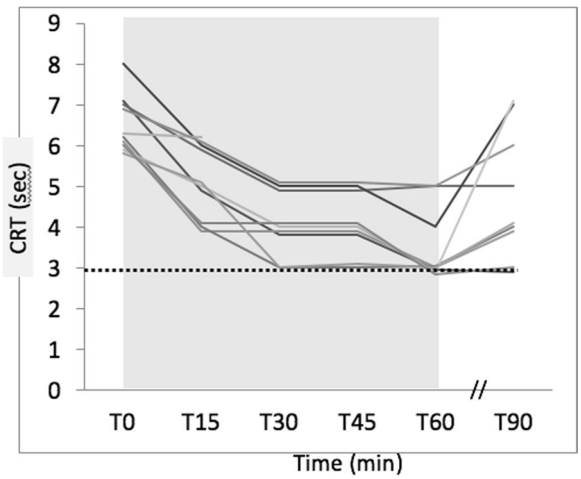

Figure (abstract 000954) Individual time course of capillary refill time (CRT) during the study protocol. Time points are defined as before the start of nitroglycerin infusion (T0), T15, T30, T45 (every 15 min increase in nitroglycerin infusion), T60 maximum dose of nitroglycerin (16mg/h), and after 30 min the end of the nitroglycerin infusion (T90). the dotted line signals the normal value for the CRT. ANOVA for repeated measures #p < 0.001 T60 vs initial value (Tukey)

Introduction: Association of Significant Elevation of NETosis and Nucleosome Biomarkers measured by Volition Nu.Q® NETs assay with Mortality in Patients with Septic Shock
Objectives: Introduction: Understanding the mechanisms underlying immune dysregulation in sepsis is a major challenge I vcn developing more individualized therapy, as early and persistent inflammation, as well as immunosuppression, play a significant role in pathophysiology. Neutrophils, release extracellular traps (NETs) as part of the antimicrobial response, which can neutralize and kill microorganisms. However, excessive NETosis may also contribute to pathogenesis, tissue damage and organ dysfunction. This process has been hypothesized to be associated with severity and mortality. Recently, a novel automated assay has been proposed for the routine measurement of nucleosomes, which are fundamental units of chromatin that are released during NETosis.
Objective: The aim was to measure nucleosome levels in septic shock patients and to determine association with mortality.
Methods: 151 septic shock patients (SEPSIS-3 definition, IMMUNOSEPSIS cohort) were included. Plasma samples were obtained at 3 timepoints (day (D) 1–2, D 3–4, D 5–8 after admission). Nucleosomes were measured using the chemiluminescent Nu.Q® NETs immunoassay, CE-IVD (Belgian Volition SRL, Belgium). IL-6 was measured with Ella automated immunoassay system (Bio-Techne). Immunological cellular parameters were measured by flow cytometry (Beckman Coulter).
Results: Main patients' characteristics were (as median): age (69), SAPS II (65), SOFA (10), day-28 mortality 45%. Immunological parameters indicated early inflammation (IL-6 = 1335 pg/mL at D 1–2) along with marked immunosuppression (e.g., mHLA-DR = 3853 AB/C and CD4 lymphocytes = 338 /µL at D 3–4). The nucleosome levels were markedly and significantly elevated at all-time points compared to the control group (Fig. 1A). We found significantly positive correlation between nucleosome levels and organ failure and severity scores, IL-6 concentrations and neutrophil count. Significantly higher values (D 1–2 & 3–4) were measured in non-survivor patients (28-day mortality, Fig. 1B). This association was still significant after multivariate analysis and was more pronounced with highest concentration (upper quartile, Fig. 1C). Early (D 1–2) increased nucleosome levels were also independently associated with D5 mortality. At D 5–8, persistent elevated nucleosome levels were negatively correlated to mHLA-DR values.
Conclusions: This study is the first to concomitantly investigate both nucleosomes and immunological parameters in septic shock, and it reports a significant elevation of nucleosome in patients during a one-week follow-up. The nucleosome levels showed correlation with neutrophil count and IL-6 and were found to be independently associated with mortality on day 5 and 28. Therefore, nucleosomes measured by Nu.Q® NETs seems to be a promising biomarker for detecting hyper-inflammatory phenotype upon a patient's admission. Additional investigations are required to evaluate the potential association between NETosis, sustained elevation of nucleosome and the development of sepsis-induced immunosuppression.

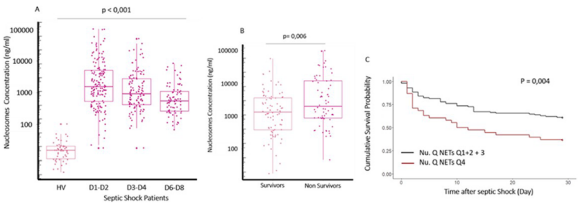

Fig. 1. (A) Level of circulating nucleosome in septic shock patients (n = 151) during first week after ICU admission and healthy volunteers (n = 50), D 1-2 (n = 151), D 3-4 (n = 116) and D 6-8 (n = 78). (B) Nucleosome concentration at D1-2 depending on 28-day mortality (C) Kaplan-Meyer curves depicting cumulative incidence of mortality stratified on D1-D2 nucleosome concentrations (Q4 = highest quartile vs Q1+Q2+Q3 quartiles).

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000967

Introduction: Mechanical ventilation (MV) is a life support technique in critically ill patients. However, it may lead to ventilator-induced lung injury (1). The contribution of driving pressure (DP) and respiratory rate (RR) to VILI was recently reported in patients according to the mathematical formula 4DP + RR (2). However, different combination of DP and RR providing the same 4DP + RR were not tested in healthy lungs to assess whether they could differently contribute to VILI.
Objectives: The aim of the study is to explore whether DP and RR could differently contribute to VILI despite keeping the same 4DP + RR in an experimental model of healthy rats.
Methods: Rats were anesthetized and mechanical ventilated for 4 h with different ventilatory strategies depending to the experimental group and keeping constant 4DP + RR = 140 as follows: Group 1, DP 10 and RR 100 (n = 4); Group 2, DP 20 and RR 60 (n = 4); Group 3, DP 25 and RR 40 (n = 4); Group 4, DP 30 and RR 20 (n = 4). Other ventilatory parameters were set as follows: I/E 50%, PEEP 2 cmH2O, and FiO2 1.0. A group of healthy non anesthetized rats was used as control. A recruitment maneuver was performed each hour (30 cmH2O × 10 s). Hemodynamics and airway pressure were monitored during MV. At

4 h, arterial blood gas analysis and respiratory system static compliance (Cpl,rs) were evaluated; a lobe from right lung was removed for wet to dry ratio (W/D); a lung micro-CT scan and bronchoalveolar lavage (BAL) were performed to evaluate lung density and cell count, respectively.
Results: After 4 h of MV, Group 4 showed a significant reduction in PaO2/FiO2 as compared to other groups and trended to a lower Cpl,rs. Edema was more pronounced in Group 4 and – accordingly – lung density was the highest among the groups by the CT evaluation (Table). The number of polymorphonuclear cells (PMNs) in BAL increased over increasing levels of DP and were significantly higher in Group 3 and 4 (Figure).

Table (abstract 000967) Pulmonary function (PaO2/FiO2 and Cpl,rs), Edema (W/D) and micro-CT scan after 4 h of MV. *p < 0.05 vs Healthy, Group 1, Group 2 and Group 3

	Healthy	Group 1 DP10RR100	Group 2 DP20RR60	Group 3 DP25RR40	Group 4 DP30RR20	ANOVA
PaO2/FiO2 (mmHg)	526 ± 24	403 ± 53	432 ± 55	474 ± 29	98 ± 38 *	P < 0.001
Cpl,rs (ml/cmH2O)	0.55 ± 0.07	0.38 ± 0.07	0.46 ± 0.03	0.44 ± 0.03	0.28 ± 0.10	p = 0.125
W/D	5.77 ± 0.34	6.39 ± 0.40	6.24 ± 0.25	7.04 ± 0.45	11.54 ± 0.82*	p < 0.001
CT (HU)	-570 ± 10	-457 ± 63	-396 ± 52	-406 ± 63	-165 ± 112	p = 0.049

Conclusions: At 4 h, in an experimental model of healthy rats undergoing mechanical ventilation by changing the levels of DP and RR contribution within the same 4DP + RR, the group with the higher DP showed a lower Cpl,rs, lower oxygenation, higher lung edema, density and PMNs infiltrates as compared to the other groups. BAL PMNs seem to gradually increase over increasing levels of DP, while respiratory mechanics, lung weight and density seem to remain stable in the presence of a DP < 25. A higher DP seems a stronger contributor to VILI as compared to a higher RR despite keeping the same 4DP + RR.

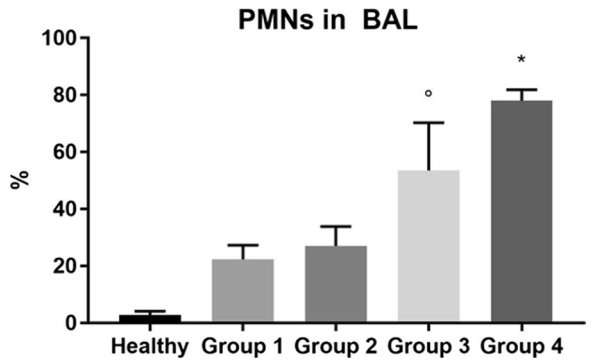

Figure (abstract 000954) PMNs in BAL after 4 h of MV. ANOVA p = 0.0005. *p < 0.05 vs Healthy, Group 1, Group 2. °p < 0.05 vs Healthy and Group 1. BAL = bronchoalveolar lavage; PMNs = polymorphonuclear cells

Introduction: Invasive mechanical ventilation is a commonly applied support in critically ill patients with acute56 respiratory failure. While often life–saving, it has the potential to induce lung injury, especially57 when too large tidal volumes (VT) are used in patients with existing lung injury, i.e., in patients with58 acute respiratory distress syndrome (ARDS). There is no consensus on whether ventilation with59 low VT prevents lung injury in patients at risk of ARDS.
Objectives: To determine whether a low tidal volume (VT) strategy is more effective than an intermediate VT strategy in preventing pulmonary complications in patients at risk of ARDS development.
Methods: A randomized clinical trial was conducted in invasively ventilated patients with a Lung Injury Prediction Score (LIPS) > 4 performed in the intensive care units of ten hospitals in Spain and one in the United States of America (USA) from November 3, 2014 till August 30, 2016. Patients were randomized to invasive ventilation using low VT (≤ 6 ml/kg predicted body weight, PBW) (N = 50) or intermediate VT (> 8 ml/kg PBW) (N = 48). The primary endpoint was development of ARDS during the first 7 days after start of invasive ventilation. Secondary endpoints included development of pneumonia and severe atelectases; length of Intensive Care Unit (ICU) and hospital stay; and ICU, hospital, 28– and 90–day mortality. For analysis of the primary endpoint, risk ratio and the 95% confidence intervals (CI) calculated with the Wald likelihood ratio approximation test and Fisher exact tests for hypothesis testing was used. Secondary binary outcomes, were also reported as risk ratio and 95% CI calculated with the Wald likelihood ratio approximation test and Fisher exact tests.
Results: In total, 98 patients [67.3% male], with a median age of 65.5 years [interquartile range 55–73], were enrolled until the study was prematurely stopped because of slow recruitment and loss of equipoise caused by recent study reports. At day 7, 5 (11.9%) patients in the low VT group, and 4 (9.1%) patients in the intermediate VT group had developed ARDS (risk ratio, 1.16 [95% CI, 0.62–2.17]; $P = 0.735$). The incidence of pneumonia and severe atelectasis was also not different between the two groups. Use of a low VT strategy did neither affect length of ICU and hospital stay nor mortality rates.
Conclusions: In patients at risk for ARDS, a low VT strategy did not result in a lower incidence of ARDS than an intermediate VT strategy.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000971

Introduction: Bronchoscopy-guided percutaneous dilatational tracheostomy (BG-PDT) is a routine procedure in the ICU setting. However, complication rate is about 4%[1] and due to low individual implementation rate, most medical registrars feel unexperienced. This was dramatically revealed in the COVID19 pandemic when BG- PDT was required in critically ill ICU patients under extreme conditions. Simulation training can be an effective tool to reduce the stress level of the proceduralist and to improve the procedural safety for the patient and the operating team.[2, 3] However, there is little data about the efficiency of simulation training in BG- PDT. Moreover, the role of conventional simulators (Csim) versus simulators generated from 3D printers (3Dsim) in simulation scenarios for airway approaches remains controversial.[4, 5].
Objectives: Aim of this study was to assess the efficiency of simulation training in BG-PDT regarding procedural performance and perceived feelings of safety of the proceduralist. Moreover, goal of this study was to assess whether 3Dsim vs Csim is more efficient in simulating BG-PDT.
Methods: TRAC-Sim-Study was conducted as a prospective, randomized, blinded single center cross-over study comparing Csim vs 3Dsim (see image 1) for simulation training of BG-PDT by doctors / medical students. All participants received a standardized theoretical training (30 min) and a questionnaire (previous implementation rate / perceived feeling of safety regarding BG-PDT). Participants were randomized to (a) Csim training (conventional tracheostomy simulator) or (b) 3Dsim training (models printed with PolyJet technology). Simulation training (20 min) was performed per standardized protocol. After simulation training, participants were assessed by 2 blinded examiners on a porcine tracheal model regarding (1) time required for completion of BG-PDT and (2) score achieved for correct performance. Moreover, participants received a second questionnaire (perceived benefit of simulation). Next, group (a) trained on simulator (b) and vice versa (cross-over design). This was followed by another blinded assessment on the porcine tracheal model/questionnaire (subjective evaluation of the 2 different simulators). The study was approved by the local Ethical Committee (22-1141_1).
Results: In this study, 44 participants (40 doctors, 4 medical students) were included: 24 participants initially trained with Csim and 20 participants with 3Dsim. There was no significant difference regarding sex, work experience (years), previous BG- PDT experience and perceived feelings of safety between both groups. Repetitive simulation training was able to significantly decrease mean procedural time ($p = 0.01$) and to increase procedural scores ($p = 0.03$) as well as experienced feelings of safety ($p = 0.01$) in the post- simulation assessments in both groups with no significant difference between the groups. No participants' preference could be revealed for any of the 2 simulator types.
Conclusions: Simulation training can be beneficial in improving procedural skills in BG-PDT and in reducing procedural stress by increasing perceived feelings of safety. This is independent of the choice of the simulator (Csim or 3Dsim) for training. Larger, randomized multicenter long-term studies are required to prove this effect. Whether the implementation of further improvements of 3Dsim according to participants´ feedback can improve efficiency of 3Dsim vs CSim remains to be investigated.

Introduction: Adulteration of illicit drugs of abuse is a well-known phenomenon that may expose consumers to unexpected adverse effects. During a 9-month period in 2021–2022 there was a large outbreak of a severe coagulopathy in northern Israel among users of synthetic cannabinoids adulterated with a long-acting anticoagulant, brodifacoum.
Objectives: Herein we describe the subgroup of patients who were admitted to the intensive care units (ICU) of the tertiary center (RMC) that cared for most of the patients affected.
Methods: We performed a retrospective cohort study based on data extracted from the Israeli National Poison Information Center database and the electronic medical patient records of patients admitted to our ICUs. Confiscated drug samples and blood samples obtained at admission in a subgroup of patients were tested for the presence of long-acting anticoagulants.
Results: We identified 98 patients affected by the outbreak. 47 patients were admitted to RMC, and 7 patients (15%) were admitted to one of 4 ICUs. All patients admitted to RMC ICUs had non-clotting blood on coagulation tests and their presenting complaint was overt bleeding in all, most commonly in the urinary (57%) and gastrointestinal tract (42%). Two patients presented with intracranial bleeding with intraventricular involvement. One required intraventricular drainage and the other died without intervention. One patient presented with pericardial bleeding and hemothorax requiring a chest drain. Three patients (42%) were mechanically ventilated, 2 patients devoloped hemorrhagic shock, and one patient died. Brodifacoum was detected in all available blood samples (median concentration, 201.0 ng/mL, IQR 105.0–335.9, range 19.1–1,117.8 ng/mL), and the drug samples contained both brodifacoum and the synthetic cannabinoid ADB-BUTINACA. All patients were treated by high-dose intravenous vitamin K1 and additionally by packed red blood cell transfusions, fresh frozen plasma, and/or 4-factor prothrombin complex concentrate when indicated. The most frequent vitamin K1 dose regimen was initially 20 mg intravenously every 8 h, and at discharge 20 mg orally three times daily.
Conclusions: Outbreaks of severe coagulopathies in users of synthetic cannabinoids adulterated with a long-acting anticoagulants continue to erupt in different regions of the world. Rapid recognition of an outbreak requires a high index of suspicion when confronting young, otherwise healthy subjects with otherwise unexplained severe coagulopathy. Severe cases may lead to intracranial hemorrhage, hemorrhagic shock and hemothorax and require ICU management and administration of high dose vitamin K1 and blood products.

Introduction: Early diagnosis of severe pneumonia and appropriate treatment is related to improved survival. The Film Array is a matrix in which the most common pathogens related to community and nosocomial pneumonia are analyzed through PCR. It has been shown to be a valid tool for early diagnosis, although its validity compared to culture (gold standard) is not yet well defined.
Objectives: -Explore the effectiveness of the Film Array as an early diagnostic tool for severe pneumonia versus conventional respiratory secretion culture (gold standard).
-Establish a cut-off point for a positive Film Array (cycles) and culture isolation.
Methods: A retrospective descriptive study was conducted based on lower respiratory tract cultures (BAS, BAL, CTT) obtained from patients with suspected pneumonia on mechanical ventilation who underwent respiratory Filmarray testing between January 2022-March 2023. The presence of legionella and pneumococcus antigenuria was also considered equivalent to positive culture.
Multiplex PCR (Filmarray® BioFire- A Biomérieux Company) was used for the Film Array.
The pneumonia criteria were based: Presence or progression of infiltrate reasonably excluding cardiac insufficiency or hypervolemia. Associated with at least one of the following variables: fever > 38 °C

without other origin, leukopenia (< 4,000/mm^3) or leukocytosis (≥ 12,000/mm^3), as well as at least one of the following variables: Purulent sputum, cough dyspnea or tachypnea, suggestive pulmonary auscultation and worsening gas exchange.
Results: A total of 74 samples were identified, of which 10 were discarded due to insufficient sample, exclusion of infection or dissociation between the Filmarray and culture samples. 64 samples were included for analysis, of which 24 (37.5%) were positive by culture. The Filmarray test was positive in 19 of the 24 culture-positive cases (79%) and in 6 of the 40 culture-negative cases (15%).
Equivalence between the microbiological results obtained by culture and the bacterial pathogens identified by the Filmarray was compared using a contingency table, evaluating positive and negative predictive values (Chi square p < 0.001, positive predictive value 76%, negative predictive value 87.2%, sensitivity 79.2%, and specificity 85%. Accuracy of 82.8%) as well as the Kappa index (Kappa 0.636, 95% CI 0.39–0.88).
The appearance of the germ in cultures was analyzed with respect to the cycles present in the Filmarray, evaluating the cutoff point for culture isolation. A cutoff point of 10^5 cycles was found for appearance on the culture plate (Significance of Montecarlo (bilateral) p 0.002; 99% CI 0.001–0.003).

Filmarray copies/ culture isolation

			Culture isolation		Total
			No	Yes	
Number of Filmarray cycles in 10^x	4	Count	7	1	8
	5	Count	2	5	7
	6	Count	0	1	1
	7	Count	2	12	14
Total		Count	11	19	30

Significance of Montecarlo (bilateral) 0.002 (IC 99% 0.001–0.003)

Conclusions: The Film array has proven to be a highly valid tool for early etiological diagnosis of severe bacterial pneumonia, with high equivalence to cultures. The germs that did not appear on the Filmarray were due to their absence in the matrix, mainly opportunistic, so its use in immunocompromised patients should be interpreted with caution.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):** 000975

Introduction: Complement overactivation has been documented in COVID-19 especially in critically ill patients (1) with C5b-9 terminal complement cascade component being a predictor of mortality and disease progression (2). CD59 is a complement regulatory protein which acts exclusively at the final step of the complement cascade by preventing C5b-9 formation and therefore cell lysis.
Objectives: To investigate CD59 expression in peripheral blood mononuclear cell (PBMCs) populations of critically ill COVID-19 patients by single cell RNA sequencing (SC-RNA Seq) analysis.
Methods: The study was approved by the "Evangelismos" Hospital Research Ethics Committee. PBMCs were isolated from COVID-19 patients with mild disease (mild, n = 4), severe disease (severe, n = 4), and critical disease (critical, n = 4) and processed for SC-RNA Seq immediately.
Results: A total of 61,022 single cells passed quality control and were used in the analysis. The mild group consisted of 22,570 sequenced single cells while the severe and critical groups consisted of 7,350 and 15,397 cells respectively. 13 distinct cell populations were identified including CD4 + T cells, CD8 + T cells, natural killer (NK) cells, CD14 + monocytes, CD14 + CD16 + monocytes, CD16 + monocytes, B cells, dendritic cells, hematopoietic stem cells, red blood cells, plasma cells, platelets and granulocytes. A trend of reduced CD59 expression levels in critically ill patients compared to severely ill was observed in the whole PBMC population. Specifically, an increase of CD59 expression was observed in severely ill patients compared to healthy controls and patients with mild COVID-19 followed by a reduction in critically ill. The increase in CD59 expression levels observed in severely ill patients was more profound in the dendritic cell population compared to monocyte, T cell and B cell population CD59 expression. Integrated analysis revealed the same trend of reduced CD59 expression in the monocyte, T cell and B-cell populations of critically ill patients.
Conclusions: Taken together the above observations point towards an inability to sustain increased levels of CD59 in COVID-19 critically ill patients. Failure to sustain increased CD59 expression levels may contribute to the increased C5b-9 levels observed in critically ill COVID-19 patients and prolonged complement overactivation.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000976

Introduction: Status epilepticus (SE) has been associated with significant morbidity and mortality but needs further study.
Objectives: This study evaluated the characteristics, management and outcomes of adult patients who had SE leading to ICU admission.
Methods: This was a retrospective study of consecutive patients aged ≥ 14 years who were admitted to the ICU in King Abdulaziz Medical City in Riyadh, Saudi Arabia between 2016 and 2021 because of SE. We described the characteristics, management, and outcomes of these patients. The Status Epilepticus Severity Score (STESS), which ranges between 0 and 6, is calculated from 4 clinical variables (age, level of consciousness, past history of seizures, and type of SE).
Results: During the study period, 115 patients were admitted to the ICU due to SE. Their median age was 38 years (interquartile range [IQR] 26, 59); 62.6% were males; and 59.1% were on prior antiepileptic therapy. At presentation, most patients (85.7%) had generalized tonic clonic seizures, the median Glasgow Coma Scale was 7 (IQR 3, 10) and the median STESS was 4 (IQR: 3, 4). Hypoglycemia (< 3.9 mmol/L) was present in 3 patients (2.6%), hyponatremia (< 120 mmol/L) in 1 (0.9%), hypocalcemia (< 1.9 mmol/L) in 20 (17.4%), hypomagnesemia (< 0.65 mmol/L) in 7 (6.1%), and hypophosphatemia (< 0.6 mmol/L) in 4 (3.5%). Brain CT showed acute/sub-acute stroke in 6 patients (5.2%), intracranial hemorrhage in 3 (2.6%), and brain tumor in 6 (5.2%). Lumbar puncture was performed in 41 patients with cerebrospinal fluid analysis showing high WBC in 8, high protein (> 0.4 g/L) in 22, positive bacterial culture in 2 and positive herpes simplex virus PCR in 2. Electroencephalography was performed for 93 patients. Most patients (80.0%) received lorazepam to abort seizures (median dose 3 mg [IQR 2, 6]). Intubation was needed in 87 patients (median duration of mechanical ventilation was 4 days [IQR 2, 10]). Tracheostomy was performed in 21 patients (18.3%). Five patients (3.5%) died in the ICU and 6 (5.2%) in the hospital. Poor outcome (discharge Glasgow Coma Scale < 14 or death) occurred in 36 patients (31.3%), with no difference pre- and post-COVID-19. On multivariable logistic regression analysis, chronic kidney disease (odds ratio: 10.4, 95% confidence interval: 1.2, 89.2) was a predictor of poor outcome. STESS and need for mechanical ventilation did not predict poor outcome.
Conclusions: Most patients admitted to the ICU due to SE were young; a minority had abnormalities in brain CT or cerebrospinal fluid and most needed mechanical ventilation. One in five patients required tracheostomy and one in 20 patients died in the hospital. STESS at presentation did not predict poor outcome.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000979

Introduction: On the 31st of January 2020, the World Health Organisation issued a declaration of a global health emergency (1); the pandemic that followed led to an unprecedented burden health care systems and especially intensive care units (ICUs) worldwide. This project was undertaken as part of a wider collaboration with the London Transformation Learning Collaborative (LTLC), commissioned by NHS England/Improvement and Health Education England to support the London region with information sharing and building resilience for the possible future demand for critical care(2).
Objectives: To gain an understanding of issues affecting health care workers in an our intensive care unit during the first wave of the COVID-19. This information was collected with the view of identifying common themes and as a secondary outcome, to derive possible strategies to manage in subsequent waves of the pandemic.

Methods: We performed a qualitative study using methodology akin to that of medical ethnography in a process of clinical engagement, data interrogation, innovation and recommendations (3,4). 36 interviews with health care workers in the multi-disciplinary team (MDT) in an ICU setting were carried out by 3 clinician researchers trained in qualitative data collection. These interviews were conducted face-to-face or virtually, depending on the participant's preferences. Data in the form of field notes was analysed in an inductive and deductive manner and then coded into pre-agreed sub-themes and themes. Our findings were then explored in focus groups with the stakeholders of the intensive care service, and recommendations generated after a process of discussion and collaboration.
Results: Our data analysis was completed using a modified thematic framework approach (5) and we followed the documented stages of the framework in a pragmatic way, in order to produce results in a timely manner, in order for recommendations to be put in to practice. Our thematic analysis revealed four broad categories as revealed from the interviews:
1) Communication.
2) Staffing.
3) Teaching and training.
4) Well-being and health.
The findings are summarised in fishbone diagrams in Figures 1–4 with each diagram showing cause and effects elicited from the interviews. Using this information gathered from the interviews, focus group meetings with senior representatives of the MDT took place, and we interrogated these themes using documented methods of innovative and divergent thinking to create recommendations for the department to implement.
Conclusions: Lessons from previous pandemic experiences have helped to inform our preparedness today, and we should leverage our learnings from current events to improve future responses. By carrying out qualitative research identifying these themes in a structured way, working practices can then be adapted to evolve with challenges presented to improve the working lives of the staff at the ICU during these trying times or indeed, improve our responses to similar major events.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000980

Introduction: The purpose of this was to clarify if outcomes have improved with time in intensive care unit (ICU) survivors treated for severe COVID-19, comparing first with second/third waves.

Methods: In this prospective single-center study, adult COVID-19 patients with respiratory distress admitted to two Swedish ICUs were included. Survivors from the first wave (1 March– 1 September 2020) were compared with survivors from the second/third waves (2 September 2020– 1 August 2021). Outcomes were differences in health-related quality of life (HRQL) and pulmonary function between waves. General linear regression and multivariable logistic regression were used to present mean score differences (MSD) and odds ratios (OR) with 95% confidence intervals (CI).
Results: Among the 456 (67%) critically ill COVID-19 patients who survived for at least 90 days after ICU discharge, 278 (61%) attended the follow-up approximately 6 months after ICU discharge. HRQL was similar between the groups, except that the second/third wave survivors scored higher in the role physical domain (MSD 20.2, 95%CI: 7.3–33.1) and lower on bodily pain (MSD 12.2, 95%CI: 3.6–20.8). On the other hand, first wave survivors had better diffusion capacity for carbon monoxide (DLCO) (OR 1.9, 95%CI: 1.1–3.5).
Conclusions: This study indicates that even though intensive care treatment strategies have changed with time, long-term HRQL and impaired respiratory health remain similar at 6 months for patients surviving severe COVID-19 in the first and second/third waves of the pandemic.

Patterns of pre-injury substance use in trauma ICU patients

S. Marks[1], J. Catlin[2]
[1]Medical Scientist Training Program, VCU School of Medicine, Richmond, United States of America; [2]Surgery, Virginia Commonwealth University, Richmond, United States of America
Correspondence: S. Marks
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000982

Introduction: Past studies have shown that trauma patients who have a positive blood or urine screen for drugs or alcohol experience differential treatment outcomes. These studies have largely focused on single substances in isolation and have not considered implications for clinical management of patients who have positive screens for multiple substances, particularly in the setting of critical illness. Little is known about patterns of multiple substance use and differences in patient and injury characteristics by the number of substances classes used.
Objectives: To identify the prevalence of polysubstance positive drug and alcohol screens, patterns of polysubstance use, and differences in patient characteristics by number of substances used among trauma ICU patients.
Methods: We used data from the American College of Surgeons' Trauma Quality Improvement Project from 2020 & 2021, a registry wiith data from over 750 hospitals. We included patients who were in the intensive care unit for three or more days and who received a drug and alcohol screen within 24 h of arrival; patients who tested positive only for substances administered as part of their care were considered to be negative for that substance. We classified substances as stimulants (amphetamine, cocaine, methamphetamine), sedatives (barbiturates, benzodiazepines), hallucinogens (ketamine, phencyclidine), opioids (methadone, opioid, oxycodone), cannabis and alcohol. We used descriptive statistics to examine the prevalence and relationships between different classes of substances and chi-square tests/ANOVA to examine difference in patient characteristics by number of substance classes.
Results: In total, 138,559 patients were included in the analysis dataset. In total, 54.5% (77,553) had positive drug and alcohol screens, with 26.2% (36,275) positive for cannabis, 20.6% (28,600) positive for alcohol, 19.2% (26,632) positive for stimulants, 9.2% (12,761) positive for depressants 6.6% (9,137) positive for opioids and 1.4% (1,990) positive for hallucinogens. Of those positive for at least one drug and/or alcohol (70,553), 40.3% (30,474) were positive for multiple classes of substances, including 15.5% (7,944) positive for three or more classes of substances. Patterns in polysubstance use is shown in Figure 1. Differences in patient characteristics by number of substances used are shown in Table 1.

Table 1 (abstract 000982) Patient and injury characteristics by number of substance classes used

	Positive for no substances	Positive for one class	Positive for two or more classes
Age (mean (95% CI))*	55.6 (55.4–55.7)	43.3 (43.1–43.4)	39.7 (39.5–39.9)
Gender (%)			
Male	66.1	77.1	80.0
Female	33.9	22.9	20.0
Previously diagnosed substance use disorder (%)*			
Yes	3.7	19.0	34.3
No	96.3	81.1	65.7
ISS (mean (95% CI))*	18.4 (18.3–18.5)	19.8 (19.7–20.0)	19.9 (19.8–20.1)

*$p < 0.05$

Conclusions: Among a national registry of trauma ICU patients, use of multiple substance classes was common; patients with positive screens for multiple substances were more likely to be younger and have a previously diagnosed substance use disorder. Greater research is needed to understand how the use of multiple substances may influence clinical trajectories and outcomes of critically ill trauma patients.

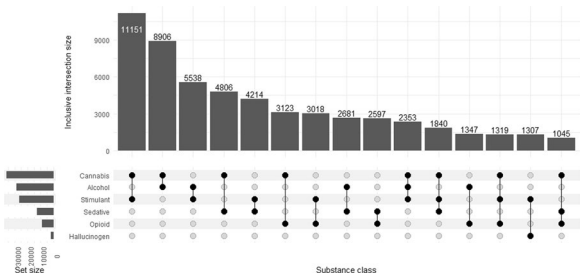

Figure 1 (abstract 000982) Patterns of substance use for patients using more than one class of substances

Detecting delirium in critically ill patients with automated EEG; a comparative study

S. Rai[1], M. Tanaka[1], H. Thomas[1], L. Mires[1], C. Gnanalingam[1], R. Sarkar[2]
[1]Intensive Care Medicine, Medway Maritime Hospital, Gillingham, United Kingdom; [2]Respiratory medicine and critical care, Medway Maritime Hospital, Gillingham, United Kingdom

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000984

Introduction: Delirium is a common and serious condition affecting acutely ill patients of all ages and backgrounds and is a manifestation of acute encephalopathy sustained by these patients. This can be of fluctuating nature, characterised by lack of awareness, attention and altered cognition and is often reversible with treatment of underlying cause. Patients experiencing delirium in the ICU have longer hospital stays, higher mortality rates, and greater long-term cognitive impairment. Despite this, delirium, particularly hypoactive delirium, remains underdiagnosed and undertreated. Different instruments, for example CAM-ICU, are widely used to diagnose delirium in ICU patients, but can lack sensitivity. There is an interest in utilising EEG based diagnosis of acute encephalopathy currently [1], but the feasibility of using this in busy ICU environment needs to be established in wider patient population.
Objectives: We aimed to measure acute encephalopathy with DeltaScan, an automated tool based on electroencephalopathy (EEG), identifying delta waves and comparing its performance to the widely used CAM-ICU tool.
Methods: We conducted a prospective study in our ICU, assessing patients with both DeltaScan and CAM-ICU. Patients who could comply with instructions for the tests were included if they did not have a pre-existing acute diagnosis involving the brain (e.g. stroke, epilepsy). In order to ensure consistency, a team made of four physicians including an advanced critical care practitioner performed CAM-ICU and DeltaScan and collected data, including demographics, length of stay, reason for admission. Within a possible range of scores of 1–5 in DeltaScan, a value between 3 and 5 are considered to be suggestive of acute encephalopathy, while a value of 1 or 2 signifies absence of it. We compared the tools' ability to detect abnormality suggestive of acute encephalopathy with or without clinically evident delirium and examined test duration for clinical feasibility.
Results: Both CAM-ICU and DeltaScan were simultaneously measured on 187 occasions for 145 patients. A total of 260 attempts were made for CAM-ICU and DeltaScan measurements. For reasons including patient wish and lack of availability, one or both the measurements were not possible on some occasions (Table 3). Median age of the cohort was 69 years, mean length of stay was 1 week and on average, it took 357 s to perform DeltaScan (Table 1). The prevalence of detecting acute encephalopathy with DeltaScan was 40% (n = 75) compared to detection of delirium by CAM-ICU at 14% (n = 26). Of the patients who were positive for acute encephalopathy with Delta Scan, 27% (n = 20) were also positive with CAM-ICU (Table). Of the 60% (n = 112) who did not have acute encephalopathy according to the DeltaScan, 5% (n = 6) were CAM-ICU positive. Physicians agreed with DeltaScan findings in 73% (n = 11) of cases in patients where the results between the 2 modalities were discordant.
Conclusions: In this study within a mixed ICU, it was possible to measure DeltaScan in patients with relative ease. There was concordance between DeltaScan and CAM-ICU in majority of patients. However, it appears that DeltaScan detected more patients with acute encephalopathy compared to number of patients being detected with delirium by CAM-ICU. It is possible that these additional patients have subclinical cerebral processes of milder encephalopathy that were not manifested by features of delirium. It may therefore be more sensitive in identifying acute encephalopathy. Furthermore, being an objective bedside test, this is less prone to inter or intra-observer variability that might be an issue with CAM-ICU. However, it remains to be proved whether this increased sensitivity equates to improved clinical outcomes in a cost-effective way and suitably designed trials need to be performed to address this issue before this new modality can be embraced as part of routine clinical care.

Table 1 (abstract 000984) Baseline charateristics of patients

Characteristics	Patients (no 145)
Age	Median: 69 years (Range: 25 - 87)
Sex Male Female	 76 (52%) 69 (48%)
Speciality Medical Surgical	 56 (39%) 89 (61%)
Emergency Elective	114 (79%) 31 (21%)
Average length of stay Range	7 days (1 to 79 days)

Table 2
Table 2 (abstract 000984) Contingency table for concordance between DeltaScan and CAM-ICU

		CAM –ICU		
		Positive	Negative	Total
DELTA	Positive	20	55	75
	Negative	6	106	112
	Total	26	161	187

Table 3 (abstract 000984) Feasibility of performing both modalities and reasons for missing observations with Delta scan and CAM-ICU

	CAM-ICU possible	CAM-ICU impossible	CAM-ICU - patient not available	CAM-ICU - patient refused
Delta possible	187	4	0	0
Delta impossible	8	18	0	0
Delta - patient not available	1	1	13	0
Delta - patient refused	2	2	0	24

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000985

Introduction: Intraoperative hypotension (IH) is a frequent phenomenon affecting a substantial number of patients undergoing general anesthesia and is related to significant perioperative complications including kidney failure, myocardial injury and even increased mortality. The Hypotension Prediction Index (HPI) algorithm is based on a machine learning systems with the complex analysis of arterial pressure waveform, which is able to inform the clinician of an upcoming hypotension event. There are several, both retrospective and prospective studies showing significant reduction of IH episode with the use of the HPI algorithm.
Objectives: The aim of the study was the comparison of the rate of perioperative hypotension in patients undergoing major abdominal surgery depending on the type of hemodynamic monitoring applied during anesthesia.
Methods: This single center retrospective study was performed in the Department of Anesthesiology and Intensive Therapy in the Poznan University of Medical Science Hospital in Poland. The analysis included 89 patients undergoing major abdominal surgery from October 2021 to November 2022 with invasive arterial pressure hemodynamic monitoring, using either the arterial pressure cardiac output (APCO) technology (FloTrac n = 61 patients) or the Hypotension Prediction Index algorithm (n = 28). The primary endpoint was the incidence and duration of hypotensive events defined as MAP < 65 mmHg evaluated by time-weighted average of hypotension.
Results: The median time-weighted average of hypotension in the FloTrac group was 0.31 mmHg versus 0.12 mmHg in the HPI group (p = 0.002). In the FloTrac group the average time of hypotension was 27,9 min (14,4% of total anesthesia time), while in the HPI group it was 11.4 min (4,4% of total anesthesia time) (p = 0.003). Finally, the average duration of each hypotensive event was 5 min in the FloTrac group compared to 3 min in the HPI group (p = 0.003).
Conclusions: The use of the HPI algorithm when compared to an arterial waveform analysis derived cardiac output alone allowed a substantial reduction in the incidence and duration of perioperative hypotension events in patients undergoing major abdominal surgery. This study provides further evidence on the possibilities of changing the perioperative hypotension management from treatment to prevention.

Intercostal Drain Insertion Training – A Pilot Quality Improvement Project at District General Hospital in Greater London

N. Vickery[1], S. Berhane[2], L. Grauslyte[2]
[1]Anaesthesia/Critical Care Medicine, Barts Health NHS Trust and CCPMRG, Queen Mary University, London, United Kingdom; [2]Critical Care Medicine, Barts NHS Trust, London, United Kingdom
Correspondence: N. Vickery
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000986

Introduction: Intercostal drain (ICD) insertion, Seldinger and surgical, is a well-established treatment modality for the management of pneumothoraces and pleural effusions. Delay in treating these conditions and incorrect procedure can lead to morbidity and mortality. (1, 2). In the United Kingdom, many doctors leave training without the ICD skills to practice independently. (3). Sim training has shown to improve confidence in skill attainment (4).
Whipps Cross University Hospital is a district general hospital in London with a 17 bedded intensive care unit. After a drain related incident, we decided to plan and institute a sim-based training intervention.

Objectives:

1. to improve the confidence and skills of ICD insertion, both Seldinger and surgical drains
2. to provide all trainees rotating through our critical care unit exposure to ICD insertion skills

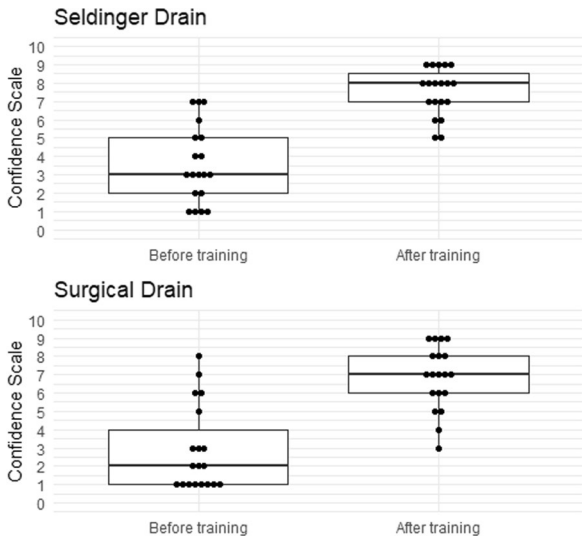
Methods: We invited all trainees to one of the multiple skills sessions, with numbers limited to eight persons per session. All participants were sent pre-course materials and they all filled out questionnaires before the course. Practical training consisted of an expert-led demonstration followed by expert-guided individual practise on part task trainers (5). Following the course, the participants filled out post-course anonymised self-reported confidence questionnaires (on a 0 – 10 scale, 10 being the most confident).
Results: We trained 19 junior doctors with grade and training experience shown in Table 1. Nine (47.37%) had had previous training.

Table 1 (abstract 000986) Showing previous training in ICDs

	Previous training in chest drain insertion		
Grade	**no n(%)**	**yes n(%)**	**Total**
core trainee	4 (21.05)	8 (42.11)	12 (63.16)
speciality trainee	3 (15.79)	1 (5.26)	4 (21.05)
senior trainee	3 (15.79)	0 (0)	3 (15.79)
Total	10 (52.63)	9 (47.37)	19 (100)

Most participants had no previous clinical experience of Seldinger (median 0, IQR 2) or surgical (median 0, IQR 0) ICD insertion.
Pre and post course confidences were represented in Figure 1, with an increase in confidence for all, with pre- to post- medians (IQR)

Seldinger increasing from 3(3) – 8 (1.5), and surgical 2 (3) – 7 (2). All 19 participants thought the teaching was helpful.
Conclusions: Reported experience and confidence with intercostal drain insertion is lacking. Our training showed an increased confidence in the procedures. Even without a well-defined relationship between self-reported confidence and competence it appears that simulation based skills sessions can be an adequate tool in improving the safety of ICD insertion and overall safety of care provision in district hospitals. A formal biannual training session is planned.



Graph 1 (abstract 000986) A box and whisker plot showing confidence improving after training

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000987

Introduction: Former critically ill patients and their relatives often experience Post Intensive Care Syndrome(-Family). Policies to promote family-centred care to improve family experience have been suggested in recent guidelines. Family participation in essential care may benefit both relatives and patients. Some studies have examined possible effects of standardised family participation programmes, though these effects are currently unclear.
Objectives: The aim of this study was to examine the effect of a programme for family participation in essential care in the ICU on relatives of ICU patients, focusing on satisfaction during ICU stay, and mental health symptoms, and ICU healthcare provider perceptions and experiences.
Methods: ICUs and their ICU healthcare providers from seven hospitals in the Netherlands participated from May 2021 until October 2022. Adult patients, and their relatives were included in the study when admitted to the ICU > 24 h and family participation in essential care was possible. A stepped wedge cluster randomised controlled trial was conducted. ICUs offered usual care in the control period. In the intervention period, after training ICU nurses on the family participation programme, relatives were invited to participate in essential care activities. A standardised menu to facilitate family participation in communication, amusement/distraction, comfort, personal care, breathing, mobilisation and nutrition was implemented. Data on relatives experience, satisfaction and mental health outcomes were collected through surveys at discharge and after three months. ICU healthcare providers completed questionnaires on their experiences.
Results: A total of 306 patient-relative pairs were included in the study. Relatives reported having participated in median 9 [IQR 2–17] of 34 possible activities after implementation of the programme. Data on satisfaction levels, anxiety scores, depression scores, and post-traumatic stress scores are currently analysed and will be available in October. ICU healthcare providers reported that a larger number of relatives knew how to participate in essential patient care: 47% in the intervention period versus 22% in the control period. They also reported that relatives had sufficient knowledge (41% versus 16% and skills (44% versus 25%) to apply family participation, odds ratios are currently calculated and will be available in October.
Conclusions: The effect on satisfaction scores and mental health symptoms in relatives after application of a standardised programme to facilitate family participation in essential care activities will be analysed and available in October. ICU healthcare providers reported increased clarity, knowledge and skills regarding family participation among relatives and ICU healthcare providers. Furthermore, performing a study during the covid-19 pandemic has yielded some unforeseen obstacles, e.g. changing visitation policies and experienced burden on ICU nurses, affecting possibilities for relatives to participate in care.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000988

Introduction: The clinical manifestations diversity of the post-COVID syndrome affects the quality of life of patients and reduces their functionality, making it difficult for them to return to their daily routine. The reduction of cognitive functions that is often observed in patients who had infected with SARS-CoV-2 virus is of particular interest.
Objectives: The main objective of this research is to investigate the SARS-CoV-2 virus impact on the quality of life and cognitive functions of patients with post-COVID syndrome; secondary aims included comparisons among groups and correlations of quality of life and cognitive function scores with clinical characteristics, vaccine coverage (complete, partial, or none), post-COVID symptoms, and comorbidities.
Methods: This is a retrospective study of patients followed-up in the "post-COVID" clinic at the Venizeleio General Hospital of Heraklion-Crete, Greece after being infected with COVID-19. The patients' quality of life was evaluated using the EQ-5D score (EQ-5D-5L, EQ-VAS)$_1$ and their cognitive function using the Mini Mental State Examination (MMSE)$_2$ within one to three months after illness. The EQ-5D is a general measure of quality of life that consists of two tools: a descriptive system (EQ-5D-5L) and a visual analogue scale (EQ-VAS). The MMSE is a widely used test of cognitive function that includes tests of orientation, attention, memory, language, and visual-spatial perceptions.
Results: Most (70.1–88.3%) of the enrolled patients (N = 250) reported post-COVID symptoms up to 8 months of re-evaluation. Patients with comorbidities (65.2%) had more severe illness and need for mechanical ventilation (50%). Abnormal EQ-VAS and EQ-5D-5L scores were independently associated with the presence of 1-month post-COVID symptoms. The EQ-VAS was lower in patients with serious or critical illness compared to those with moderate disease (69.2% vs. 80%, p = 0.001). The more severe quality of life symptoms, such as pain/discomfort, stress/distress, were reported by patients with comorbidities (Figure 1A) and females. Cognitive function problems (MMSE < 25) concerned orientation, concentration, recall, and language. Abnormal EQ-5D-5L, EQ-VAS (p < 0.003), and MMSE (r = -0.48, p < 0.001) correlated with prolonged LOS. Age (ROC 0.92 (0.83–0.99), p = 0.001) and severity of illness (ROC 0.758 (0.56–0.96), p = 0.031) could predict a pathological MMSE score among post-COVID patients (Figure 1B).
Conclusions: The presence of post-COVID symptoms, demographic characteristics, comorbidities, severity of illness, and prolonged length of stay are associated with poor quality of life and cognitive dysfunction following COVID-19 illness.

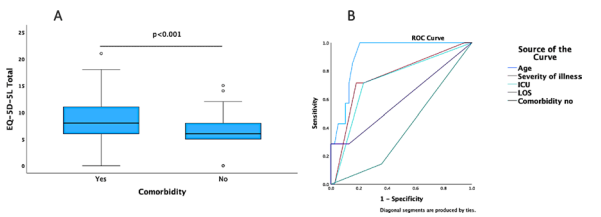

Figure (abstract 000988) 1. A. Poor quality of life (EQ-5D-5L total) for post-COVID patients with comorbidities; **B.** Old age and severity of illness are strong predictors of cognitive dysfunction after COVID-19 illness

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000989

Introduction: Tracheostomy is an invasive procedure conducted in ventilation weaning difficulties in intensive care units (ICU). Although it is a life saving measure, it is not risk-free. Therefore, follow up of tracheostomized patients is important to ensure a decent quality of life after discharge ICU.
Objectives: To describe the follow up and the aftermath of patients who were discharged from ICU with a tracheotomy.
Methods: We conducted a prospective observational study in the ICU of Zaghouan hospital, Tunisia between January 1st 2019 and Mars 31st 2023. Were included all patients who were discharged from ICU with tracheotomy and are followed up regularly (for at least 1 year) at the post ICU visit. Quality of life after ICU was evaluated based on need for oxygen therapy and/or resumption of normal activity.
Results: In the study period, 1240 patients were admitted in our unit, among them 531 needed invasive mechanical ventilation. Tracheostomy were indicated in 37 patients, 21 were discharged alive from ICU. Mean age was 56 [15–75 years]. Sex ratio was 2.5. Reasons for ICU admission were respectively trauma secondary to motor vehicular accident (n = 10), acute respiratory failure (n = 9) and coma (n = 2). Intubation was needed in the first day upon admission in most combine cases. Mean time for tracheostomy was day 15 after admission with IQR [12–23]. Mean reasons for tracheostomy were persistent coma (n = 9) followed by respiratory weaning difficulties from invasive mechanical ventilation (n = 6), tracheal stenosis (n = 4) and critical illness weakness (n = 2). Mean duration of ICU stay was 41 days [15–96]. Five patients were discharged with at home oxygen therapy, it was stopped in three cases at the time of consultation. Mean time for the first post ICU consultation was 4 weeks. One patient was discharged with at home mechanical ventilation. In the follow up three patients were deceased in a mean time of approximately 6 weeks. Death was due to massif hemorrhage complication of the tracheostomy site in two patients. Mean time for oxygen weaning was six weeks after ICU discharge. Long term complication related to tracheotomy was noted in one patient. It was a tracheal stenosis. Decannulation was conducted in nine patients with a mean time of 2 months after ICU discharge and IQR [1–11.75] months. It was carried out without complications after an otorhinolaryngological examination by nasofibroscopy. Six patients resumed normal every day activities, two still needed help from a third party and three patients did not resume a normal activity.
Conclusions: Tracheotomy is a solution for patients with weaning difficulties in ICU whether it is associated with a respiratory or neurological reason. Follow up is necessary to provide a good quality of life for this category of patients.

Topic: Acute respiratory failure and mechanical ventilation

Optimising capacity—coordination and management of critical care capacity—the Welsh approach

T. Hirst[1], M. Slattery[1]
[1]ACCTS Cymru, Emergency Medical Retrieval and Transfer Service (EMRTS Cymru), Cardiff, United Kingdom
Correspondence: T. Hirst
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000991

Introduction: Provision of critical care is a scarce and precious resource at a hospital, regional and national level. Centralisation of specialist care has inevitably resulted in need for interhospital tranfser of critically ill patients to access treatment, but movement between facilities to optimise capacity has traditionally been far less common in UK practice. During the COVID-19 pandemic, critical care networks were forced to move patients both within and between regions to optimise capacity at individual sites. In parallel, transfer of patients has moved from ad-hoc teams of local junior clinicians on unfamiliar vehicles, to dedicated transfer teams, now commissioned across the UK to ensure equity of critical care.
In Wales our Adult Critical Care Tranfser Service (ACCTS) provide 2 critical care tranfer teams as well as a dedicated transfer nurse practitioner to host a virtual daily meeting of all 13 critical care units nationally. By democratising data on capacity and staffing for all units, and facilitating direct communication between centres, tranfsers can be arranged in a timely and efficient fashion, allowing optimal patient flow through the network. Centres approaching safe capacity can easily identify sites with receiving capacity, saving valuable time and multiple conversations, and can directly interface with transfer clinicians to allow seamless transfer of care.
Methods: We describe the operation of our daily national critical care sitrep meeting, network capacity and associated interhospital transfer activity for our first commissioned year of operation.
Results: Attendence at the critical care sitrep meeting had a mean attendence of 9 units (69%) with a weekday mean attendence of 11 (85%). Individual unit attendence over the year ranged from 56 to 85%. Units spent a mean of 82 days at or above fully staffed capacity and a mean of 29 days at a level of activity utilising surge beds outside of critical care. During this time we facilitated 279 planned interfacility tranfsers, accounting for 52% of all interhospital transfer activity.
Conclusions: By combining reporting of critical care capacity across our network with coordination of critical care transfer in an innovative virtual meeting, we have reduced the steps to organising interfacility tranfser at a time of unprecedented critical care demand, allowing earlier and more frequent interhospital tranfser by our specialist service.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000992

Introduction: Respiratory tract colonization is common in critically ill patients. However, its epidemiology and prognostic value in patients with hematological / solid organ malignancies is poorly investigated.
Objectives: To describe the epidemiology of respiratory tract colonization with *Candida species* in patients with solid organ cancer or hematological malignancies and to assess its prognostic impact.
Methods: Retrospective study conducted in two intensive care units. All patients with solid organ / hematological malignancies admitted between 01.01.2021 and 31.12.2022 requiring mechanical ventilation for $\geq$ 48 h were included. We excluded patients considered for end-of-life care. Two groups were compared: patients who grew *Candida spp* in their endotracheal aspirates (Candida (+)) and those who had negative endotracheal cultures for *Candida spp* (Candida(-)).
Results: We included 131 patients. Mean agewas 59.6 $\pm$ 15 years. Mean SAPSII was 55.8 $\pm$ 20.3. Mean duration of mechanical ventilation was 19.4 $\pm$ 16 days. Eighteen (13,7%) patients had underlying hematological malignancies while 113 patients (86.3%) had solid organ cancer. Forty patients (30.5%) were on active chemotherapy and 7 patients (5.3%) were neutropenic on admission. Twenty patients (15.3%) grew *Candida species* from the respiratory tract (*Candida albicans* and *Candida tropicalis* in 9 patients each and *Candida Dubliniensis* in two patients). Mean ICU length-of-stay was 19.7 $\pm$ 17.8 days. 28-day mortality rate was 39.7%.
Baseline characteristics were comparable between both groups. The incidence of ventilator-acquired pneumonia was also similar (40 Vs 41.5%; p = 0.794 in Candida (+) and Candida (−) groups respectively). Candiduria was significantly more common in Candida (+) group (55% vs 26.1%; **p = 0.01**). Although bloodstream infection rate was comparable between Candida (+) and Candida (−) groups (35% Vs 26.3%; p = 0.195), the rate of candidemia was significantly higher in candida (+) group (25% Vs 7.2%; **p = 0.029**). The duration of mechanical ventilation and the length of stay in ICU was comparable between Candida (+) and Candida (−) groups (19.6 $\pm$ 11.4 vs 17.5 $\pm$ 20.8 days; p = 0.237 and 20.8 $\pm$ 15 vs 15.3 $\pm$ 20 days; p = 0.666). 28-day mortality rate was significantly higher in Candida (+) group (65% Vs 41.2%; **p = 0.024**).
Conclusions: Respiratory tract colonization is common in patients with underlying malignancies. It is associated with higher incidence of candidemia and higher 28-day mortality rate.

Correspondence: K.S. Kim
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000993

Introduction: Unintentional fall injuries are common in elderly population and cause significant morbidity and mortality worldwide.
Objectives: To identify factors associated with serious fall-related injuries and deaths.
Methods: EDISS (Emergency Department-based Injury Surveillance System) data of Korea Disease Control and Prevention Agency from 2015 to 2018 was retrospectively analyzed. Inclusion criteria were age $\geq$ 65 years old and fall injuries. Exclusion criteria were intentional injury and missing data. The serious injuries were defined as Injury Severity Score (ISS) over 15 or in-hospital deaths.
Results: A total of 81,768 unintentional fall injuries were observed during study period. Total admission rate, operation rate, intensive care unit admission rate, and mortality rate were 40.9%, 17.4%, 5.6%, and 1.6%, respectively. A total of 36,647 (44.8%) visits were classified as having serious injury. As a result of multivariate logistic regression

analysis, female sex (odds ratio [OR], 0.95; 95% confidence intervals [CI], 0.92–0.98), age group ($65 \leq$ Age < 75 [Reference]; $75 \leq$ Age < 85 [OR, 1.50; 95% CI, 1.45–1.54]; $85 \leq$ Age [OR 2.05; 95% CI, 1.96–2.14]), insurance status (National health insurance [Reference]; Medical aid [OR, 0.98; 95% CI, 0.93–1.03]; Uninsured [OR, 1.21; 95% CI, 1.07–1.35]), alcohol use (OR, 1.06; 95% CI, 1.00–1.13), and activities at the time of injury (Daily activity [Reference]; Leisure [OR, 0.94; 95% CI, 0.90–0.99]; Sports [OR, 0.62; 95% CI, 0.54–0.70]; Work [OR, 1.07; 95% CI, 0.99–1.15]; Housework [OR, 0.70; 95% CI, 0.67–0.73]; Others [OR, 1.42; 95% CI, 1.29–1.55] were independently associated with serious injury.
Conclusions: In Korean elderly population, 44% of unintentional fall injuries had serious injuries defined as ISS over 15 or in-hospital deaths. Male sex, old age, insurance status, alcohol use, and activities at the time of injury are associated with serious fall-related injuries and death. Based on these findings, active fall prevention interventions are warranted.

The effect of increased speech and language therapist staffing on patient centred outcomes following tracheostomy
R. Cherian[1], A. Mcmahon[2], A. Murphy[1], B. Marsh[1], R. Morris[1], B. Elgammal[2], S. Keilthy[1], B. Sam Cherian[1], E. Mckeon[1], N. O'leary[1], A. Flannery[1], S. Duggan[1]

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000995

Introduction: Tracheostomy is the commonest surgical procedure performed in intensive care units (ICUs). The majority are performed to facilitate prolonged ventilatory weaning[1]. Previous research focused on timing, morbidity, and mortality following tracheostomy. Recently, focus has shifted to patient centred outcomes including mobility, communication, and oral intake. These are outcomes that really matter to patients. We have already shown that around two thirds of our patients achieve these outcomes[2]. Tracheostomy patients benefit from multidisciplinary input, including Speech & Language Therapy (SLT). Recent evidence has suggested that centres that do not have ready access to such resources may not see the same benefits in their tracheostomy patients [3].
Objectives: To assess the impact of an uplift in SLT staffing on tracheostomy patient centred outcomes and mortality.
Methods: This a longitudinal observational retrospective single-centre study. Data was collected from November 2020 to July 2022. All consecutive patients undergoing tracheostomy for any indication within 1 year of SLT uplift in staffing from 0.5 full time equivalent (FTE) to 2.5 FTE were included.De-identified patient data was retrieved from existing SLT and Advanced Nurse Practitioner databases and the critical care electronic patient record (IntelliSpace Critical Care and Anaesthesia, Phillips). Information was collected on patient demographics, severity of illness as assessed by APACHE II score, ICU and hospital length of stay (LOS). In addition to mortality, the main outcomes assessed were timing of tracheostomy, time to non-invasive ventilation (NIV), to ventilatory free breathing (VFB), duration of sedation, mobility, and SLT specific patient centred outcomes; days to verbal communication via one way valve (OWV), whether patients required fibreoptic endoscopic evaluation of swallowing (FEES) and ultimately when they commenced oral intake. We compared outcomes for patients pre and post SLT uplift. Mortality data was compared using Chi-square testing. Non-parametric outcome data was compared using the Mann–Whitney U test. A two-tailed P value of < 0.05 for each test was used for statistical significance. Data was analysed using Microsoft Excel and Prism 9 GraphPad.
Results: 96 patients underwent tracheostomy; 43 pre SLT uplift and 53 post. 74% were male, the mean age was 61, and mean APACHE II score was 22. Comparing pre-uplift and post-uplift, ICU mortality was 14% vs 8% ($p < 0.01$), and hospital mortality was 16% vs 23% ($p < 0.01$). Following tracheostomy, days of sedation were reduced from 3 to 1 ($p < 0.01$). Days to decannulation were 20 vs 28.5 ($p = 0.45$). Stepdown to Level 2 care was 10 vs 12 days ($p = 0.64$), days to first NIV trial was 6 vs 2 ($p < 0.01$) and days to 24 h VFB was 16 vs 19 ($p = 0.8$). Days to cuff deflation was 11 vs 4 ($p < 0.01$), OWV was 6.5 vs 5.0 ($p < 0.01$). Days to FEES was 21 vs 12 ($p = 0.07$). Time to verbal communication via OWV was decreased from 7 to 4 days ($p < 0.01$). Days to commencing oral intake was reduced from 18 to 9.5 days ($p = 0.03$). Days to sitting out of bed was 9 vs 7 ($p < 0.06$) and days to standing was 15 vs 14.5 ($p = 0.85$).
Conclusions: An increase in SLT resources reduced the time required to attain patient centred outcomes. We noted earlier SLT assessment and improved access to FEES. Patients had earlier oral intake, less sedation post tracheostomy, earlier NIV and mobilisation and reduced time to restoration of speech.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000997

Introduction: Patients with severe preeclampsia without complications are admitted to the intensive care unit (ICU) for monitory during 24 to 48 h. However, an unexpected ICU prolonged stays has been present in the 25% of patients.
Objectives: The main of the present study is to assess the clinical characteristics of patients with severe preeclampsia who had a prolonged stay in the intensive care unit.
Methods: We retrospectively analyzed the patients admitted from January 2021 to December 2022 with diagnoses of severe preeclampsia, who did not meet the help syndrome criteria, without requiring vasopressor or ventilatory support. The clinical characteristics of the patients at ICU admission were analysed.

Results: During the study period, 185 patients were admitted in the intensive care unit, 88 patients met the inclusion criteria. 25% of the patients had a ICU stay for more than 48 h (average of 4.04 days). The age was 34.4 years, the Apache II severity score was 7.56 vs 6 of the patients with an expected stay. The history of hypertension and Diabetes Mellitus type 2 ware higher in the group of patients with prolonged stay (36 and 18%, respectively). Likewise, the use of intravenous vasodilators prior to admission to the ICU was higher (40%). The clinical criterials for a prolonged stay were inadequate blood pressure control (36%) and the development of HELP syndrome criteria (22%). No differences were found in Transnamians, Lactic Deshydrogens or renal function. There was no mortality.
Conclusions: At our institution, intensive care monitoring of patients with severe preeclampsia without complication criteria is less than 48 h. However, in our study, 25% of the patients had longer-than-expected stays, with a history of AHT and Dm, the use of vasodilators prior to ICU admission, and the APACHE II score being factors associated with unexpected prolonged stays.

Secondary peritonitis – can we de-escalate?
I. Cordeiro[1], M. Almeida[1], L. Cunha[1], A. Valente[1], P. Lavado[1], A. Baptista[1]
[1]Intensive Care Medicine Department, Serviço de Medicina Intensiva 2, Centro Hospitalar Universitário do Algarve – Unidade de Portimão, Portimão, Portugal

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000998

Introduction: Secondary peritonitis, the most common form of peritonitis, is one of the causes of sepsis in patients in intensive care units globally. It is defined as an acute peritoneal infection resulting from loss of integrity of the gastrointestinal tract. The gold-standart for the treatment consists in draining the septic focus and broad-spectrum antibiotics. Antimicrobial de-escalation is the discontinuation of one or more components of combination empirical therapy, and the change for a narrower spectrum antibiotic.
Objectives: This study aims to evaluate empiric antibiotic prescription in patients with the diagnostic of secondary peritonitis in an Intensive Care Unit in a distrital hospital.
Methods: We performed a retrospective study on patients with the diagnostic of secondary peritonitis admitted in our Intensive Care Unit from 1 January of 2021 until 31 December of 2022. We use SPSS, version 27. In the description of variables, frequencies and percentages were used in categorical variables, medians and quartiles, in continuous variables. The evaluation of the association of categorical variables was performed using the chi-square test, or Fisher's test, in case of non-compliance with Cochran's rules. The evaluation of the association of continuous variables was performed using the Mann–Whitney test, as they were compared between two groups. The significance level considered was 5%.
Results: The total number of patients suffering from secondary peritonitis during the 2 years was 69 with a prevalence of 0,069%. Among the patients enrolled 60% were male. The mean age was 70 y.o. In 71% of the patients the local of perfuration was above duodenojejunal flexure. The vast majority went to the operation room (n = 68) and 79% of cases peritoneal fluid was collected but only 68% had blood cultures collected. The most common isolated agent was *Escherichia Coli* which was present in 19 patients (27,5%). The antibiotic therapy most popular between our physicians was ceftriaxone and metronidazole (30,4%) followed by cefuroxime plus metronidazole. Antifungal was empirically prescribed in 10 patients, but only 2 had peritoneal cultures positive for fungus. Nevertheless, in the group that was not treated with antifungal, 11 patients had peritoneal cultures positive for fungus. Antibiotic de-escalation was possible in just 36% of patients based on cultures and sensitivity tests from the peritoneal fluid. The overall mortality in the ICU was 27,5%. The median number of agents isolated in the peritoneal fluid was 1 in the patients that survived but was 2 in the patients that died, with no statistical significance (p = 0.109). We identified a trend between the de-escalation of antibiotics and the lower number of agents isolated in peritoneal fluid (p = 0.086).
Conclusions: Secondary peritonitis is one of the most common fatal surgical emergencies. The mortality rate is about 20%, even in well equipped and trained environments. Although our study has some limitations, our data suggest that the broad-spectrum antibiotics are the best choice available. Our study also alert us about the incidence of peritoneal cultures positive for fungus. The decision to de-escalate antibiotic therapy remains for a selective group of patients with identified microorganisms and clinical improvement.

Improving the electronic documentation of daily reviews in intensive care to comply with the national standards of medical record keeping
G. Vellacott[1], T. Ali[2]
[1]Critical Care, Stoke Mandeville Hospital, Aylesbury, United Kingdom; [2]Anaesthetics and Critical Care, Stoke Mandeville Hospital, Aylesbury, United Kingdom.
Correspondence: G. Vellacott
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**000999

Introduction: Thorough and accurate documentation of the daily patient review is an integral component of intensive care practice. A high standard of documentation is crucial for clear communication between healthcare professionals, monitoring of patient progress, ensuring continuity of care as well as providing valuable evidence in legal settings. There are clear standards outlined by the General Medical Council (GMC) for which all medical record keeping should adhere to (1). The introduction of electronic patient records (EPRs) has become increasingly prevalent in intensive care units due to numerous proposed benefits over traditional paper-based record keeping including improving the clarity and quality of documentation, reducing potential errors and improving patient safety (2). However, despite the recent introduction of an electronic system to our intensive care unit (ICU), inaccuracies and incomplete documentation of the daily reviews persist.

Objectives:

1. To determine whether the documentation of daily reviews on a recently introduced EPR system adheres to national standards in an ICU in a District General Hospital (DGH).
    a) Specifically, to evaluate whether the daily review documentation includes both the name of the reviewing doctor and the time of the review as outlined by the GMC in Good Medical Practice (1).
2. Improve the documentation of the daily review

Methods: Anonymised data was collected retrospectively from EPRs over a 2-week period both pre and post intervention in a DGH ICU. The intervention involved a departmental teaching session on the standards of medical record keeping and using the new system, department-wide email with the results and regular prompting from the consultant body. Data were analysed using MS Excel. Chi-squared analysis was used for comparing both periods. $P < 0.005$ was deemed statistically significant.
Results: There were 230 and 233 daily reviews included in the pre and post-intervention periods, respectively. 59.13% (136/230) of daily reviews included both the name of the reviewing doctor and the time of the review in the pre-intervention period, compared to 77.25% (180/233) in the post-intervention period. This increase was statistically significant with $P < 0.005$.
Conclusions: These results demonstrate that the introduction of EPRs into our intensive care unit has not completely resolved the inaccuracies and incompleteness associated with traditional paper records. Further improvements are still needed to meet the desired standard of 100% in keeping with the GMC's recommendations. However, this has demonstrated that simple interventions such as raising awareness, senior-led direction and regular prompting led to significantly improved documentation which is necessary to improve communication amongst the multidisciplinary team, protect patient safety and negate medicolegal implications.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001001

Introduction: Continuous renal replacement therapy (CRRT) is a treatment for critically ill patients with acute kidney injury, with the aim of offering support to renal function for a long time, for which its efficacy must be monitored; FUN/BUN ratio, is the relationship between BUN of the effluent liquid and the blood BUN, with a normal value of 1.0 ± 0.2, which is suggested as a marker of adequate filter efficiency, determining it as an adequate marker to assess the removal of solutes and filter efficiency. Downtime, which is the percentage of time in which the CRRT process is not carried out effectively and entails a dose delivered less than that prescribed, ideally < 20% being an easily obtainable measure, at no extra cost, and could be considered more effective. To meet the goals of continuous renal replacement therapy, including recovery of renal function and optimization of supplies in places with limited resources. It is suggested that Downtime compared to FUN/BUN is equal or superior for monitoring the response to CRRT in critically ill patients.
Objectives: Compare the Downtime with the FUN/BUN for the response to the CRRT.
Methods: Ambispective, observational, longitudinal study. Through the review of records of patients who have been admitted to the ICU of Hospital Juárez de México from March 2022 to February 2023. Patients > 18 years in the ICU with CRRT requirement for > 24 h are included. The sample is not normal. Spearman's correlation were performed, to evaluate the efficacy of renal replacement therapy.
Results: 14 patients were identified, 8 women (57.2%), SOFA 15.07, APACHE II 28.01, SAPS II 59.7, mortality 43% (6), 87.1% (12) with sepsis, 57.1% (8) with a surgical component, 14.2% (2) neurocritical and 7.1% (1) autoimmune. Initiating continuous renal replacement therapy due to metabolic acidosis in 92.8% (13), hyperkalemia 35.7% (5), fluid overload 21.4% (3), associated with oliguria in 64.2% (9). With initial VEXUS at 1, IVC 1.9 cm, CVP 12.6 mmHg, uresis 0.26 ml/k/h, Renal resistive index (RRI) 0.71. A FUN/BUN ratio of 0.95 was found, Downtime of 7.6% equivalent to 110 min, in a range of 2 to 24%, maintaining an average transmembrane pressure of 75 mmHg, a filtration fraction of 12.6%; In the measurements at 24 h, urea excretion fraction of 36%, VEXUS 0.57, IVC 1.87 cm, uresis 0.24 ml/k/h, CVP 9.6 mmHg, RRI 0.69 and 0.70 are reported. Among the patients who recovered renal function, a total of 60 h was reported for said outcome and a total of 70.6 h for the withdrawal of the CRRT. In the correlation of FUN/BUN with Downtime, no significant difference ($p = 0.054$) was found to assess the efficacy of CRRT. We also found that absence of renal function recovery is associated with higher mortality ($p = 0.035$).
Conclusions: In our study, Downtime is not inferior to FUN/BUN for monitoring the efficacy of CRRT with respect to the response to CRRT.

Therapeutic removal of cfDNA/NETs with NucleoCapture® apheresis in a Prolonged Clinically Relevant Porcine Intensive Care Sepsis Model

A. Aswani[1], D. Genkin[2], K. Surkov[2], P. Skorup[3], R. Varsebroucq[4], M. Wargnies[4], J. Candiracci[4], M. Herzog[4], J. Micallef[4], M. Lipcsey[5]

Correspondence: A. Aswani
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001002

Introduction: Cell-free DNA (cfDNA)/Neutrophil Extracellular Traps (NETs) are associated with sepsis. We previously demonstrated that NucleoCapture® selective cfDNA/NETs apheresis improved organ function and survival in a 7-h model of porcine sepsis. We therefore investigated the use of NucleoCapture® in an extended 24-h clinically relevant porcine intensive care model of sepsis.
Methods: We induced sepsis in two pigs with a 2-h intravenous infusion of Pseudomonas aeruginosa. Antibiotics were administered at either 6 h or earlier if the norepinephrine requirement was greater than 0.1 mg/kg/min. One pig was subjected to NucleoCapture® apheresis using the Terumo Optia system with regional citrate anticoagulation for 8 h, followed by a further dose of antibiotics. A second NucleoCapture® treatment was then applied for another 8 h. The other pig was subjected to the same protocol with sham column apheresis. We measured cfDNA/NETs using the NuQ H3.1 nucleosome assay (Volition).
Results: The baseline levels of circulating cfDNA/NETs measured in the NucleoCapture® and sham treated pigs were 2.52 ng/ml and 1.64 ng/ml, respectively. Infusion of Pseudomonas aeruginosa resulted in an increase in cfDNA/NETs to 82.6 ng/ml and 87.4 ng/ml, respectively.
The level of cfDNA/NETs in the sham treated pig rose continuously during the experiment reaching 508.9 ng/ml. In contrast, NucleoCapture® treatment caused a sustained decrease in cfDNA/NET levels to 20.9 ng/ml by the end of the experiment (Figure 1).
The suppressed cfDNA/NETs level in the NucleoCapture® treated pig was consistent with the attenuation of septic shock as evidenced by a marked fourfold reduction in the total norepinephrine requirement: 3,725 µg vs 13,841 µg (Figure 2). The NucleoCapture® treated pig also produced more urine: 3,260ml vs 2,531ml.
Conclusions: In this extended 24 h clinically relevant model of porcine sepsis, which included the use of antibiotics and intensive care support, prolonged selective cfDNA/NETs apheresis with NucleoCapture® effectively removed cfDNA/NETs from the circulation and resulted in improved physiological indicators. We aim to progress the investigation of NucleoCapture® to clinical trials in sepsis and other indications.

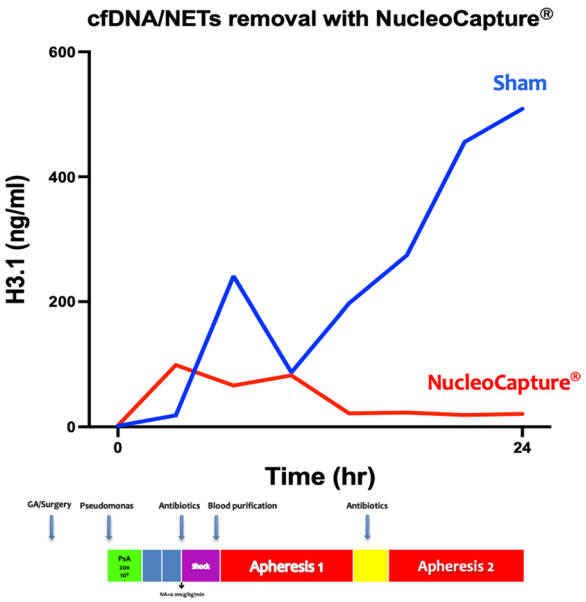

Figure 1 (abstract 001002) Plasma cfDNA/NETs levels in PsA challenged animals over 24h. The NucleoCapture treated animal (red line) showed consistently low levels of cfDNA/NETS as measured by the NuQ H3.1 assay (Volition) compared to the Sham treated animal (blue line)

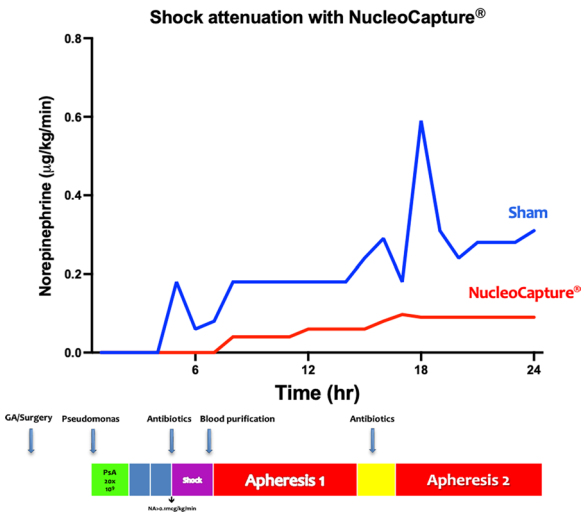

Figure 2 (abstract 001002) Shock attenuation with NucleoCapture. Hourly norepinephrine requirements (mcg/kg/min) are depicted for the NucleoCapture (red line) and Sham treated animals (blue line). The total norepinephrine requirement was 3,725 µg (NC) vs 13,841 µg (Sham)

Usefulness of high flow nasal cannulas (HFNC) in the Intensive Care Unit (ICU) in patients with mild to moderate Acute Respiratory Failure (ARF)

R. Carbajal-Serrano[1], A. Sanchez-Calzada[1], P. Mora-Ruiz[1], J. Aguirre Sánchez[1]
[1]Intensive care unit, The American British Cowdray Medical Center, City Mexico, Mexico
Correspondence: R. Carbajal-Serrano
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001007

Introduction: The (HFNC) have demonstrated their usefulness in various clinical scenarios, pulmonary and extrapulmonary pathologies. They provide a flow of up to 60 L/min. The potential benefits of this therapy are: improvement of the respiratory pattern with improvement of the RR and peripheral saturation, the Rox index (SpO2/FiO2)/RR has a high sensitivity to predict HFNC failure, greater than 4.88 at 12 h predict success of therapy**.**
Objectives: To evaluate the usefulness of HFNC in the ICU in patients with mild to moderate ARF.
Methods: Retrospective, observational study. Sociodemographic, clinical, and gasometric data were recorded. Inclusion criteria: both sexes, over 18 years of age, stay of more than 24 h, HFNC therapy for ARI. Exclusion criteria: severe ARF, under 18 years of age, without central venous catheter. ARF was classified as mild (SAFI > 200), moderate (100–200), the qualitative variables are reported in frequencies and percentages, normality tests were performed for quantitative variables, those of normal distribution were reported mean and SD, confidence intervals (CI). For variables of free distribution median and percentiles 25 and 75. For comparison of qualitative variables, X2 will be used, quantitative parametric variables t of student, a $p < 0.05$ as significant.
Results: 71 patients, 59% male (N = 42) and 41% female (n = 29), were analyzed. Mean age was 69 ± 12 (28–96 years), APACHE II mean 16 ± 6 (5–31), SAPS II mean 32 ± 13 (8–71), SOFA at admission 6 ± 3 (1–15), SOFA at the beginning of HFNC 4 ± 2 (1–10). 80% (n = 57) medical admission, 15% (n = 11) surgical; pulmonary pathology 59% (n = 42) and extrapulmonary 41% (n = 29), 60% (n = 43) type 1 insufficiency, 23% (n = 16) type 2. Most frequent site of pulmonary infection 42% (n = 30), abdominal 15% (n = 10). Ventilatory support before HFNC: 73% (n = 52) simple nasal prongs, 3% (n = 2) required IMV. Mean days of HFNC use of 4 ± 3 days, 42% (n = 30) with oncological pathology, most frequent colon cancer 23% (n = 7), days of stay in the ICU median 15 days (1–54) and mortality 19% (n = 14). The most frequent cause of death was septic shock of pulmonary and abdominal origin. At the time of initiation of HFNC therapy, a statistically significant difference was obtained with $p < 0.05$ in PH, PCO2, PO2, FiO2, RR, SaO2/FiO2 and central venous saturation, no statistically significant difference was obtained in peripheral oximetry.
Conclusions: The HFNC are useful in pathologies such as pneumonia, septic shock (pulmonary and abdominal) and oncology. Patients after the use of HFNC improved both hypoxemic and hypercapnic acute respiratory failure. The corrected blood gas changes were pH, PO2, PCO2, respiratory rate, and central venous saturation from the time of HFNC onset.

Table 1. Demographic characteristics of patients with high-flow nasal cannulas

Characteristics	n=71
Age	69 ± 12.5 (28-96)
Male	59 % (42)
SOFA income	6 ± 3 (1-15)
SOFA at start HFNC	4 ± 2 (1-10)
APACHE income	16 ± 6.4 (5-31)
SAPS II income	32 ± 13 (8-71)
Type of hospital admission	
Medico	80% (n=57)
Surgical	15% (n=11)

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001008

Introduction: About 25% of oncologic patients will require management in the Intensive Care Unit. Currently, survival is comparable with non-oncologic patients. Survival rates depend on the intensity and timing of interventions, including oncologic treatment (chemotherapy, immunotherapy, and radiotherapy), however, there is uncertainty in the safety of these interventions.
Objectives: To describe the safety of antitumor treatment in critically ill patients in an ICU of a high complexity cancer center in Bogotá.
Methods: Retrospective cohort of patients hospitalized in an oncologic ICU from July 2022 to January 2023. Relative and absolute frequencies were used to describe qualitative variables. For quantitative variables central tendency and dispersion measures were calculated. A bivariate analysis was performed with the calculation of a crude Odds Ratio (OR) for the variables related to sepsis and a multivariate analysis by logistic regression for the calculation of adjusted OR for sepsis and mortality.
Results: 105 patients were analyzed, 47.6% were female, the sample mean age was 60 years SD 15.7. The ratio of medical Vs surgical patients was nearly 1:1, 76.2% of the sample had solid tumors, 56.2% received chemotherapy, 10.5% immunotherapy and 2.9% received radiotherapy in the ICU. Thirty-one patients had sepsis, 30.5% presented with shock and 22.9% received mechanical ventilation. Mortality was 18.1%. In the bivariate analysis the factors associated to sepsis were medical patients, hematological tumor, chemotherapy, immunotherapy, mechanical ventilation and shock. The multivariate analysis showed that the only variable that kept its association with sepsis was medical patient OR 7.9 (95% CI 1.8-7.35). The analysis for mortality showed that medical patient and vasopressor use were the only variables with a role in said outcome. Table 1. Chemotherapy and immunotherapy were not associated with sepsis or mortality.

Table 1 (abstract 001008) Data distribution and adjusted odds ratio for sepsis in oncological patients

Variable	Cohort(105)	No sepsis (74)	Sepsis(31)	p- value	OR (CI 95%)	Adjusted OR for sepsis	Adjusted OR for mortality
Age*	60,3 ± 15,7	59,6 ± 16,1	61,8 ± 14,9	0,5			
Gender Female †	50 (47,6)	37(74)	13(26)	0,45			
Medical patient	52 (49,5)	25(48,1)	27(51,9)	0,0001	6,8(2,5–18,2)	7,9 1,8–7,35	17,8 3,2–98,3
Surgical patient	53 (50,5)	49(92,5)	4(7,5)				
Neutropenia	9(8,6)	4(44,4)	5(55,6)	0,07			
Solid tumor	80(76,2)	65(81,3)	15(18,8)				
Hematological	25 (23,8)	9(36)	16(64)	0,0001	3,4(1,9–5,8)		
SAPS III	58,4 ± 21,7	52,1 ± 19,6	58,4 ± 21,7	0,0001			
Type of oncologic treatment received in the ICU†							
chemotherapy	59(56,2)	36(61)	23(39)	0,016	3 (1,2–7,6)	1 0,2–4,0	0,32 0,06–1,5
Immunotherapy	11(10,5)	2(18,8)	9(81,8)	0,0001	14,7(2,9–73,2)	0,10,01–1,6	1,6 0,2–11,2
Radiotherapy	3(2,9)	2(66,7)	1(33,3)	0,88			
Organ dysfunction, supports and outcomes †							
Shock	32(30,5)	12(37,5)	20(62,5)	0,0001	9,3(3,5–24,5)		
Vasopressor	8(45,7)	29(60,4)	19(39,6)	0,03	2,4(1–5,8)		29,7 5,5–160,5
Inotropic	24(22,9)	11(45,8)	13(54,2)	0,003	4,1(1,5–10,7)		
M. ventilation	24(22,9)	10(41,7)	14(58,3)	0,0001	5,2(1,9–13,9)		
Length of stay*	4,3 ± 4	3,7 ± 2,6	5,7 ± 6,1	0,01			
Bacteremia†	15(14,3)	7(46,7)	8(53,3)	0,029	3,3(1–10,1)		
Mortality †	19(18,1)	6(31,6)	13(68,4)	0,0001			

* Mean ± standard deviation † Frequency (percentage).

Conclusions: Antitumor treatment was not associated in this cohort with sepsis or death in the ICU suggesting that it is a safe therapy to administer in critically ill patients with cancer that doesn't necessarily increase the risk of critical outcomes.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001010

Introduction: The rapid response team (RRT) has the role of early detection of patient liability and managing to prevent patient derangement. After screening the patient by RRT, unstable patients should be transferred to ICU and should be managed actively. Sometimes we can not transfer the patient to the ICU immediately, depending on many circumstances, such as the ICU capability.
Objectives: We observed the ICU mortality rate and 28 days mortality rate according to the time difference from RRT screening to ICU transfer (ICU transfer time).
Methods: We reviewed RRT cohort of Yonsei University Wonju Severance Christian Hospital from March 2022 to January 2023, and analyzed the data of patients transferred to MICU from the general ward. We compare the ICU mortality rate and 28 days mortality rate according to ICU transfer time.
Results: The total analyzed patient number was 260(149 were screened (RRTS), 111 were RRT non-screened (RRTNS). The ICU and 28 days mortality rates of total patients were 27.7% and 30.8%.
The ICU and 28 days mortality rates of RRTS and RRTNS groups were 26.8% vs 28.8%($P > 0.05$) and 30.9% vs 30.6%($P > 0.05$).
ICU mortality and 28 days mortality rates of patients transferred to ICU within the 5th hospital day were lower than after the 5th hospital day (25/121(20.7%) vs 47/139(33.8%), $P = 0.018$).
The median ICU transfer time was 9 h (0.5-24h). Seventy-one patients (52.3%) among 149 RRTS were transferred to MICU within 9 h after RRTS.
The ICU transfer times of ICU survivors and non-survivors were 8.4 ± 4.1 h vs 9.2 ± 4.1 h ($P > 0.05$) and the ICU transfer time of 28days survivors and non-survivors were 8.4 ± 4.0 days, 8.9 ± 4.2 days($P > 0.05$).
The ICU and 28 days mortality rates were lower in the shorter ICU transfer time group($\leq$ 9h) than longer ICU transfer time group(> 9h) [(24.4% vs 29.6%($p > 0.05$), 28.2% vs 33.8%, $P > 0.05$).
Conclusions: The shorter ICU Transfer time after RRT screening seemed to make lower ICU and 28 days mortality rates after ICU transfer.

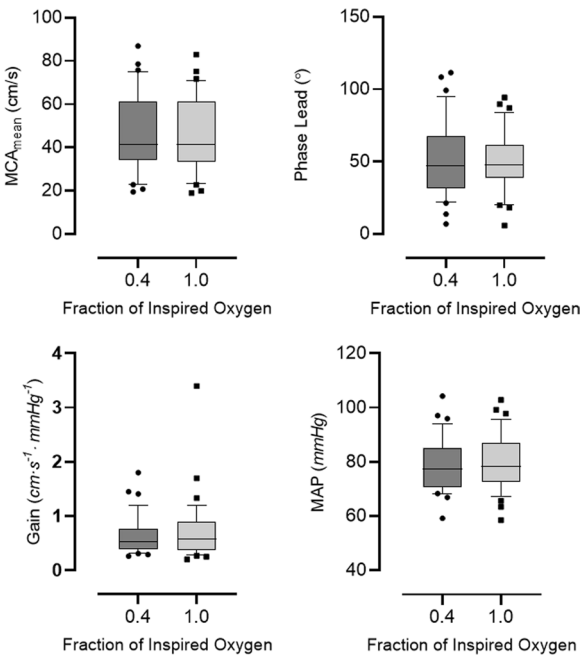
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001011

Introduction: Introduction: The recommendation of the World Health Organization to increase the intraoperative fraction of inspired oxygen (FiO2) to 0.8 throughout surgery has sparked much debate (1). Although meant to decrease the incidence of surgical site infections (SSI) (1–3), its safety is controversially discussed (4). Hyperoxia may be detrimental to the brain, as some studies have reported an association between hyperoxia and increased mortality in neurocritical care patients (5, 6). The effect of hyperoxia on cerebral hemodynamics during general anesthesia is still not fully elucidated. While hyperoxia leads to a small reduction in CBF in awake patients, it is unknown whether anesthetics could affect this relationship. Furthermore, there is circumstantial evidence that increased cerebrovascular tone leads to an improved cerebral autoregulation (CA) (7–9). Here, we quantified the effect of intra-operative hyperoxia (FiO2 of 1.0) compared to FiO2 0.4 on CBF and cerebral autoregulation (CA). We hypothesize that during hyperoxia and general anesthesia, CBF is lowered and dynamic CA improves.
Objectives: The aim of this study was to quantify the effect of intraoperative hyperoxia on CBF and CA during general anesthesia.
Methods: We studied ASA I/II patients undergoing non-cardiothoracic, non-neurosurgical and non-laparoscopic surgery under general anesthesia. During stable hemodynamic conditions, we increased FiO2 from 0.4 to 1.0. Mean middle cerebral artery blood velocity (MCA*V*mean) was measured to estimate changes in CBF. Dynamic CA was determined using transfer function analysis and expressed as the phase lead (°) between MAP and MCA*V*mean oscillations, created with positive pressure ventilation with a frequency of 6 min-1.
Results: Thirty-five patients were included for this study. Twelve patients received propofol-based anesthesia, and 23 patients received sevoflurane-based anesthesia. No statistically significant differences in cerebral hemodynamics were found between FiO2 0.4 and 1.0 during general anesthesia.
Conclusions: CBF and CA did not differ within patients in the presence of FiO2 0.4 and 1.0 during general anesthesia. Cerebrovascular changes induced by hyperoxia seem relatively small compared to changes already induced by anesthesia. However, because arterial oxygen content is increased, a beneficial effect is possible.



Box-plots of MCAVmean, phase lead, gain and MAP between FiO2 0.4 and 1.0. Data points outside the 10-90th percentile are displayed individually

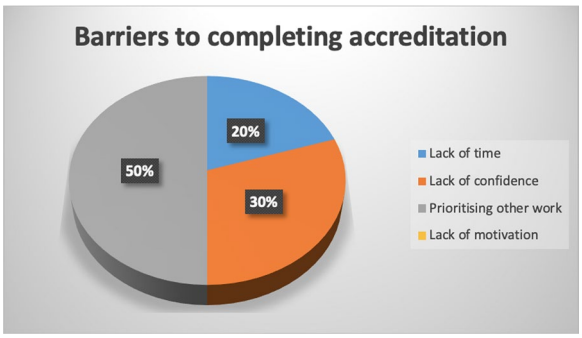
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001012

Introduction: In acute patient deterioration, point-of-care-ultrasound (POCUS) can inform early targeted management, potentially improving patient outcomes 1,2. Part of a wider project evaluating nurse-led POCUS in acute sepsis, here we describe the feasibility of POCUS training for nurse members of a critical care outreach team (CCOT) in a large teaching hospital.
Objectives: Among a sample of CCOT nurses:
1. To evaluate the feasibility of POCUS training.
2. To explore barriers and facilitators to POCUS training.
Methods: To gain POCUS accreditation, nurses were required to complete the UK Resus Council's Focused Echocardiography in Emergency Life Support (FEEL) course, consisting of a one-day taught course and 50 assessed echocardiogram scans. Feasibility was assessed as numbers achieving accreditation. An electronic survey explored barriers and facilitators to accreditation. Descriptive data are presented. Appropriate institutional approvals were obtained.
King's College Hospital is a large, 950 bed, multi-specialty, tertiary referral and teaching hospital. The CCOT provides 24/7 specialist support and stabilisation for the most unwell patients on the wards. The CCOT is multi-disciplinary consisting of critical care trained nurses and doctors and a consultant lead.
Results: A total of 10 nurses commenced the FEEL course: six in 2021 and four in 2022. All completed the taught one-day course. Amongst the 2021 cohort at 18 months, 3 nurses (50%) had completed 50 assessed scans and achieved full accreditation, 1 nurse (17%) is likely to achieve accreditation within 24 months, 1 nurse (17%) re-located and 1 nurse (17%) paused their studies due to personal reasons. Amongst the 2022 cohort at 6 months, 3 nurses (75%) had completed > 50% of scans, but none had achieved accreditation. Survey responses (n = 10) revealed that lack of confidence, prioritising other work, and general time constraint amongst nurses and assessors were the main barriers to training completion (Chart 1). Back-fill cover facilitated by charity funding, was a main facilitator as this reduced time constraints. All survey respondents reported that the FEEL course had improved their job satisfaction.
Conclusions: Training CCOT nurses in POCUS is feasible. The process required significant commitment from the nurses, supervisors and managers, and would not have been possible without a charity grant that allowed an additional nurse to back fill study time.



Legend on chart.

Mobilisation in the EveNing to TreAt delirium: a qualitative study of patient and staff perceptions on acceptability

E. King[1], O. Gustafson[1], D. Barghouthy[2], D. McWilliams[3]
[1]Oxford Allied Health Professions Research and Innovation Unit, John Radcliffe Hospital, Headington, United Kingdom; [2]Critical Care, University Hospitals Coventry & Warwickshire, Coventry, United Kingdom; [3]Centre for Care Excellence, University Hospital Coventry & Warwickshire, Coventry, United Kingdom
Correspondence: E. King
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001013

Introduction: Delirium is a common complication for patients admitted to intensive care units (ICUs) and is associated with an increase in

mortality and hospital length of stay, and poor long-term outcomes. [1,2]. Non-pharmacological interventions such as care bundles are recommended for the management of ICU acquired delirium [3]. However, evidence for specific interventions is lacking. We recently completed a feasibility trial to evaluate the impact of evening mobilisation (delivered between 7 and 9 pm) to improve sleep and reduce the incidence of delirium [4]. The provision of evening physiotherapy and mobilisation is not routine practice in the UK. Therefore, it is essential to establish its acceptability to both patients and staff.

Objectives: To explore the acceptability of patients receiving and staff delivering additional evening mobilisation in ICU.

Methods: A UK-based bi-centre qualitative study of patients recruited to the MENTAL trial. We purposively sampled patients who received the evening mobilisation intervention and staff who were involved in its delivery. Qualitative data was collected through semi-structured interviews which were audio-recorded and transcribed verbatim. The interviews were thematically analysed.

Results: We completed interviews with seven patients and nine staff members (three nurses and six physiotherapists). Four key themes were identified; balancing fatigue; spinning plates with time and care needs; normalising 24-h routines and late-night staffing. Whilst some logistical challenges and competing priorities were cited as barriers, positive feedback and the perceived benefits of evening mobilisation were identified from participants and staff. It was suggested that evening mobilisation could increase the amount of time that patients were active during the day, which may better reflect their usual daytime pattern and could increase their rehabilitation dosage. An interplay between physical and non-physical health promotion was also recognised through increased patient motivation and facilitating patient recovery in ICU.

Conclusions: Additional evening mobilisation in ICU was considered acceptable to both patients and staff. Benefits included increasing the patient's active day and supporting evening routines which might aid natural sleep. Staff suggested it could increase the rehabilitation dosage on ICU and could indicate an evolution of rehabilitation provision. These findings can be used to inform the design of interventions to reversible potential factors of ICU-acquired delirium.

Table 1. Patient and staff quotes.

Themes	Quotes
Balancing fatigue	'Some days it was good and some days I was too knackered..' (Patient one)
Spinning plates with time and care needs	'Seven and nine...we'll be doing our final writing, our shift reviews. (Staff four, nurse)
Normalising 24-hour routines	'....a better routine for them. So they won't routinely be in bed for four, five, six hours a day...' (Staff one, physio)
Late-night staffing	'There's quite a lot of operational challenges associated with deploying the intervention.' (Staff nine, physio)

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001014

Introduction: The evaluation of prognosis in patients (pts) with Acute Heart Failure (HF) is based on Ejection Fraction (EF), whereas Cardiac Output (CO), essential for organ perfusion, with relevant diagnostic, prognostic and therapeutic implications is not usually measured due to its complexity.

Objectives: The aim of this study was to evaluate in pts admitted to the Intensive Cardiac Care Unit patients (ICCU) the predictive value of left ventricular output tract velocity time integral (LVOT VTI) for a composite in-hospital outcome and to assess the accuracy of different markers of ventricular function in predicting the risk for adverse events.

Methods: We enrolled 446 consecutive pts admitted to the ICCU in Pertini Hospital of Rome and University Hospital of Pisa with diagnosis of Acute Heart Failure (AHF), Cardiogenic Shock (CS) and Acute Myocardial Infarction (AMI). We measured left ventricular dimension, LVOT VTI, left ventricular Ejection Fraction (LVEF) and we collected intra-hospital events as respiratory Failure (RF), Acute Kidney Injury (AKI), Multi-Organ Failure (MOF) and Death). We divided the population, according to the EF (> or < 40%) and into two groups respect the presence or not of intrahospital events.

Results: The group of pts who developed intra-hospital events (N: 254—57,1%) showed significant lower LVOT VTI value respect to control group [AKI (LVOT VTI $19,4 \pm 4,5$ vs $17,1 \pm 5,6$; $p < 0.001$), RF (LVOT VTI $18,6 \pm 4,9$vs $\pm 5,9$; $p < 0.001$), MOF (LVOT VTI $18,7 \pm 4,9$ vs $16,2 \pm 6,6$; $p = 0.006$) and Death (LVOT VTIO $18,6 \pm 4,9$ vs $15,8 \pm 6,8$; $p = 0.004$)]. Among the group of pts with EF > 40%, the mortality was higher according to LVOT VTI value (LVOT VTI > 10 cm 50%; in LVOT VTI 10–15 cm 7,5%, and in LVOT VTI > 15 cm 3,1%; $p < 0,001$).

Conclusions: LVOT VTI could represent an alternative and complementary method which satisfies the need for an effortless parameter in acute setting to predict intra-hospital events. We were able to measure LVOT VTI in all patients and it has proven to be a non-invasive tool, easily available and a reliable managing pathophysiological approach for critical patients. In a mare magnum of technologies, increasingly advanced and sophisticated, we tried to rediscover a simple and basic parameter that was useful in the management of critical patients. However, it needs to be tested in larger series of patients and multivariate adjustments for other prognostic predictors.

Incidence of early onset Group B Streptococcus sepsis in term neonates with second line prophylaxis of maternal intrapartum antibiotics: A multi-center retrospective study

J. M. Low[1], J. H. Lee[2], H. Foote[3], C. Hornik[4], R. Clark[5], R. Greenberg[6]
[1]Neonatology, NUHS, Singapore, Singapore; [2]Children's Intensive Care Unit, KK Women's and Children's Hospital, Singapore, Singapore; [3]Pediatric Cardiology, Duke University, Durham, United States of America; [4]Pediatric Critical Care Medicine, Duke University, Durham, United States of America; [5]Center for Research and Education, Pediatrix Medical Group, Sunrise, United States of America; [6]Neonatal-Perinatal Medicine, Duke University, Durham, United States of America
Correspondence: J.H. Lee
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001015

Introduction: Group B Streptococcus (GBS) is a major cause of neonatal infection. The difference in incidence of GBS early onset sepsis (EOS) in term neonates whose mothers receive first versus second-line intrapartum prophylaxis remains poorly described.
Objectives: To compare the incidence and outcomes of term neonates with GBS EOS whose mothers received first versus second-line intrapartum prophylaxis.
Methods: We queried the Pediatrix Medical Group Clinical Data Warehouse1 to evaluate the outcomes of term neonates born to GBS positive mothers between 1997 and 2020. Primary outcome was GBS EOS (i.e. < 7 days of life); secondary outcomes were maternal antibiogram and occurrence of neonatal morbidities. First line antibiotics were penicillin, ampicillin and ampicillin/sulbactam; others were considered second line. Data were summarized as count (percentage) and mean (standard deviation) for categorical and continuous variables, respectively. Multivariable logistic regression adjusting for maternal and infant factors was performed to calculate the risk of GBS EOS based on intrapartum prophylaxis received.
Results: Among 547,194 term neonates, 112,250 (20.5%) were born to GBS positive mothers. Out of these GBS positive mothers, 49,234 (43.8%) and 12,679 (11.3%) mothers received first-line and second-line intrapartum prophylaxis, respectively. 50,607 (45.0%) mothers had no or received unspecified antibiotic therapy. Maternal antibiotic usage for first line prophylaxis were 54%, 45% and 1% for penicillin, ampicillin and ampicillin/sulbactam, respectively. Commonly used antibiotics for second-line prophylaxis were cefazolin (46%), clindamycin (28%), and vancomycin (9%). Incidence of GBS EOS among all term neonates with maternal GBS carriage was 0.23% (263/112,520). Term infants whose mothers received second-line intrapartum antibiotics and unknown/no prophylaxis had higher risk of GBS EOS compared to first-line intrapartum antibiotics [adjusted odds ratio (aOR) 3.50 (95% confidence interval (CI) 1.43–8.54) and aOR 2.11 (95% CI 1.04–4.29) respectively]. There was no significant difference in the risk of GBS EOS in term infants born to mothers who received second line and unknown/no prophylaxis [aOR 0.60 (95% CI 0.28–1.32) compared to second line]. There was no difference in neonatal mortality, pressor or invasive ventilator use in first week of life across all groups.
Conclusions: There appears to be increased risk of GBS EOS with use of second-line compared to first-line maternal GBS prophylaxis. Notably, there was no significant difference in EOS GBS incidence between second line versus unknown/no treatment in mothers with GBS carriage. Future work needs to be carried out to delineate utility of second-line antibiotics in GBS prophylaxis.

Correspondence: B. Noè
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001016

Introduction: Traumatic brain injury (TBI) in pediatric population is a major cause of disability and death. The anatomical and physiological differences between adults and pediatrics may entail different presentations and important implications for the management and care of TBI.
Objectives: This study objective is to compare the intensity of treatment for intracranial pressure (ICP) among pediatrics, adults and elderly.
Methods: CENTER-TBI patients admitted to the Intensive Care Unit (ICU) and with ICP monitoring were included. Pediatric patients (< 18yrs) were compared with adults (18-65yrs) and elderly (> 65yrs). Clinical data considered for the analysis were ICP and daily Therapy Intensity Level (TIL) for each patient during the first week of ICU stay. A five-category scale was used for TIL classification [1]. Specific TIL variables were described in detail, focusing on neuromuscular blockade, metabolic suppression for ICP control, hypocapnia, hyperosmolar therapy and secondary decompressive craniectomy. Clinical variables were expressed by mean (standard deviation), or frequency (%).
Results: Among 2138 patients admitted to the ICU (132 pediatrics, 1480 adults, 526 elderly), we included patients with ICP monitoring who were not treated with primary decompressive craniectomy ($n = 814$; 6% pediatrics, 73% adults, 21% elderly). Fig*0.1 shows the daily TIL trend in patients from day 1 to day 7 of ICU stay. Pediatrics and adults showed an increase of intensity level of treatment during the first day in the ICU. High TIL (TIL3-4) were less performed in elderly, with low increase in frequency during the first week of ICU stay. Comparing specific levels of treatment, significative differences were found between pediatrics and elderly; similar trends were found comparing pediatrics with adults (Table 1).

Table 1 (abstract 001016) Differences in Theraphy Intensity Level among pediatrics, adults and elderly

	Pediatrics	Adults	Elderly	p
n	49	595	170	
Secondary DC (%)	4(8)	68(11)	16(9)	0.626
High dose of barbiturates or propofol (%)	12(24)	205(34)	36(21)	0.003
Neuromuscolarblockade (%)	19(38)	205(34)	31(18)	< 0.001

	Pediatrics	Adults	Elderly	p
Mild Hypocapnia (PaCO2 35–40 mmHg (%)	28(57)	321(53)	67(39)	0.003
Moderate Hypocapnia (PaCO2 30–35 mmHg) (%)	16(33)	149(25)	21(12)	0.001
Intensive Hypocapnia (PaCO2 < 30 mmHg) (%)	4(8.2)	43(7.2)	6(3.5)	0.202
Hyperosmolar theraphy with Mannitol up to 2 g/kg/24 h (%)	11(22.4)	122(20)	31(18)	0.743
Hypertonic saline up to 0.3 g/kg/24 h	17(34.7)	191(32)	38(22)	0.04

Conclusions: Children are less aggressively treated during the first day of ICU stay, reflecting a more conservative approach to therapy in this category. In the elderly, a TIL4 is less represented compared to adults and pediatrics, with no increase in trend of high TIL performed in ICU, probably refers to poor prognosis.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001017

Introduction: We conducted the EMPRESS randomised controlled trial to assess the feasibility of delivering a protocolised early rehabilitation in three ICUs in the UK. The study was open when delivery of clinical research was widely impacted by the COVID-19 pandemic. Protocol amendments enabled some trials to mitigate this impact, however significant modifications were not possible with the EMPRESS protocol (1) due to trial design and patient population. Our only amendment was to extend the duration of recruitment.
Objectives: To understand how the delivery of EMPRESS was impacted by the COVID-19 pandemic and explore mitigating strategies.
Methods: We used fortnightly video operational meetings between sites to evaluate progress of the study and to identify challenges. We proactively developed strategies to facilitate optimal delivery as the study and the pandemic progressed.

Results: EMPRESS was recruiting at two sites when all non-COVID research was suspended in respsonse to the pandemic. The trial was paused on 12th March 2020, just 10 days after the second site opened to recruitment. Recruitment to EMPRESS recommenced in August 2020. The third site opened to recruitment in October 2021 and approval of a study extension allowed recruitment at the second and third site until July 2022 as in Figure 1. Whilst the pause to recruitment spanned five months, the impact of the pandemic persisted for the duration of the study. Specific barriers impacting the study and mitigation strategies are described in Table 1.

Table 1 (abstract 001017) Barriers and mitigations to the delivery of EMPRESS following the pause to recruitment due to Covid-19

Barriers	Mitigations
Covid-specific research prioritised, preventing recruitment of otherwise eligible participants	Sought co-enrolment agreements as soon as possible
Study funded staff redeployment led to them embedding into the clinical team	Education of clinical colleagues on purpose of role and importance of protecting research time
Patients transferred to ICUs out of area	Follow up data obtained from summary care records
Patients transferred to other site recovery wards	Therapy assistant travelled to perform hospital discharge assessments
Patient restrictions or concerns attending hospital for three month follow up	Completion of PROMs over the telephone where possible
Advances in treatment of Covid-19 meant less patients were intubated and ventilated	NIHR and HRA approval of recruitment extension to allow for higher numbers of eligible patients to be admitted to ICUs
Government recommendations: lockdowns, shielding, self-isolation, mask wearing and social distancing, meant less incidence of common ICU admissions	
Site C R&D staff redeployed to covid-specific research	Proactive engagement of newly appointed EMPRESS project manager with Site C R&D department and Sponsor to overcome barriers to opening the site

Conclusions: Whilst we acknowledge there are often challenges and delays at many stages of research studies regardless of the pandemic, we have identified multiple COVID-specific limitations and recommend mitigating strategies, which may promote resilience in future clinical trial delivery.

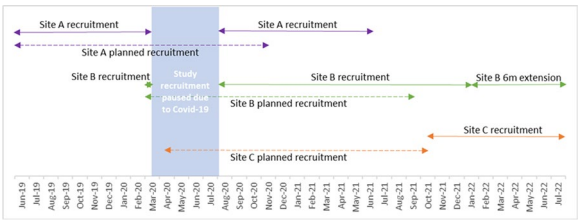

Figure 1 (abstract 001017) Contrast between actual and planned recruitment timelines at Sites A, B and C

Electromagnetic stimulation of the phrenic nerve to generate contraction of the diaphragm in anaesthetised and intubated patients with obesity – a proof-of-concept study

M. A. Verfuß[1], A. Panelli[1], H. G. Bartels[1], A. Grimm[1], S. Krause[2], J. Grunow[1], T. Niederhauser[2], S. Weber-Carstens[1], S. J. Schaller[1]

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001019

Introduction: Critically ill patients are at high risk to develop ventilator-induced diaphragm dysfunction (VIDD), leading to a deterioration of clinical outcomes, such as mortality and weaning success [1]. Diaphragm training by repetitive bilateral phrenic nerve stimulation in mechanically ventilated patients might prevent or ameliorate diaphragm atrophy or VIDD. The feasibility to generate diaphragm contractions via non-invasive electromagnetic phrenic nerve stimulation (NEPNS) was successfully demonstrated in normal-weight healthy anaesthetised patients [2]. However, as the effect decreased linearly with increasing distance to the phrenic nerve, it is uncertain whether the technique is feasible in obese patients as well.
Objectives: The aims of this analysis were to investigate (1) the time to find an adequate stimulation point and (2) the influence of positional changes of the stimulation coils using NEPNS in anaesthetised and intubated patients with obesity.
Methods: Five obese patients (Body Mass Index of ≥ 35) without severe general illness scheduled for elective surgery received bilateral NEPNS following induction of general anaesthesia and endotracheal intubation. For this purpose, coils intentionally designed for NEPNS were used. Time to achieve an adequate stimulation was measured. The position of the coils was changed in anterior–posterior and cranio-caudal direction in three 5 mm movements away from the initial stimulation point. Per position three stimulations were performed at 50% intensity and the tidal volume was documented by the ventilator.
Results: The time to find the adequate stimulation point of the phrenic nerve was 35 ± 30 s. The tidal volume declined with increasing coil distance from the initial stimulation point. (Absolute decline of tidal volume from 0 mm; mean ± standard deviation; anterior–posterior manoeuvre: -1.79 ± 1.06, -1.67 ± 0.96, -2.50 ± 0.31 ml/kg ideal body weight [IBW] per 5, 10 and 15 mm, respectively; cranio-caudal manoeuvre: -1.31 ± 1.68, -1.49 ± 1.66, -1.82 ± 0 ml/kg IBW per 5, 10 and 15 mm, respectively). There was a linear relationship between increasing distance in the anterior–posterior direction and decreasing tidal volume ($p = 0.011$, Figure 1A), whereas this could not be confirmed for the cranio-caudal direction ($p = 0.0504$; Figure 1B), most likely due to the limited number of measurements caused by the anatomical limitations (i.e., restricted neck size).
Conclusions: Finding an adequate stimulation point to perform NEPNS in obese patients was feasible within one minute. An anterior–posterior change of the stimulation point resulted in a linear decrease of the stimulated tidal volume, whereas in the cranio-caudal direction anatomical restrictions did not demonstrate such a relationship statistically.

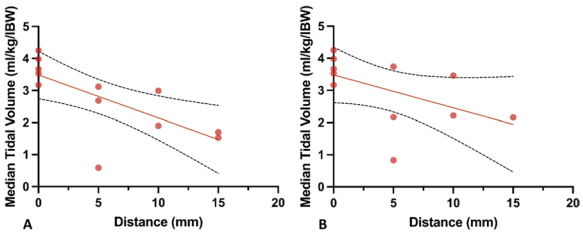

Figure 1 (abstract) Linear relationship between median tidal volume (ml/kg/IBW) induced by bilateral non-invasive electromagnetic phrenic nerve stimulation with increasing anterior–posterior distance (mm) (**A;** $r2 = 0.495$, $p = 0.011$) but not cranio-caudal distance (mm) (**B;** $r2 = 0.331$, $p = 0.0504$) to the initial stimulation point. Limited by anatomical restrictions, positional changes were feasible for anterior–posterior manoeuvres in $n = 3$, $n = 2$, $n = 2$ and for cranio-caudal manoeuvres in $n = 3$, $n = 3$, $n = 1$ patients per 5mm, 10mm and 15mm, respectively. IBW: Ideal Body Weight

Retrospective clinical study: computed tomography and inflammatory markers as outcome predictors in Covid-19 infection

F. Hohmann[1], F. Galdino[1], M. R. Kraft[1], S. Custodio[1], E. Paolinelli[1], G. Veiga[1], I. Machado[1], B. Bravim[1], J. Silva Jr[1]
[1]Department of Critical Care Medicine, Albert Einstein Israelita Hospital, São Paulo, Brazil
Correspondence: F. Hohmann
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001020

Introduction: It is known that Covid-19 has, at least initially, a nonspecific clinical course and that up to 17% of patients may require invasive mechanical ventilation (1). Chest computed tomography scans with ground-glass opacities and consolidations, as well as C-Reactive Protein (CRP), D-Dimer, Lactic Dehydrogenase, Ferritin and Interleukin-6 (IL-6) can be considered important tools in discriminating clinical worsening in patients with Covid-19 (2, 3, 4).
Objectives: To analyze whether lung tomographic changes as well as inflammatory markers may be associated with a higher risk of intubation in patients with Covid-19.
Methods: We performed a cohort study considering all COVID-19 patients consecutively admitted between March 2020 and December 2020 requiring supplemental oxygen. The primary outcome was the need for tracheal intubation. An adjusted regression model was used to assess the effect of changes in chest CT and inflammatory markers on the intubation outcome.
Results: A total of 250 patients were evaluated and 73.6% Covid-19 patients were intubated. Overall, the median to intubation time was 4 (2–7) days after hospital admission. Among all inflammatory markers, only higher IL-6 mensuration was associated to the need for intubation, 37.5 (16–102) vs 63 (25–172) difference 19 (95% CI, 6.0

to 36). When we assess pulmonary involvement on chest computed tomography, an involvement greater than 50% of the parenchyma corresponded to 60 (50.4%) patients intubated vs 11 (25%) non intubated. Adjusted intubation odds ratio to IL-6 was 1.002 (95% CI, 1.001 to 1.003) and pulmonary involvement > 50% was 2.42 (95% CI, 1.13 to 5.18).

Conclusions: Higher IL-6 (Figure 1) and pulmonary involvement in chest tomography greater than 50% (Figure 2) may be associated with higher risk of intubation in Covid-19 patients.

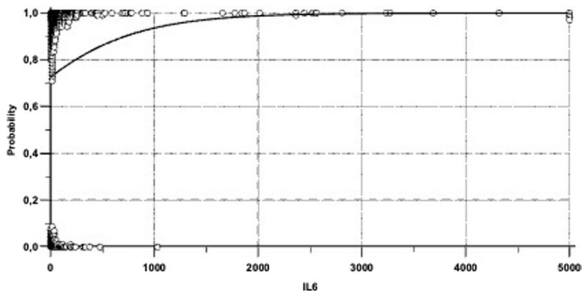

Figure 1 (abstract 001020) Odds Ratio for intubation vs IL-6

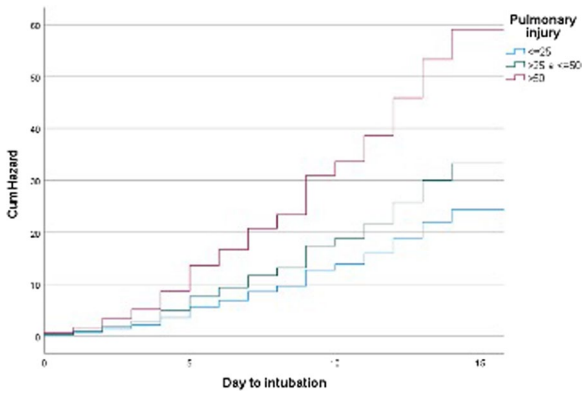

Figure 2 (abstract 001020) Kaplan–Meier curve demonstrating cumulative hazard at 16 days for intubation according to lung involvement ≤ 25%, > 25% and ≤ 50%, > 50%

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001021

Introduction: Providing an accurate prognosis in traumatic brain injury (TBI) patients is challenging. Besides clinical and radiological evaluation, serum biomarkers are promising to assess the severity of TBI. However, literature on biomarkers' prognostic and predictive value is limited, with scarce evidence on pediatric patients.

Objectives: This study aims to correlate the presence and the concentration of blood-based biomarkers in TBI with the severity of damage among age groups. The second aim is to associate biomarkers concentration with 6-month unfavorable neurological outcomes and mortality.

Methods: Patients from CENTER-TBI admitted to the ward or Intensive Care Unit (ICU) were included. Six admission biomarkers for each patient were considered for the analysis. We compared pediatrics (< 18y) to adults (18-65y) and elderly (> 65y), and age groups in pediatrics were compared (0-4y, 5-12y, 13-17y). The effect of the biomarker on outcomes was assessed by a logistic regression model adjusted for patients' characteristics at baseline (age, Glasgow Coma Scale, pupils' state, and Injury Severity Score).

Results: Among 3661 patients included, 1523 (95 pediatrics, 957 adults, 471 elderly) were admitted to the ward, and 2138 (132 pediatrics, 1480 adults, 526 elderly) were admitted to ICU. Fig*0.1 shows the distribution of biomarkers among ICU and non-ICU patients and age groups. Overall, ICU patients show a higher concentration of every biomarker detected compared to patients admitted to the ward, with a significant difference among age groups for NSE ($p < 0.001$), Neurofilaments light (NFL) (p 0.004), Glial Fibrillary Acid Protein (GFAP) ($p < 0.001$), and Ubiquitin Carboxyl-terminal Hydrolase isoenzyme L1 (UCH-L1) (p 0.007). Adults and elderly have a significative increased level of all serum biomarkers except for S100B. Increased neuron-specific Enolase (NSE) is the most represented biomarker in pediatrics, both in the ward and ICU ($p < 0.001$), even if its concentration is not associated with mortality or unfavorable neurological outcome. Unfavorable neurological outcomes (Glasgow Outcome Scale-Extended, GOSE ≤ 4) in ICU patients were associated with significantly higher levels of GFAP, UCH-L1 and, in pediatrics, Tau protein. Similar results are obtained considering 6-month mortality. In ICU pediatric patients, a lower level of UCH-L1 and GFAP are associated with a 6-month good recovery (GOSE ≥ 7). The model confirmed the association of UCH-L1 and NFL on 6-month unfavorable neurological outcomes and mortality in the overall population.

Conclusions: ICU patients show a higher release of all the serum biomarkers. UCH-L1 and NFL might play a role in predicting prognosis in TBI patients in ICU.

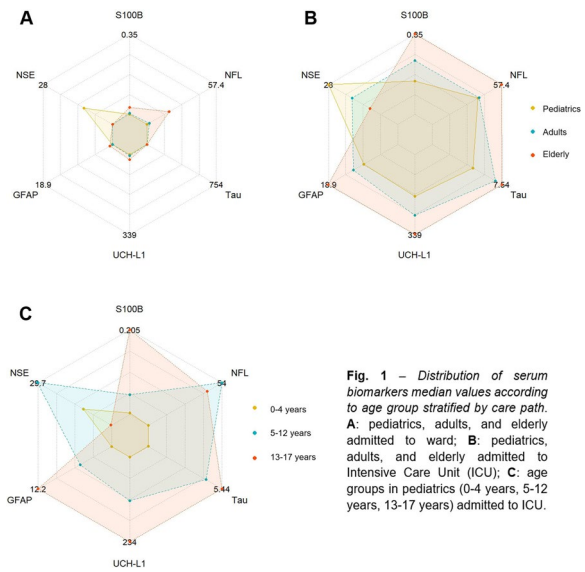

Fig. 1 – *Distribution of serum biomarkers median values according to age group stratified by care path*. **A**: pediatrics, adults, and elderly admitted to ward; **B**: pediatrics, adults, and elderly admitted to Intensive Care Unit (ICU); **C**: age groups in pediatrics (0-4 years, 5-12 years, 13-17 years) admitted to ICU.

Implementing a post-ICU follow-up protocol in a single-center university hospital in Portugal

R. F. Gomes[1], M. Sá Machado[1], M. Maneira Sousa[1], J. M. Ribeiro[1]
[1]Intensive Care Medicine Department and ECMO Referral Center, Centro Hospitalar Universitário Lisboa Norte, Lisboa, Portugal
Correspondence: R. F. Gomes
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001025

Introduction: Post-intensive care syndrome (PICS) affects up to 80% of intensive care unit (ICU) survivors, leading to reduced quality of life and increased consumption of health care resources. Current evidence supports the implementation of follow-up strategies, but there are no standardized recommended approaches, demanding the need for a personalized protocol for each country and center.
Objectives: To implement a multi-professional and multidisciplinary follow-up protocol in a single-center university hospital to identify patients at risk of developing PICS, prevent post-ICU morbidity, and improve the overall quality of life.
Methods: The ICU medical *staff* approved and implemented the protocol in October 2022, based on the *Society of Critical Care Medicine* recommendations and in recent single-center studies, using validated scores for the Portuguese population. Social and nutritional evaluations were also warranted. Inclusion criteria were defined as ICU length-of-stay > 5 days, highest SOFA score > 5 points, and average life expectancy > 6 months. The protocol is performed at five different time points: 1) ICU admission, 2) ICU discharge, 3) 2 weeks after ICU discharge, by phone call or in person if the patient remains hospitalized, 4) 2 months after ICU discharge, and 5) 4–6 months later, according to medical evaluation. The inclusion of other patients is allowed, according to an individual medical decision. Each time point has a standardized assessment (Figure 1), and referrals to other medical specialties are made whenever deemed necessary.
Results: A total of 34 patients were included from 27th October 2022 to 6th April 2023. 61.8% were males, the mean age was 50.2 ± 11.3 years-old, and the mean SAPS II was 44 ± 19 points. All patients underwent mechanical ventilation, 26.5% (n = 9) renal replacement therapy, and 14,7% (n = 5) ECMO. ICU-AW was diagnosed in 76.5% (n = 26) and cognitive deficit in 67.6% (n = 23), mainly in the patients who had delirium during ICU stay (23.5%, n = 8). A total of 21 patients were evaluated 2 weeks after ICU discharge (M1) and 11 patients at 2 months (M2). The preliminary data points to an improvement in physical (ICU-AW 18.8% at M2) and cognitive (cognitive deficit 18.2% at M2) impairments, probably reflecting the role of rehabilitation, monitored during the follow-up period. However, the incidence of positive screening for post-traumatic stress disorder increased from M1 (n = 7, 33.3%) to M2 (n = 5, 45.5%).
Conclusions: This personalized follow-up protocol is in constant update. Closer collaboration with psychiatry/psychology, the implementation of ICU diaries, and the overall management in an outpatient clinic are under evaluation. Further, we plan to develop a prospective study protocol to evaluate the impact of this approach on quality of life and physical, mental, cognitive, and nutritional outcomes.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001026

Introduction: Post-intensive care syndrome (PICS) affects critically ill patients and their families. Family PICS (PICS-F) can have a prevalence close to 50% and includes psychological disorders such as anxiety, depression, post-traumatic stress disorder (PTSD) and complicated grief. We report the preliminary results of a study that explored spiritual care at preventing PICS-F.
Objectives: To compare the effect of systematic and periodic spiritual care (SPSC) versus standard spiritual care (SSC), on the rate of psychological disorders associated with PICS-F.
Methods: Relatives of invasively ventilated patients without treatment limitations, admitted in the ICU of Complejo Asistencial Dr. Sótero del Río, Chile, were included. The study had a quasi-experimental design, with 2 groups and a follow-up of 3 months. Relatives recruited in the first group received the SSC provided by the hospital (chaplain assistance at request of the family). Relatives recruited in the second group received the study intervention (SPSC), that included telematic, transreligious, spiritual accompaniment (3 Zoom sessions), delivered by trained volunteers (1 volunteer/relative). The SPSC was given while the participants' loved ones were in the ICU. SSC and SPSC groups were evaluated via psychological tests (telephone interview), at the time of recruitment and after 3 months. The Hospital Anxiety and Depression Scale (HADS) was used to assess depressive symptoms and anxiety, and the Impact of Event Scale-Revised (IES-R) to assess PTSD. Socio-demographic variables of the participants and relevant clinical data from the patients were registered. Results are described using mean ± standard deviation (SD) and percentages, and are compared with Student's t-test and ANOVA. The study was approved by the hospital Institutional Review Board.
Results: 61 relatives were recruited in the SSC group and 51 in the SPSC group (1 relative/patient), between November 2021 and May 2022. Fifty relatives in the SSC group and 43 in the SPSC completed the 3-month evaluation. Most of the participants were women (79%), with a mean age of 47 ± 12 years, 51% had a formal employment and 21% had a previous history of mental health problems. The patients' mean age was 57.3 ± 16.6 years and 45% were women. The most frequent diagnoses for ICU admission were acute respiratory failure (40%), half of them due to COVID-19, and septic shock (23%). Participants of the SPSC group had a higher baseline score in the HADS anxiety subscale. No other differences in baseline characteristics were found, between relatives or patients.The IES-R score was significantly lower in the SPSC group compared to the SSC group at 3 months (Table 1). In each group the HADS scores decreased during the study period, without statistical significance. However, a significant difference over the 3 month-period was found in the IES-R score in the SPSC group (P value = 0,002).

Table 1 (abstract 001026) Results of the psychological tests at recruitment (baseline) and at 3 months

Psychological test	SSC baseline results (mean + SD)	SPSC baseline results (mean + SD)	P value (baseline comparison)	SSC 3months results (mean + SD)	SPSC 3months results (mean + SD)	P value (3months comparison)
HADS (anxiety subscale)	11.9 + 4.6	13.5 + 4.2	0.04	10.9 + 4.3	10.4 + 4.8	0.57
HADS (depressive symptoms subscale)	8.2 + 3.8	8.7 + 4.1	0.52	7.7 + 3.9	6.8 + 4.3	0.28
IES	45.1 + 15.3	44.1 + 15.1	0.69	46.1 + 15.2	38.2 + 20.5	0.03

The results are compared with Student's t-test.
HADS: A cutoff of 8 points in each subscale indicates a possible case of anxiety or depressive symptoms.
IES-R: A cutoff of 23 points suggests a case of moderate PTSD and cut-off of 43 a case of severe PTSD.
Conclusions: A SPSC intervention could decrease the rate of PTSD related to PICS-F.

Introduction: Following traumatic brain injury (TBI), coagulopathy upon hospital admission is found in about 25–35% of patients, with a wide range of 7 to 97% reported among series(1). The contributions of head injury and concomitant extracranial lesions to coagulopathy have been poorly investigated. We hypothesized that the risk of coagulopathy on hospital admission following TBI would increase with

increasing head injury severity, and to a greater extent with severe associated extra-head injuries as compared to no associated extra-head injury.

Objectives: To determine at hospital admission: 1/the incidence of post-TBI coagulopathy, according to the presence or absence of associated severe extracranial injuries, and 2/ the independent risk factors for post-TBI coagulopathy.

Methods: Observational study from a multicenter prospective French trauma registry (Traumabase®). All adult patients directly admitted to one of the participating centers from January 2012 to December 2021 following TBI (AIS (Abbreviated Injury score) head ≥ 1) were included. Post-TBI coagulopathy was defined by at least 1 of the following criteria: prothrombin ratio < 70% or platelets < 100 G/L or fibrinogenemia < 1.5 g/L on hospital admission. Severe associated extracranial lesions were defined by at least 1 of the AIS extra-head scores ≥ 3. To identify risk factors independently associated with admission coagulopathy, bivariate and multivariate analyses were performed.

Results: Among 33,875 patients admitted to 22 trauma centers, 9610 patients had TBI and were included in the analysis. The overall incidence of admission coagulopathy was 28.5%. Coagulopathic patients were significantly more severely injured (higher ISS, extracranial AIS, SAPS2, serum lactate, base excess) and especially more severely head-injured (lower prehospital GCS, higher AIShead and osmotherapy requirement), when compared to non-coagulopathic patients. Figures 1 and 2 show the relationship between admission coagulopathy and the severities of head and extra-head injuries. The higher the AIShead, the higher the proportion of patients exhibiting coagulopathy ($p < 0.001$), whatever the presence of extracranial lesions. When compared to patients with AIShead = 1, the increased incidence of coagulopathy with TBI severity was observed at an earlier stage of TBI severity when severe extracranial lesions were present (Figure 1). In multivariable analysis, severe extracranial injury was independently associated with the risk of post-TBI coagulopathy (OR 2.0 (1.8 – 2.3), $P < 0.001$) (Table 1).

Table 1 (abstract 001027) Risk factors independently associated to admission coagulopathy in TBI patients

Variable	OR (IC 0.95)	*P* value
Unstable pelvic trauma	2.2 (1.7–2.8)	< 0.001
AIS extrahead ≥ 3	**2.0 (1.8–2.3)**	**< 0.001**
Male	2.0 (1.7–2.3)	< 0.001
Gunshot	1.6 (1.1–2.5)	0.03
Osmotherapy	1.6 (1.3–1.9)	< 0.001
AIS head ≥ 3	**1.4 (1.2–1.6)**	**< 0.001**
Prehospital shock index ≥ 1	1.4 (1.2–1.6)	0.001
Vasopressors at admission	1.3 (1.1–1.5)	0.002
Open extremities trauma	1.3 (1.1–1.5)	0.005
Pupillary abnormality	1.3 (1.1–1.5)	0.012
Prehospital intubation	1.3 (1.1–1.6)	0.007
Serum lactate atadmission	1.2 (1.1–1.2)	< 0.001
Age	0.98 (0.97–0.99)	< 0.001

Conclusions: In the present study, a continuously graded association between the severity of head injury and coagulopathy at hospital admission was shown, and this increased incidence of coagulopathy was observed at earlier stage of TBI severity when severe extracranial lesions were present. The presence of severe extracranial injuries was one of the most important risk factors for coagulopathy following TBI.

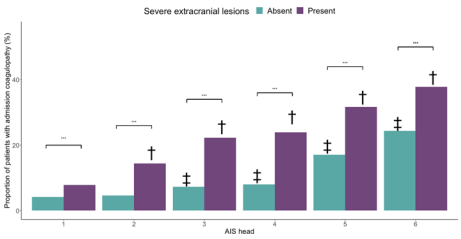

Figure 1 (abstract 001027) Incidence of coagulopathy on hospital admission according to the severity of TBI (assessed by AIShead) and the presence (purple) or absence (blue) of severe extracranial lesions. *** $P < 0.001$ severe extracranial lesions absent vs present. + $P < 0.001$ vs AIShead = 1 and severe extracranial lesions present. ± $P < 0.001$ vs AIShead = 1 and severe extracranial lesions absent

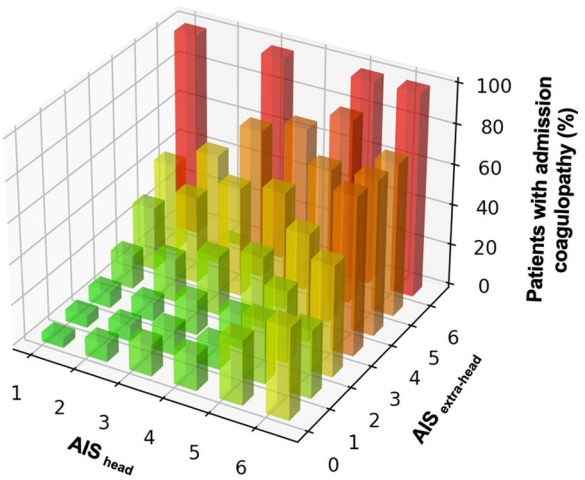

Figure 2 (abstract 001027) Relationship between admission coagulopathy and the severities of head (assessed by AIShead) and extra-head injuries (assessed by the maximum value of extracranial AIS)

Acute kidney injury in critically ill COVID-19 patients in Tyrol, Austria

T. Mayerhöfer[1], F. Perschinka[1], M. Joannidis[1]
[1]Division of Intensive Care and Emergency Medicine, Department of Internal Medicine, Medical University Innsbruck, Innsbruck, France

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001030

Introduction: Acute kidney injury (AKI) is frequently seen in critically ill COVID-19 patients and associated with increased mortality. Reports of the incidence of AKI in COVID-19 varied widely between different cohort studies and the Acute Disease Quality Initiative (ADQI) expressed the need for more detailed epidemiological data (1).

Objectives: The aim of this analysis was to investigate the incidence, outcome and risk factors of AKI in critically in COVID-19 patients in Tyrol, Austria.
Methods: This multicenter prospective registry study included all patients with a SARS-CoV-2 infection confirmed by polymerase chain reaction, who were treated in one of the 12 dedicated ICUs (from 8 hospitals in Tyrol, Austria) during the period from 1st February 2020 until 1st May 2022 of the COVID-19 pandemic. AKI was classified according to the Kidney Disease: Improving Global Outcomes (KDIGO) guidelines as increased serum creatinine or decreased urine output. Risk factors were evaluated with logistic regression analysis.
Results: In total, 1042 patients were included during the study period. The median age of the overall cohort was 66 years. Of the included patients, 244 (23.2%) developed AKI during the ICU stay. According to the KDIGO classification 7.8% had AKI stage 1, 5.0% AKI stage 2 and 11% AKI stage 3. Patients with AKI were older, had more often the pre-existing diagnosis of hypertension, cardiovascular disease, or a known renal comorbidity (Table 1). Compared to patients without AKI, patients with AKI had higher SOFA and SAPS-3 scores at admission and stayed significantly longer in the ICU (19 days vs. 9 days, $p < 0.001$) and in the hospital (28 days vs. 20 days, $p < 0.001$). In total 126 (12.3%) required renal replacement therapy (RRT) and the median duration was 9 (3–18) days. In patients with AKI the IMV rate was significantly higher with 88% (n = 227) compared to 41% (n = 312) in the no AKI group ($p < 0.001$). The most important risk factors for AKI were IMV (OR = 4.5 $p < 0.001$), age (OR = 1.01, $p = 0.013$), vasopressor use (OR = 3.13, $p < 0.001$) and renal comorbidities (OR = 2.17, $p < 0.001$) in a multivariable logistic regression analysis. Overall hospital and ICU mortality in our cohort were 26.4% and 23.1% respectively and significantly higher in the AKI group (Figure 1).

Table 1 (abstract 001030) Patient characteristics

	Overall	no AKI	AKI	*p value*
n	1042	761	267	
Sex = male/female (%)	710/332 (68.1/31.9)	507/254 (66.6/33.4)	193/74 (72.3/27.7)	0.088
Age (median [IQR])	66 [56 -75]	65 [54—74]	70 [59—78]	< 0.001
Hypertension (%)	600 (57.6)	406 (53.4)	186 (69.7)	< 0.001
Cardiovascular (%)	387 (37.1)	252 (33.1)	131 (49.1)	< 0.001
Renal comorbidities	197 (18.9)	110 (14.5)	83 (31.1)	< 0.001
SAPS III score (median [IQR])	53 [46—61]	51 [46—60]	58 [51—65]	< 0.001
IMV (%)	545 (52.4)	312 (41.0)	227 (85.0)	< 0.001
RRT (%)	126 (12.3)	16 (2.1)	110 (41.4)	< 0.001
ICU LOS (median days [IQR])	11 [5—22]	9 [4—17]	19 [10—33]	< 0.001
Hospital LOS (median days [IQR])	21 [13—36]	20 [13—32]	28 [15—47]	< 0.001
Death in ICU (%)	241 (23.1)	112 (14.7)	126 (47.2)	< 0.001
Death in Hospital (%)	275 (26.4)	131 (17.2)	139 (52.1)	< 0.001

Conclusions: As in non-COVID-19 patients AKI was associated with an increased mortality in critically ill COVID-19 patients in our cohort. Among known risk factors IMV has been an independent predictor for AKI in our analysis. Therefore, the prevention of invasive ventilation may be an important strategy in the reduction of AKI in critically ill COVID-19 patients.

End-tidal carbon dioxide monitoring during noninvasive ventilation in patients with acute respiratory failure due to cardiopulmonary edema: a pilot clinical study

M. Sakuraya[1], W. Iwata[1]
[1]Department of emergency and intensive care medicine, JA Hiroshima General Hospital, Hatsukaichi, Japan
Correspondence: M. Sakuraya
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001032

Introduction: In the previous study (shown in references), we demonstrated that the end-tidal partial pressure of carbon dioxide(PETCO2) can be used among patients undergoing noninvasive ventilation (NIV) to prevent postextubation respiratory failure. However, the usefulness of PETCO2 monitoring is unclear among patients with respiratory failure.
Objectives: This pilot study aimed to investigate the usefulness of PETCO2 monitoring during NIV among patients with acute respiratory failure due to cardiopulmonary edema.
Methods: Eight patients who underwent NIV for acute respiratory failure due to cardiopulmonary edema between October and December 2022 were included. We collected patient characteristics and following data up to 24 h or NIV separation, whichever shorter: NIV parameters (e.g., mode, settings, tidal volume, minute ventilation, PETCO2, and leakage), respiratory rate, blood pressure, heart rate, and blood gas analysis.
Results: Two patients were male, and median age (interquartile range) was 90 (74.5–92.5) years old. One patient had chronic obstructive

pulmonary disease (COPD) as a comorbidity. The ratio of arterial oxygen partial pressure to fractional inspired oxygen (P/F ratio), pH, arterial partial pressure of carbon dioxide (PCO2) and minute ventilation at a NIV initiation were 193 (133–293), 7.31 (7.29–7.37), 38.4 (35.2–41.4) mmHg, and 10.1 (8.0–17.3) L/min, respectively. All patients were managed at care units for critically ill patients and avoided intubation for worsening respiratory failure. Among 7 patients, excluding one patient with COPD, the difference between PCO2 and PETCO2 was 9.6 (6.9–11.2) mmHg at a NIV initiation. After starting NIV, we observed a decrease in the difference (4.9 [4.2–7.7] mmHg at 1–2 h and 2.7 [0.2–5.8] mmHg at 4–6 h). Meanwhile, the difference remained around 15 mmHg in the patient with COPD.

Conclusions: In patients with acute respiratory failure due to cardiopulmonary edema, the difference between PCO2 and PETCO2 was decreasing gradually with improvement in respiratory status after NIV was applied. However, the difference remained high in the patient with COPD.

Mortality in patients with chronic kidney disease admitted to the ICU of a county hospital

M. Salgado[1], A. Alonso[1], M. Cózar[1], A. Alvarez[1], A. Ubeda[1]
[1]Intensive care unit, hospital Punta de Europa, Algeciras, Spain
Correspondence: A. Ubeda
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001033

Introduction: The prevalence of chronic kidney disease is increasing. These patients have a higher risk of developing critical illness and also have a higher prevalence of comorbid disease that puts this population at higer risk for worse outcomes following ICU admission compared to the general population.

Objectives: To analyze factors associated to mortality in patients with Chronic kidney disease (CKD) admitted to the Intensive Care Unit (ICU) of the Hospital Universitario Punta de Europa.

Methods: Retrospective descriptive analysis on a prospective cohort performed in a 15-bed ICU from 2019 to 2022. Demographic outcomes, comorbidities, severity scores (APACHEII and SAPSII), treatment received, mechanical ventilation (MV), risk factors, ICU acquired infections, antibiotherapy, ICU and hospital length of stay (LOS) and mortality were collected. Statistical analysis: categorical variables (frequencies and percentages) and quantitative variables (mean and standard deviation or median and interquartile range). Comparisons: X2 test (percentages), Student's t test (means) and Mann–Whitney U test (medians). Multivariate logistic regression. Statistical significance at $p < 0.05$.

Results: 1470 patients were included: Patients with CKD (n = 183) vs. non-CKD (n = 1287) were compared: Male (57.9% vs. 66.5%, p = 0.027), age (71.7 [± 12.1] vs. 62.0 [± 15.4], p < 0.001). SAPS II (40 [30;52] vs. 27 [18;41], p < 0.001), APACHE II (16 [11;23] vs. 10 [6; 16], p < 0.001). GCS at admission (15 [11;15] vs. 15 [13;15], p < 0.001). Comorbidities: Diabetes mellitus (DM) (64.4% vs27.2%, p < 0.001); Immunosuppression (9.8% vs. 4.1%, p = 0.001); Chronic obstructive pulmonary disease (COPD) (15.3% vs. 7.6%, p = 0.001). Risk factors: Prior antimicrobial therapy (48 h) (36.6% vs. 28.7%, p = 0.036); Total parenteral nutrition (TPN) (25.1% vs. 14.6%, p < 0.001); Renal Replacement therapies (RRT) (20.7% vs. 5.9%, p < 0.001); central venous catheter (CVC) (74.8% vs. 59.4%, p < 0.001); Urinary catheter (UC) (88.5% vs. 68.9%, p < 0.001). Hospital-LOS(13 [7; 27] vs. 9 [5; 19]; p < 0.001). ICU-LOS (4 [2; 9] vs. 3 [2; 7], p = 0.010). Days of CVC (3 [0; 8] vs. 2 [0; 6], p = 0.006), first period of CVC (days)(3 [0; 7] vs. 2 [0; 5], p = 0.003). Days of UC (4 [2; 8] vs. 3 [0; 7], p < 0.001). Mortality (44.2% vs. 27.3%, p < 0.001).

Survivors (n = 102) vs. dead (n = 81) were compared: SAPS II (36 [26; 45] vs. 47 [32; 59], p < 0.001), APACHEII (13 [9; 20] vs. 18 [13; 25], p < 0.001). GCS at admission (15 [15; 15] vs. 15 [7; 15], p < 0.001). Comorbidities: COPD (9.8% vs. 22.2%, p = 0.034). Risk factors: Prior antimicrobial therapy (48h) (28.4% vs. 46.9%, p = 0.015), TPN (17.6% vs. 34.5%, p = 0.014), CVC (61.7% vs. 91.3%, p < 0.001), UC (81.3% vs. 97.5%, p < 0.001), MV (19.6% vs. 64.1%, p < 0.001), RRT (12.7% vs. 30.8%, p = 0.004). Tracheostomy (0% vs. 8.6%, p = 0.002). ICU-LOS (4 [2; 7] vs. 6 [2; 12], p = 0.018). Days of MV (0 [0; 0] vs. 1 [0; 7], p < 0.001), Duration of CVC: total (2 [0; 6] vs. 5 [1; 11], p < 0.001), 1st CVC period (2 [0; 5] vs. 5 [1; 9], p < 0.001). Days of UC (4 [2; 7] vs. 6 [2; 11], p = 0.006). Days of Arterial catheter (AC)(0 [0; 0] vs. 1 [0; 5], p < 0.001). Multivariate logistic regression: RRT (OR 2.45 [1.07–5.77], p < 0.036), MV (OR 4.98 [2.44–10.46], p < 0.001), SAPS II (OR 1.02 [1.00–1.05], p = 0.041).

Conclusions: ICU mortality in patients suffering from CKD was 44.2%. SAPS II score, the need for MV as also for RRT were observed as independent risk factors for mortality.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001034

Introduction: Acute respiratory distress syndrome (ARDS) is a common cause of hypoxemic acute respiratory failure (HARF). There are some emerging causes, such as viral pneumonia, specifically during the COVID-19 pandemic, that have increased the incidence of ARDS, which is now known as CARDS (COVID-associated ARDS). The pathophysiology of ARDS is very complex and not entirely understood since it involves numerous lung injuries and inflammation pathways. The most accepted definition of ARDS was the 2011 Berlin criteria. Although most of the patients with HARF included in high-flow nasal cannula (HFNC) treatment meet most of the Berlin criteria, it remains debated whether these patients can actually be designated as having ARDS. Amid the COVID-19 pandemic, it has been found that between 20–67% of patients with pneumonia and severe hypoxemia associated with SARS-CoV-2 infection develop ARDS. Our research group developed a study in 2017 with the aim of determining the existence of differences or similarities between mechanically ventilated (MV) patients and HFNC-treated patients. To do so, levels of epithelial, endothelial, and inflammatory plasma biomarkers were analyzed and no significant differences were found, supporting the idea that patients treated with HFNC, with HARF and bilateral radiologic infiltrates could be diagnosed with ARDS.

Objectives: The current project's main goal is to identify, in COVID patients with CARDS, differences between invasive and non-invasive respiratory support and to identify, comparing COVID and non-COVID-ARDS, differences between biomarker concentrations of systemic, epithelial and endothelial inflammation in order to find similarities in MV COVID patients and those treated with HFNC.

Methods: An unicenter prospective cohort study was performed during 3-year (2020–2022), recruiting patients admitted to a general ICU who met the Berlin definition for ARDS. Hypoxemic non-intubated patients ($PaO2/FiO2 \leq 300$ or pulseoximetry $SpO2/FiO2 \leq 315$) with bilateral radiographic opacities not fully explained by cardiac failure who were treated with HFNC were also included. Baseline-recorded data included demographic, comorbidities, and general respiratory and hemodynamic variables. Blood samples were collected 24 h after the onset. The biomarkers concentrations analyzed were systemic

inflammatory (interleukin-6 [IL-6] and interleukin-8 [IL-8]), epithelial (receptor for advanced glycationend products [RAGE] and surfactant protein D [SP-D]), and endothelial (angiopoietin-2 [Ang-2]). Baseline characteristics were matched based on age, sex, APACHE II, PaO2/FiO2 to compare biomarker plasma levels. The results of COVID patients were compared with non-COVID ARDS patients from the a previous project of our group. CEIC: 2020/9657.
Results: 135 patients with CARDS were enrolled. 22 patients needs MV at ARDS onset, whereas 113 where initially treated with HFNC. The MV group was older (72 vs 59;p < 0.001), with higher severity scores (APACHE II: 19.5 vs 13;p < 0.001 and SOFA: 7 vs 3;p < 0.001), worse PaFI (126 vs 156; p < 0.029) and worse outcomes as length of stay (19 vs 9;p < 0.001) and mortality (68.2% vs 12.4%;p < 0.001). After the performed matching by age, sex, PaFI and severity, 22 MV patients and 44 treated with HFNC were compared and no significant differences in biomarkers analyzed (RAGE, SP-D, Ang-2, IL-6 and IL-8) were found. In the HFNC matched group, 28(63.6%) patients needed to be intubated during their ICU stay (HFNC failure). Comparing biomarkers concentrations we found, in HFNC failure group, higher levelsof RAGE biomarker (5260 vs 1974;p = 0.001) and lower levels inIL-6 (403 vs 476;p = 0.041). We also identify that levels of RAGE ≥ 3338.5 pg/mL was an independent predictor of need of HFNC failure, even adjusted by severity (APACHE II and SOFA score) and IL-6 levels. Comparing COVID with non-COVID ARDS we found that patients with CARDS were older (68 vs 60;p < 0.001) and with better PaFi (141 vs 107;p = 0.003). About biomarker levels, RAGE (3591 vs 2394;p = 0.003) and IL-6 (315 vs 106;p < 0.001) were higher and SP-D (8.4 vs 13.6;p = 0.009) and Ang-2 (3359 vs 7075;p < 0.001) lower in COVID patients.
Conclusions: COVID patients with HARF treated with HFNC presented similar patterns of biomarkers of inflammation and injury to ARDS patients undergoing MV. This suggests that patients treated with HFNC could be considered ARDS patients also when infected with SARS-CoV-2.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001035

Introduction: Critically ill patients hospitalized at Intensive Care Units (ICU) are characterized by an accelerated muscle wasting, particularly of respiratory muscles, occurring early due to mechanical ventilation (MV). Although active muscle activation may prevent these alterations, it is usually not available at early stages of care because of sedation, favoring a vicious circle. Neuromuscular electrical stimulation (NMES) represents an alternative to achieve muscle contraction in this setting, being able to prevent local muscle wasting, and according to some reports, has the potential to shorten MV time, suggesting a systemic effect through myokines, a diverse range of chemokines secreted by myocytes during contraction. However, no studies have evaluated whether NMES applied to peripheral muscles in critically ill patients can exert distant muscle effects over the diaphragm, and if such effects are associated to changes in myokine concentrations.
Objectives: To determine the effects of NMES on myokine plasmatic concentrations, and on peripheral and respiratory muscle function and structure, in mechanical ventilated ICU patients when initiated at an early phase of their critical illness.
Methods: Exploratory randomized controlled trial of NMES applied twice a day, for 3 days, in comparison to standard care. For myokine characterization (IL-6, BDNF, Myostatin and Decorin), blood samples were obtained at baseline (T0), at the end of NMES session (T1), and 2 and 6 h later (T2 and T6). This sampling was repeated on days 1 and 3. For the control group (CG) blood were obtained only at T0 and T6. Muscle characterization [ultrasonography of quadriceps muscle layer thickness (MLT), and diaphragmatic thickening fraction (TFdi), along with tracheal tube pressure derived from phrenic nerve magnetic stimulation (Ptr,tw), for diaphragmatic function] were performed at days 1 and 3 (T0 and T6 respectively).
Results: 11 patients were randomized: 6 to CG and 5 to NMES. No differences were observed between groups at baseline [Median of 57 and 64 years old for CG and NMES, respectively (p-value of 0.57); median Body Mass Index of 26.5 and 24.8 kg/m2 for CG and NMES, respectively (p-value of 0.79); median of 48 h of MV for both groups (p-value of 0.29); and a median APACHE II score of 27.5 and 27, respectively (p-value of 0.89]. The median quadriceps MLT of CG decreased 27% from day 1 to day 3 [from 1.78 cm (1.3–2.7) at day 1, to 1.3 cm (1.1–2.4) at day 3, with a p-value < 0.01], while no significant change was observed in the NMES group, which experienced a 13% decrease in MLT from day 1 to day 3 [1.7 cm (1.3–2.3) at day 1, to 1.5 cm (1.1–2.3) at day 3, with a p-value < 0.06], (Figure 1). With regard to TFdi, no significant change was found between days 1 and 3 for either the CG or NMES group (p-value of 0.06 and 0.31 respectively). Interestingly, the NMES group exhibited a slight increase in TFdi (from a median of 19.5% to 22%), while the CG showed a slight decrease (from a median of 25.2% to 15%). For Ptr,tw a median decrease of 1.73 cmH20 from day 1 to 3 was observed in the CG (p-value of 0.03), with no significant change in the NMES group (p-value = 0.19) (Figure 2). There was no significant difference between NMES and CG at either day 1 or day 3 for MLT (p-value of 0.66 and 0.83, respectively), TFdi (p-value of 0.52 for both days), or Ptr,tw (p-value of 0.25 and 0.9,respectively). Regarding myokine's plasmatic concentrations, there were no significant differences between NMES group and CG at any time point, or within either group (p-value of 0.92 and 0.62 for Decorin in the NMES and CG, respectively; p-value of 0.92 and 0.41 for Myostatin in the NMES and CG, respectively; p-value of 0.71 and 0.92 for IL-6 in the NMES and CG, respectively; and a p-value of 0.33 and 0.13 for BDNF in the NMES and CG, respectively).
Conclusions: Preliminary results from this exploratory randomized study, showed a peripheral muscle preservation, indicated by an amelioration of quadriceps MLT decrease, as well as improved diaphragm function (significative increase of Ptr, Tw) in the NMES group. No significative change was found regarding myokines in response to NMES. However, more data are needed from a larger number of patients to establish a more clear conclusion.

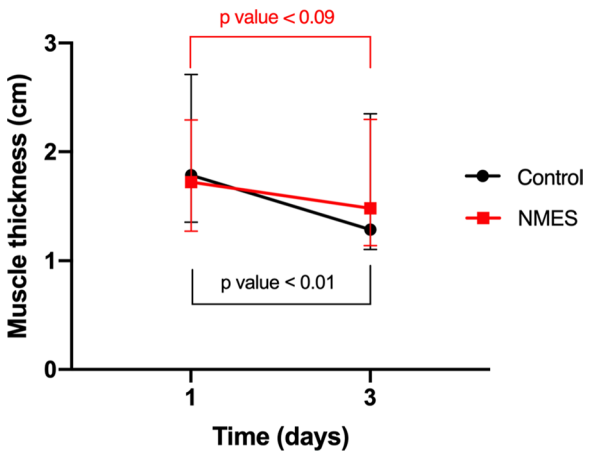

Figure 1 (abstract 001035) Quadriceps muscle layer thickness. In red lines median values for muscle layer thickness (right and left leg

combined), from day 1 to 3, in the neuromuscular electrical stimulation group (NMES). In black lines, median for quadriceps muscle layer thickness in control group, also for right and left leg combined. P value for intragroup comparison

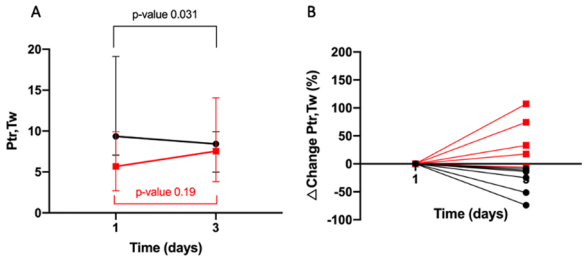

Figure 2 (abstract 001035) Twitch tracheal pressure. A) Absolute changes in twitch tracheal pressure (Ptr,Tw) from day 1 to 3. B) Relative changes for Ptr,tw from day 1 to 3. In red the neuromuscular electrical stimulation group (NMES). In black, changes in control group (CG). All individual values has been normalized according to baseline values and expressed as percent

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001037

Introduction: Patients suffering from chronic obstructive pulmonary disease (COPD) requiring mechanical ventilation and admission to ICU after elective surgery are prone to airway infections caused by airway obstruction from hypersecretion of inflamed airways. [1] As a consequence, patients with COPD present with a higher mortality rate, a longer interval of MV and an increased length of ICU- stay.[2–4] High frequency chest wall oscillation (HFCWO) can improve the mobilization of airway secretions and reduce the amount of atelectasis in patients with COPD.[5, 6] However, so far, there is little data about the benefit of HFCWO in patients with COPD in the ICU setting.

Objectives: Aim of this study was to assess, whether HFCWO plus standard ICU care including chest physiotherapy versus sole standard ICU care including chest physiotherapy is able (a) to reduce the rate of pneumonia, (b) to diminish the length of MV/ICU- stay and (c) to improve distribution of lung ventilation (monitored by electrical impedance tomography (EIT)) in adult patients with COPD admitted to ICU after elective surgery.

Methods: Prospective, randomized, single center pilot study including adult patients with COPD, admitted electively after surgical treatment to a German ICU of a quaternary care hospital from 12/2022- 04/2023. Planned total sample size of the pilot study: 50 patients (student-T-test, power 80%, alpha 0.05, effect size 0.4). Prior to study inclusion severity of COPD (FeV1, Bode- index, mMRC-Score) is assessed. Patients with contraindications for the use of HFCWO / EIT are excluded from the study. All patients are randomized to either (a) control group with standard ICU care with chest physiotherapy or to (b) interventional (HFCWO) group including standard ICU Care with chest physiotherapy plus HFCWO (15Herz, 2 mbar, 15 min once daily for 5 days or until discharge from ICU). Primary endpoints of the study: Length of MV and length of ICU- stay. Secondary endpoints: Rate of pneumonia and results from EIT-monitoring (Win of compliance in %). This study was approved by the local Ethical Committee (22-1140_1).

Results: So far, 20 patients could be included (interventional group $n=12$, control group $n=8$), tolerating HFCWO well without any side effects. In the HFCWO group 10/12 patients were male vs 3/8 in the control group ($p=0.04$). There was no significant difference regarding age, body mass index, SOFA-Score, COPD- severity (FeV1, Bode-Index, mMRC) in HFCWO vs control group. The rate of pneumonia was higher in the control- ($n=4$) vs HFCWO- group ($n=1$; $p=0.04$). Regarding EIT-monitoring, win of compliance (%) after treatment was higher in the HFCWO group ($32.03\pm18.79\%$) vs control group ($6.5\pm4.12\%$; $p=0.05$). However, HFCWO was not associated with a reduction of length of MV or ICU stay.

Conclusions: HFCWO as an additional treatment of patients with COPD in the ICU-setting after elective surgery can potentially reduce the rate of pneumonia and improve respiratory compliance by reducing atelectasis. However, in this study, HFCWO plus chest physiotherapy versus sole chest physiotherapy was not able to reduce length of MV or ICU- stay. After completion of the pilot study, a larger, randomized, multicenter study is required to prove this association.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001038

Introduction: Since 2011 the implementation towards the acquisition of Electronic health records (EHR) has been a priority for Europe (1). EHRs hold the promise of significantly improving clinical outcomes by merging information, introducing prescription's monitoring and safety alerts, providing clinical decision support systems, and improving data availability for research purposes, particularly in Intensive Care Units (ICUs).
Objectives: The actual diffusion of EHRs and user experience evaluation in Italian ICUs have not been assessed yet (2, 3). We, therefore, carried out a survey to investigate the prevalence of EHRs adoption in Italian ICUs and their performance evaluation by healthcare workers.
Methods: The survey was launched on social networks (Facebook, Twitter, Linkedin, and Whatsapp) and shared by email from May 17th, 2022 and was closed on October 30th, 2022. The survey consisted of an anonymous questionnaire on Google Forms and was addressed to consultants, residents, and nurses working in Italian ICUs. Participants were asked to rate the overall experience with EHRs on a scale of 1 to 10 and individual tasks on a scale of 1 to 5.
Results: A total of 1,047 questionnaires were filled, with a completion rate of 100%. Health workers employed in 20 different Italian regions (out of 21) took part in the survey: 47.7% were consultants, 29% residents, and 23.3% nurses. Among participants, 58.2% declared to use EHRs while the remaining 41.8% declared to still use paper records. The prevalence of participants using EHRs was not homogeneous, being higher in Central (71.2%) and Northern (67.2%) Italy and markedly lower in the south (15.7%). The overall evaluation of EHRs had a median score 8 (IQR 6–8). However, all individual tasks got a median score below or equal to 3 (Table).
Conclusions: The majority of participants declared to use EHRs, however the diffusion seems to be not uniform in different Italian regions. Overall, participants reported high levels of satisfaction in EHRs use, however, analysing individual functions critical issues emerged. Individual tasks received low scores and seem not to fulfil users' expectations. This suggests that while EHRs are perceived as beneficial, there may be room for improvement in specific tasks performance.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001039

Introduction: Handheld vital microscopy is a largely used technology for scientific research in the Intensive care setting. However, due to previous technological limitations, mainly related with the images analysis, and lack of consistent results regarding its application at the bedside, its use is still limited to research. In 2019, our group developed MicroTools, the first validated software for automatic analysis of images of the microcirculation [1] Subsequently, we developed the rationale for the application of the "three pillars of digital transformation" in the field of microcirculation by developing the Microcirculation Network Research Group (MNRG) [2]. The mission of the MNRG is to finally bring the technology of microcirculation monitoring to the bedside.
Objectives: To test the entire MNRG concept and its workflow in two different scenario including 1) the development of a new parameter and 2) the validation of an AI-based algorithm.

Methods: The MNRG workflow includes the following steps illustrated in the Figure: 1) the signature of a collaboration agreement, 2) the transfer of the data and images to a cloud and the images analysis by MicroTools, 3) the definition of the rationale to be explore with the definition of the approach (prototyping, 4) the validation of the hypothesis on the data, 5) the publication of the results, 6) the availability of the algorithm for external validation and further improvements. All data are stored in a relational database with limited and regulated access and includes quality gates. The entire process warrants a continuously growing dataset with complete information and containing data standardized and of high-quality.
Results: The two concepts tested in the MNRG regarded 1) the validation of a new parameter aimed to provide a unique number describing the overall perfusion of the observed tissue by red blood cells defined as tissue Red Blood Cell perfusion (tRBCp) and 2) the development and validation of an AI-based algorithm able to differentiate severe COVID-19 patients from volunteers only by the assessment of the sublingual microcirculation. The rationale and the development of tRBCp was described in an individual paper [3] and subsequently clinically validated on data from patients undergoing noncardiac surgery from Hamburg [4]. The rationale, development, and validation of the AI algorithm detecting COVID-19 patients was obtained from data provided by four different centers and published on the Critical Care [5]. Each individual step for both projects is described in the Figure. Nowadays, the MNRG is actively collaborating with 23 centers in 11 countries on 26 different projects and it is continuously expanding.
Conclusions: The MNRG together with the recent technical and methodological developments including the introduction of a validated software for automatic analysis, will markedly contribute to the technological transfer of microcirculation monitoring from a research tool to a clinical decision support system to use at the bedside with defined and validated clinical applications able to guide therapeutic decision with a significant impact on patient prognosis. Other potential implications will involve the identification of microcirculatory patterns, the investigation of compensatory mechanisms, the development of new parameters and applications.

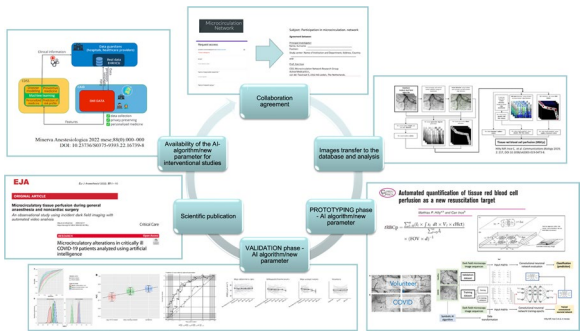

Image providing the standardized workflow of the Microcirculation Network Research Group (MNRG) reporting two examples of collaborations regarding the development of a new parameter and the development and validation of an algorithm based on artificial inteligence distinguishing severe COVID19 patients from health volunteers based on sublingual microcirculation.

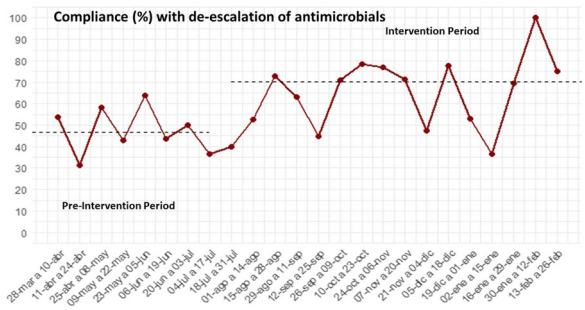
Introduction: Antimicrobial resistance (AR) is the inevitable result of antimicrobial (AM) use, and it is exacerbated by its inappropriate use and overuse. ICUs are areas with more risk of AR. An increase in the incidence of AR posed collateral damage during and after the COVID-19 pandemic. Antibiotic Stewardship Programs (ASP) have been developed for optimizing the treatment of infections, reducing infection-related and limiting the appearance of multidrug-resistant organisms (MDROs). In this research, a Quality Improvement Collaborative (QIC), preceded by a formative phase was proposed to improve the use of AM using stewardship strategies.
Objectives: To implement a multifaceted intervention to enhance the quality of AM prescription throughout the reduction of AM days of therapy (DOT) and AM defined daily dose (DDD), and the increase in AM de-escalation compliance.
Methods: Quasi-experimental design, before-after analysis, carried out in 9 ICUs of the public sector in Argentina, from March 2022 to February 2023. The QIC followed the Institute for Healthcare Improvement's Breakthrough Series Model.
There were 16 and 32 weeks of measurements in Pre-Intervention period (Pre-IP) and Intervention period (IP). Inclusion criteria was AM requirement within 28 days of ICU admission. The IP included learning sessions and periods of action using Plan-Do-Study-Act (PDSA) cycles. The Antibiotic Stewardship Program consisted of audit and feedback of antibiotics use, facility-specific treatment guidelines or clinical pathway, infection-based interventions-focused on improving diagnostic accuracy-, pharmacy-based interventions, education, tailoring of therapy to culture results, and optimization of the duration of treatment (antibiotic timeout). Medians of weekly proportions of AM DDD/1000

patient-days, AM DOT/1000 occupied bed-days, and compliance with AM de-escalation (proportion of empirical therapy changed to pathogen-directed therapy up to 24hs after culture results became available) were compared between both periods using Wilcoxon rank-sum test or Chi2. A p value ≤ 0.05 was considered significant for all comparisons.

Results: A total of 912 patients were included, 357 in Pre-IP and 555 in IP. Patient characteristics in Pre-IP and IP were Age 51 [34–64] vs 50 [36–65]; Sex fem 143 (40%) vs 213 (38%); APACHE-II score 15[11–20] vs 17[12–21]; SOFA 5[3–8] vs 6[4–9]; mechanical ventilation (MV) requirement 270 (76%) vs 420 (76%); MV-days 10[4–18] vs 9[4–18]; renal failure 118 (33%) vs 231 (42%); septic shock 185 (34%) vs 325 (40%) and ICU mortality 94 (26%) vs 189 (34%).

There were not significant differences in AM DOT/1000 occupied bed-days Pre-IP: 1149 [p251042-p751272] vs IP 1112 [p251073-p751163], p = 0.54; neither in AM DDD/1000 patient-days: 1192 [p251066-p751399] vs IP 1163 [p251056-p751309], p = 0.62. Compliance with AM de-escalation improved from 45 to 61% (p = 0.004) (Fig*0.1).

Conclusions: The QIC was effective to improve compliance with ATM de-escalation as part of an Antibiotic Stewardship Program. It was not possible to reduce AM DDD/1000 patient-days, and AM days of therapy (DOT)/1000 occupied bed-days. However, population in the IP presented more severity of illness and these results will possibly benefit of an illness severity adjustment. This first initiative highlights the need to continue working on how to address and improve topics of antimicrobial resistance.



Compliance with antimicrobial de-escalation.

Correspondence: V.A. Martha Mayoral

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001041

Introduction: Septic shock is the more severe form of sepsis that, in spite of advances in diagnosis and treatment, remains with a high mortality ratio in all intensive care units around the world. Many scores are used to assess severity at admission, which reflects in prediction of mortality, although sepsis related serum biomarkers C- reactive protein and procalcitonin are a useful diagnostic tool, evidence is controversial about if they could be used to predict mortality, and there is currently little or no evidence that the ratio between both biomarkers could be used to predict mortality.

Objectives: Describe association between C reactive protein/Procalcitonin ratio and mortality in patients with septic shock.

Methods: A retrospective, observational, transverse, single tertiary care center study in patients with septic shock admitted between January 2022 and January 2023 was conducted. Demographic, laboratory and microbiological data were analyzed and pooled.

Results: A total of 142 patients were enrolled, of which 113 survived (79.6%) and 29 died (20.4%). In the survivor group, 26 (18.3%) had a < 0.5 CRP/PCT ratio vs 87 (61.3%) of the > 0.5 group, while in the non-survivor group, 11 (37.9%) had a < 0.5 CRP/PCT ratio vs 18 (62.1%) of the > 0.5 group (RR 0.489, CI 0.205–1.166, $p = 0.107$).

Conclusions: Although not statistically significant, we found that lower CRP/PCT ratios could correlate with a higher mortality rate. Larger populations would be needed to correlate this association.

A descriptive retrospecti40635_2023_546ve study: micronutrient intake levels in critically-ill patients on enteral tube feeding

R. G. J. Ramos[1], C. J. Balalta[1], N. Mustofa[1]

[1]Internal Medicine, Asian Hospital and Medical Center, Muntinlupa, Philippines

Correspondence: R. G. J. Ramos

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001042

Introduction: Most enteral nutrition (EN) formulas are designed also to meet the increased micronutrient needs in critically-ill patients.For this reason, determining the potential excess or deficiency of certain micronutrients is essential especially forpatients on enteral formula tube feeding. Despite the widespread use of EN, both in hospitals and at home, studies onthe micronutrient compositions in the enteral mixtures are deficient, thus an evaluation of the amount of vitamins

andtrace elements in the currently used enteral feedings requires consideration.
Objectives: GENERAL OBJECTIVETo describe the micronutrient intake levels among ICU patients who were tube fed for at least three days at AHMC andidentify the percentage of ICU patients achieving the recommended energy and nutrient intake on micronutrient intake.
SPECIFIC OBJECTIVES1) To describe the demographic profile of critically-ill patients with enteral feedinga. Ageb. Genderc. Co-morbidities2) To determine the type of tube feeding formula used and average three-day amount of micronutrientintake levels among ICU patients3) To determine the percentage of patients who achieved the Recommended Energy and Nutrient Intakefor Filipinos.
Methods: This is a descriptive retrospective study (using chart review of admissions last January 1 to December 31, 2020)conducted at the Asian Hospital & Medical Center, a 296-bed capacity tertiary hospital in Muntinlupa, Philippines. Allpatients admitted at the Asian Hospital & Medical Center Intensive Care Unit from January 1, 2020 to December 31,2020, who had enteral feedings for at least three days were included in the review. Descriptive statistics were used tosummarize the demographic characteristics and pertinent variables needed for the study. One- way Analysis of Variancewas used to compare the average three days amount of micronutrient intake levels among ICU patients according tothe type of feeding. Pairwise comparison using Least Significant Difference (LSD) was carried out to determine pairwisecomparison.
Results: 60 patients were included in the study, with a mean age of 68.72 years, with most patients in the 61–70 years age group(20 (33%)). Majority of the patients were male (34 (56.7%) and the rest were female (26 (43.3%). Arterial hypertension (65%) and diabetes mellitus (insulin and noninsulin requiring, 50%) were the most commonly reported co-morbiditiesamong included patients.The macro minerals included in this study are potassium, sodium, phosphorus and magnesium. The average potassiumlevel intake of ICU patients reached at least 45% of the RENI, magnesium levels were able to attain 69% of the RENI, phosphorus levels reached 72%, sodium levels exceeded the RENI by 129%. Trace minerals included in the study werezinc and selenium. Both zinc and selenium exceeded RENI by 180% and 129%, respectively. For vitamin C, it alsoexceeded by 184%, while vitamin B1 also exceeded by 129%, vitamin B6 levels were at 168% and vitamin B12 alsoexceeded it by 179%. Among tube fed patients, Vitamin A attained 115% of the recommended intake and Vitamin Dlevels were at 64% of recommended intake.
Conclusions: In this study, enteral feeding is able to achieve the percentage of recommended intake on certain micronutrients whichincluded sodium, zinc, selenium, Vitamin C, Vitamin A, Vitamin B1, Vitamin B6 and Vitamin B12. However, low intakelevels of certain micronutrients were also documented which included potassium, magnesium, phosphorus and VitaminD which may signify need for proper supplementation.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001043

Introduction:: Acute respiratory failure (ARF) is associated high mortality. Early identification of patients at risk for developing respiratory failure could give the clinician opportunity to conceive strategies for preventions. We developed machine learning models mainly using biosignals to predict the development of respiratory failure in patients visiting emergency department (ED).
Methods: We collected biosignals and clinical data of patients after admission to the ED for four hours, excluding those already receiving mechanical ventilation support within collection time.
We built our ML model based on convolutional recurrent neural networks (CRNN) which integrate feature extraction from continuous biosignals and sequence modeling (Fig. 1).
Results: A total of 4068 patients' data and biosignals were analyzed and ARF occurred in 1078 patients (mean age: 67.34 years old; 59.4% male patients).
Our ML models performed well in predicting ARF with an area under receiver operating curve (AUROC) up to 0.818 ~ 0.840, area under the precision-recall curve (AUPRC) up to 0.470 ~ 0.560, sensitivity up to 0.728 ~ 0.769, PPV up to 0.315 ~ 0.415 while maintaining high NPV of 0.923 ~ 0.954 in the best performing model.
Conclusions: we created a highly predictive AI model for ARF that occurs within 4 to 72 h in patients without ARF within 4 h of hospitalization using only biological signals and initial clinical data (age, gender, consciousness, and body temperature).

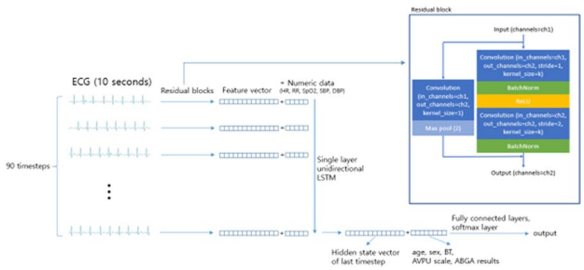

Figure 1 (abstract 001043) Architecture of the AI model. The AI model architecture was based on convolutional recurrent neural networks (CRNN), which integrate feature extraction from the ECG (convolutional neural network [CNN] part) and sequence modeling (recurrent neural network [RNN] part). AI: artificial intelligence. ECG: electrocardiogram. HR: heart rate. RR: respiratory rate. SBP: systolic blood pressure. DBP: diastolic blood pressure. LSTM: long short term memory. Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001044

Introduction: Prone positioning was shown to decrease mortality in patients with the most hypoxemic forms acute respiratory distress syndrome (ARDS) [1]. The factors associated with gas exchange improvement during prone position are currently not well identified.
Objectives: Our main objective was to determine variables associated with positive response to prone positioning. We also wanted to identify impact of the response to the first proning session on the patients' ICU survival.
Methods: This single-center observational study was performed in the medical ICU of Kremlin-Bicêtre Academic hospital between March 2020 and May 2021. Patients receiving mechanical ventilation for COVID-19 induced ARDS (C-ARDS) who underwent at least one session of prone position with respiratory mechanics measurement and arterial blood gas drawn before and at the end of sessions were included. We considered patients to be positive prone responders if they

fulfilled at least one of the following criteria: a PaO_2 to FiO_2 (PF) ratio increase ≥ 20 mmHg; a PF ratio increase ≥ 20%; and/or a decrease in $PaCO_2$ ≥ 5 mmHg. To take into account repeated measurement (most patients had several sessions), we performed a mixed effect level logistic regression to determine covariables associated with our outcome of interest. This two-level random intercept binary logistic regression comprised session related covariates and patients related covariates. We also performed a single level logistic regression including demographic, variables and first prone position characteristics to identify factors associated with ICU survival.

Results: During the inclusion period, 145 intubated patients with C-ARDS underwent at least 1 session of prone positioning in our ICU. Among them, 121 patients were included in this analysis, aged [mean (± SD)] 63 (± 12), with a BMI of 29.6 (± 5.6) kg/m^2, admission SAPS-2 of 39.0 (± 14.2) and median [IQR] SOFA of 4 [3;6]. Most of them (76.9%) presented at least one comorbidity, mainly hypertension (47.1%), obesity (38.0%) diabetes (28.1%) and/or chronic kidney disease (15.7%). First proning session occurred at day 1 [1;3] after intubation.

These patients underwent a total of 628 sessions of proning and we analyzed the results of the 551 prone sessions with available data (87.8%). Most sessions (71.5%) led to a positive response. In the multivariable analysis, adjusting on age, sex, frailty, presence of chronic obstructive pulmonary disease (COPD), body mass index (BMI), delay from intubation to the session of proning, pre-proning arterial partial pressure of CO_2 and pre-proning static airway compliance, only a lower PF ratio (OR = 0.82 [0.75;0.89] for 10 mmHg) and a lower SAPS-2 at admission (OR = 0.75 [0.57;0.99] for 10 points) were associated to a positive response to prone positioning (Figure 1).

ICU survival at day 28 was 40.5%. After adjustment on age, SAPS-2, BMI, and change of driving pression during the first proning session, we found that a only a PF ratio improvement was associated with a better survival (OR = 1.07 [1.01;1.13] for 10 mmHg).

Conclusions: In this single center study including patients with COVID-19 related ARDS treated with prone position, patients with most severe hypoxemia before prone positioning and those with lower admission severity seem to benefit the most from this technique with greater improvement of gas exchange. The amplitude of the response in terms of oxygenation to the first session of proning seems to be associated with better survival and should be investigated in further studies.

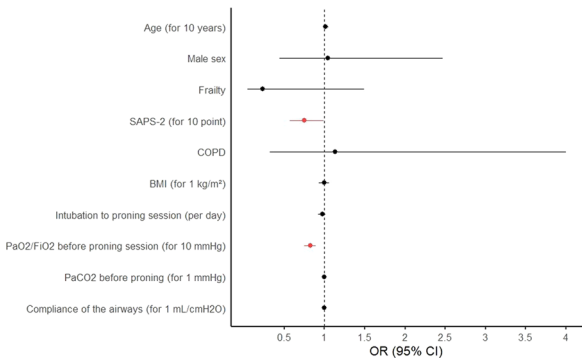

Figure 1 (abstract 001044) Odds ratio (95% CI) of association with positive response to prone positioning in a multi-level multivariable analysis. SAPS-2, simplified acute physiology score 2; COPD, chronic obstructive pulmonary disease, BMI, body mass index

Perioperative outcome prediction using cardiopulmonary exercise testing (CPET) and machine learning (ML)

P. Arina[1], M. R. Kaczorek[2], E. B. Mazomenos[2], J. Whittle[3], M. Singer[1]
[1]Bloomsbury institute of intensive care medicine, University College London, London, United Kingdom; [2]Wellcome/EPSRC Centre of Interventional and Surgical Sciences and Department of Medical Physics, UCL Main Campus, London, United Kingdom; [3]Human Physiology and Performance Laboratory, Centre for Perioperative Medicine, University College London, London, United Kingdom
Correspondence: P. Arina
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001046

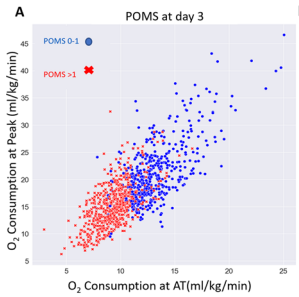
Introduction: Approximately 16% of patients experience serious complications following surgery1. Preoperative cardiopulmonary exercise testing (CPET) can identify patients at higher risk of complications2. Machine Learning (ML) algorithms have the potential to improve the predictive accuracy of CPET and develop useful clinical tools.

Objectives: To design a machine learning-based clinical tool that combines patient data with CPET data to improve prediction of adverse outcomes after major surgery.

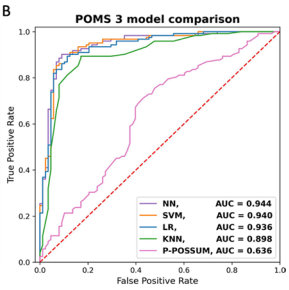
Methods: A single-centre database of 1190 patients who underwent a diverse range of surgery over 10 years at University College Hospitals NHS Trust, London, UK was analysed. Outcomes examined included a postoperative morbidity survey (POMS) and 1 year mortality. The Physiological and Operative Severity Score for the enumeration of Mortality and morbidity (P-POSSUM) was used as a comparator risk model. Using Python, data were processed for feature selection. Preliminary data analysis used linear regression and clustering to examine the relationship between features and outcomes. We then developed and evaluated four machine learning models—logistic regression (LR), support vector classifier (SVM), k-nearest neighbours classifier (KNN), and neural network (NN)—for their performance in a classification task.

Results: Cumulative POMS scores for patients on postoperative day 3 revealed a correlation between oxygen consumption at aerobic threshold and cumulative POMS score (r2: 0.68, p:0.001). Feature ranking analysis identified CPET-derived features as the most important. Machine learning models demonstrated superior performance to P-POSSUM in classifying patients at day 3 with the neural network performing the best (AUC: 0.944, Accuracy: 0.866, Sensitivity: 0.853, Specificity: 0.842, F1-Score: 0.862). For 1-year mortality (6%), all models outperformed P-POSSUM, with the SVM model performing the best (AUC: 0.817, Accuracy: 0.782, Sensitivity: 0.688, Specificity: 0.788, F1-Score: 0.294). All models had low sensitivity for mortality, indicating a high number of false positives.

Conclusions: Using preoperative CPET, we created a ML-based tool that could predict, with high discrimination, surgical patients at risk of morbidity. While predictions of mortality were superior to those made using P-POSSUM, the models were affected by low discrimination regarding true and false positives. To improve these results, we will investigate CPET time series with ML models and deep learning.



Scatter plot of patients cumulative postoperative morbidity survey (POMS) at day 3 post operation. X axis: Oxygen Consumption (O_2) at Aerobic Threshold (AT) (ml/kg/min), y axis: Oxygen Consumption (O_2) Exercise Peak (ml/kg/min).



Machine Learning model performances, classification task, cumulative patients, cumulative postoperative morbidity survey (POMS) at day 3 post operation; POMS 0-1 or >1; P-POSSUM used as clinical comparator.

A retrospective analysis of life-threatening complications of maxillofacial space infection in a tertiary care hospital

M. García Marín[1], M. Gascón Castillo[1], M. Fernández Caro[1], T. Villalobos Herrera[1]
[1]Medicina Intensiva, Virgen del Rocío University Hospital, Sevilla, Spain
Correspondence: M. García Marín
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001047

Introduction: Infections of the maxillofacial space, with extension to deep tissues, are a significant cause of morbidity and mortality in previously healthy patients, frequently requiring admission to intensive care, according to the potential development of serious complications that can be life-threatening. We present a case report of patients admitted to a tertiary ICU for this pathology.
Methods: We reviewed the medical record of 65 patients with a diagnosis of maxillofacial space infection requiring admission to Intensive Critical Unit at Virgen del Rocío Hospital (Sevilla, Spain), from January 2019 to January 2023. Age, personal history, need for surgical intervention and reintervention are collected, as well as the characteristics of the antibiotic treatment used, microbiological isolates and mortality. The SOFA and APACHE II scores were obtained within the first 24 h after admission.
Results: 65 patients were included in the study, all of them requiring urgent surgery within the first 24 h of admission to the ICU.
Among our patients, the mean age was 47 years (17–77), with a mean ICU stay of 10 days, with a wide range (1–79). 23% of patients were treated with prior prolonged antibiotic therapy, understood as > 7 days of broad-spetrum antibiotic.
Twenty-eight percent were admitted in a situation of septic shock, with a relatively low SOFA in the first 24 h of admission (average SOFA of 2), APACHE-II at 24 h on average of 8. 25% required more than 1 surgical intervention for adequate focus control.
Initial empirical treatment was performed with ceftriaxone + clindamycin in 83%, based on local antimicrobial therapy guidelines, with 34.6% of patients requiring antibiotic escalation at some point during admission. Intraoperative cultures were taken in 98% of patients, microbiological isolation was obtained in 63.5% of these. The isolates were usually polymicrobial (81.3%), 69% of these also included anaerobic microorganisms. Mean antibiotic treatment was 27 days, performing de-escalation or sequential treatment at discharge during this period in 89% of patients. Only 6 patients had complications with associated thrombophlebitis, and 3 of them with mediastinitis. 3 patients died during their hospital admission.
Conclusions: Infections of the maxillofacial area are a relevant disease, with potentially fatal complications, and frequently affects young patients with low comorbidity, commonly requiring several surgical interventions during admission, who probably benefit from multidisciplinary management, as well as management specific in an intensive care unit. An antimicrobial policy based on the local flora is necessary, as well as established protocols for optimal management of our patients.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001048

Introduction: The increased time required to care for ICU children translates into a nursing workload (NW) and is greater than in other nursing departments. Nursing workload can affect both the quality of care provided and patient safety. The use of tools to assess the nursing workload that can contribute to the proper utilization of logistical and human resources expressed by the ratio of patients per nurse in pediatric ICUs is important. Correlating nursing workload with severity and risk scales of pediatric ICU patients is also important because they are particularly susceptible to experiencing adverse events when NW is high.
Objectives: The present study aims to measure and quantify the burden of nursing workload (NW) with reliable scales, to compare them, and to correlate NW with indicators of clinical severity and outcome of pediatric patients hospitalized in an academic PICU and in the calculation of optimal staffing.
Methods: This is a prospective cohort study conducted in the Pediatric ICU (PICU), University Hospital of Heraklion, Greece. Children aged 1 month to 18 years, who were hospitalized between June and December 2021 were eligible. The pediatric scales NAS (Nursing Activities Score), TISS-28 (Therapeutic Intervention Scoring System 28) and NEMS (Nine Equivalents of nursing Manpower use Score) were used to measure the nursing workload. Clinical severity scales were Glasgow Pediatric Scale, pediatric logistic organ dysfunction (PELOD-2) the Pediatric Mortality Index III (PIM III) and PRISM III/IV. Optimal nurse

staffing was measured in hours per patient per day needed (NAS score of 100 equals to one registered nurse per 8-h shift).
Results: In the total population studied (N = 106), 60% were boys, median age was 3.7 (0.7–11.8) years, emergency admissions were 69.1%, median length of stay was 5 (3–16) days, comorbidities were found in 41.8%, clinical severity (PELOD-2) scale showed that the risk of death was 4.91% and crude mortality was 7.3%. Mean NAS score was 76.75 (± 15.18) corresponding to a mean provided nursing care time of 1105.27 (± 218.64) minutes, TISS-28 score was 26.78 (± 6.84) that is 851.67 (± 217.61) minutes, and NEMS was 27.41 (± 7.01) minutes, equivalent to 871.66 (± 222.76) minutes. TISS-28 scale was found to have a moderate positive statistically significant linear correlation with the NAS scale ($r = 0.543$, $p < 0.001$) and a strong positive correlation with the NEMS scale ($r = 0.764$). The Bland–Altman concordance test showed that 5.4% of the total recordings differed from the upper and lower limits of agreement of the P-NAS and TISS-28 scales. Patients admitted to PICU from the Emergency Department had a significantly higher daily NAS nursing workload compared to patients admitted from the Operating Room [76.64 (± 10.29) vs. 67.82 (± 10.67), $p = 0.003$]. NAS nursing workload was found to have a positive linear statistically significant correlation with the length of stay of patients in PICU ($r = 0.562$, $p < 0.001$), that is, patients with a higher NAS score tended to have a longer length of stay. The discriminative ability of the severity and outcome prognostic scale scores and nursing workload scales between patients who survived and those who died was high (AUC 0.929, 95% CI 0.849–1.0, $p < 0.001$) (Fig. 1). According to NAS scale, shortage of registered nurse staffing were identified in all rotation shifts; morning shift -0,70 (± 0,99) nurses, evening shift -0,84 (± 0,95), and night shift -0,85 (± 0,94) (all $p < 0,001$).
Conclusions: NAS, TISS-28 and NEMS proved to be reliable and valid tools in pediatric ICUs. The NAS scale is superior to others in assessing nursing workload. The discriminative ability of the severity and outcome prognostic scale scores and nursing workload scales between patients who survived and those who died was high. Addtionally, NW scales demonstrated that optimal nurse staffing in the PICU requires additional nurses.

Introduction: Traumatic Brain Injury (TBI) outcomes are determined by the severity of the primary injury and secondary injuries (SIs) – such as hypoxia and hypotension [1–2]. SIs can boost the initial damage and ultimately worsen long-term disability and mortality [3–4].
Objectives: This study explores the incidence of early SIs and their association with derangements in metabolic profile, the higher therapeutic burden in the acute phase, six-month mortality, and neurological outcome.
Methods: This is an observational analysis of adult TBI patients admitted to the Intensive Care Unit enrolled in the CENTER-TBI study [5]. To detect the occurrence of early SIs, we examined data recorded in the prehospital setting and at hospital arrival. A hypotensive episode was defined as a measured systolic blood pressure (SBP) < 90 mmHg or a clinical definition of shock. A hypoxic episode was described as an estimated arterial partial pressure of oxygen (PaO2) < 60 mmHg and/or peripheral oxygen saturation (SpO2) < 90% or as evidenced by cyanosis, apnea, or respiratory distress.
According to the occurrence of secondary insults, patients were allocated into four different groups: "Hypoxia", "Hypotension", "Both" and "None". For each group, we evaluated: demographics, TBI mechanism, Glasgow Coma Scale at admission, Marshall CT score, strategy for intracranial pressure management, presence of extracranial injuries, need for neurosurgery and extracranial surgery (e.g., damage control interventions), need for mechanical ventilation (and eventually tracheotomy), rate of blood transfusions, biochemical profile. Comparison between the characteristics of the groups was conducted by chi-squared or Wilcoxon rank sum test – depending on the nature of the variables.
Glasgow Outcome Scale – Extended (GOSE) was used to determine 6-month neurological outcome and mortality; any value ≤ 4 was considered as an "unfavorable outcome".
Results: Among the study population ($n = 1,695$ patients), a hypoxic event was reported in 158 (9.3%) patients, a hypotensive event in 142 (8.4%), and both hypoxia and hypotension in 115 (6.8%).
Both SIs were associated with the most deranged biochemical profile and the highest rate of extracranial injury. Hypotension alone or combined with hypoxemia was independently associated with the need for extracranial surgery and unfavorable neurological outcome (Figure 1). Ultimately, a higher 6-month mortality was observed among patients suffering from both SIs.
Conclusions: The incidence of early SIs was lower compared to previous studies [6–7]. However, SIs still represent an important factor contributing to patient's outcomes. Thus, prompt recognition of SIs and their risk factors can be pivotal in early and ICU clinical management.

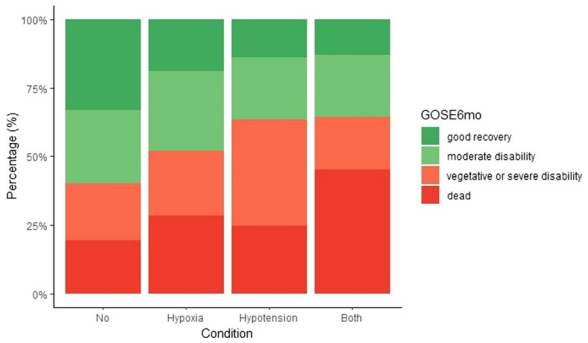

Figure 1 (abstract 001049) Outcome distribution in patients with and without SIs. GOSE6mo: Glasgow Outcome Scale—Extended at 6 months from TBI. GOSE 1: dead (red). GOSE 2–4: vegetative state or severe disability (orange). GOSE 5–6: moderate disability (light green). GOSE 7–8: good recovery (dark green)

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001050

Introduction: Extracorporeal carbon dioxide removal (ECCO2R) allows protective ventilation in patients with acute respiratory failure (1, 2), but requires systemic anticoagulation with subsequent increased risk of hemorrhage, especially with low blood flows (3). In clinical setting, citrate represents the most widespread molecule used for regional anticoagulation (RA); however, because of limited clearance, citrate can only be applied to extracorporeal blood flows lower than the ones required for ECCO2R. New techniques have been proposed to overcome these limitations (4).

Objectives: This study aims to evaluate feasibility, safety, and efficacy of a new extracorporeal technique that combines a low flow ECCO2R and continuous renal replacement therapy (CRRT) using a RA with citrate and a novel system for citrate removal.

Methods: Six healthy swine (39 ± 7 kg) were mechanically ventilated and connected to a low-flow (0.35 L/min) custom-made venous-venous extracorporeal circuit for ECCO2R and CRRT which includes anionic ion-exchange resins charged with chloride for citrate removal, and cationic resins charged with sodium for calcium removal. Hydroelectrolytic balance was achieved through ultrafiltration (1000 ml/h) and three different anionic ion-exchange resins (100% bicarbonate (HCO3-); 100% hydroxide (OH-); 60% HCO3- and 40% OH-) tested in a randomized 1-h steps. A 0.2 M solution of sodium citrate (66%) and citric acid (34%) was continuously infused at the circuit inlet (4 mmol/L). Plasma citrate and free calcium concentrations were measured on arterial blood, and on extracorporeal blood inlet (downstream of citrate infusion) and outlet. Minute ventilation (MV) was changed to maintain a constant arterial pressure of carbon dioxide (50 ± 2 mmHg). Samples were collected at the end of each step for blood gas, electrolytes, and citrate dosage. Data were also collected at baseline before connection to the extracorporeal circuit.

Results: During ECCO2R, MV decreased from 7.27 ± 1.31 l/min to 3.4 ± 0.70 l/min, and it remained stable during 60%HCO3-/40%OH- (3.05 ± 0.64 l/min, *p 0.68*), further decreased during 100% OH- step (1.86 ± 1.04 l/min, *p < 0.01*), and slightly increased during 100% HCO3- (4.23 ± 0.91 l/min, *p 0.04*, Figure *1*). During citrate infusion, regional free calcium concentrations remained below the RA threshold, while citrate concentration, downstream the infusion port, was 5.51 ± 0.68 mmol/L and decreased after the citrate-removal system (*Table *1*). At the end of the study, the arterial total calcium/ionized calcium ratio was 1.99 ± 0.25. Minimal changes occurred in arterial pH and sodium concentration, but not in chloride concentration. The blood outlet pH during OH- step was significantly higher compared to all the others.

		Baseline	ECCO2R	100%HCO3-	60%HCO3-/40%OH-	100%OH-	p
ARTERY	Ca++(mmol/l)	1.44 ± 0.07	1.30 ± 0.08	1.32 ± 0.08	1.28 ± 0.07	1.27 ± 0.07	< 0.01
	Citrate (mmol/l)	0.05 ± 0.03	/	0.60 ± 0.21	0.64 ± 0.14	0.73 ± 0.17	< 0.01
	pH	7.41 ± 0.02	7.42 ± 0.02	7.45 ± 0.03	7.44 ± 0.02	7.43 ± 0.03	< 0.01
	Na+(mmol/l)	136.3 ± 2.5	137.7 ± 2.6	138.8 ± 2.0	139.5 ± 1.6	138.7 ± 1.6	< 0.01
	Cl-(mmol/l)	104.0 ± 1.4	102.3 ± 1.6	103.3 ± 2.7	103.2 ± 1.6	103.3 ± 1.8	0.3
INLET	Ca++(mmol/l)	/	1.32 ± 0.08	0.35 ± 0.03	0.33 ± 0.14	0.33 ± 0.10	< 0.01
	pH	/	7.39 ± 0.01	7.08 ± 0.03	7.05 ± 0.11	7.04 ± 0.09	< 0.01
OUTLET	Ca++(mmol/l)	/	1.00 ± 0.05	0.25 ± 0.03	0.20 ± 0.02	0.21 ± 0.03*	< 0.01
	Citrate(mmol/l)	/	/	1.13 ± 0.13	1.17 ± 0.24	1.32 ± 0.30	0.05
	pH	/	7.84 ± 0.04	7.71 ± 0.05	7.88 ± 0.06	8.14 ± 0.11	< 0.01

Conclusions: Combining ECCO2R with blood flow of 0.35 l/min and CRRT with citrate regional anticoagulation and a novel ion exchange resin-based system for citrate removal was feasible. System for citrate removal based on ion exchange resins was feasible and enabled a reduction in MV. The OH- anion exchange resulted in the most significant reduction in MV, albeit with the lowest safety profile.

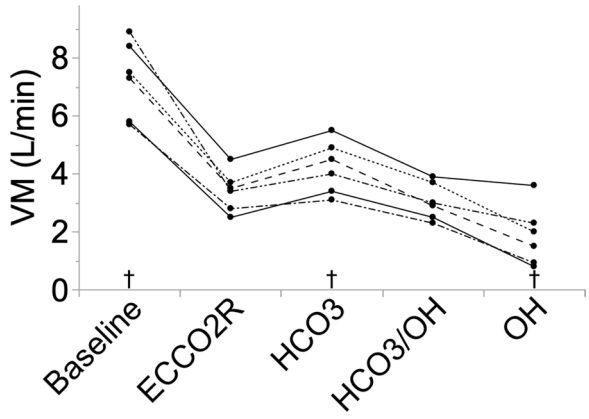

Figure 1 (abstract 001050) Minute Ventilation (VM) of each swine before extracorporeal CO2 removal initiation ("Baseline"), during standard extracorporeal CO2 removal run ("ECCO2R"), and after novel citrate removal system initiation. For citrate removal, anions have been exchanged with only bicarbonate (100% bicarbonate, "HCO3-"), with a solution of bicarbonate/hydroxide 60%/40% respectively (60%/40% bicarbonate/hydroxide, "HCO3-/OH-"), and with only hydroxide (100% hydroxide, "OH-"). Linear mixed model fit by maximum likelihood. † = P < 0.05 in the post hoc analysis (Tuckey 's range test) *vs* ECCO2R step

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001051

Introduction: The consequences of intensive care unit acquired weakness (ICUAW) are a major long-term problem of surviving critically ill patients. Inflammation and therefore proinflammatory cytokines may contribute to muscular changes in the critically ill [1]. To counteract these perturbations, mobilization (e.g., passive mobilization by in-bed cycle ergometry) seems to be promising [2]. Currently, there are no studies on the kinetics of proinflammatory cytokines induced by robotic mobilisation compared to standard treatment.
Objectives: The primary aim of this randomized controlled feasibility study was to investigate the influence of robot-assisted early mobilization compared to standard care. Here we present the analysis of the secondary objective concerning the influence of mobilisation by robotics on proinflammatory cytokines.
Methods: For the feasibility study 20 invasive mechanically ventilated critically ill patients (age > 18 years, invasive ventilation, and planned intensive care stay of more than 24 h) were randomized 1:1 into intervention and control group.
The intervention group received five days of early mobilization twice daily for at least 20 min using the Vemotion® system (Reactive Robotics GmbH, Munich, Germany), which enables mobilization in the own bed and verticalization up to 90 degrees during mobilization. The control group received standard of care without robotic support.
For the cytokine analysis, a blood sample was taken immediately before and after mobilization of the first day. We measured IL 6, IL 8, TNF alpha using LUNARIS™ Reader 96/384 (Ayoxxa Biosystems, USA). We analysed the cytokine change within each group using the Wilcoxon-cox test, and the group difference using the Mann–Whitney-U test. The significance level was set at 0.05. The statistical analysis was performed in SPSS 27 (IBM, USA).
Results: A total of 21 were randomized, with 1 patient withdrew his consent, i.e., 20 patients were analysed. The patients were 65 [IQR 53–78.75] years old, 1.77 [1.65–1.80] cm high, weighed 80 [60.88–84.25] kg, with a Charlson Comorbidity Index of 4.0 [1.3–5.0], an APACHE II score of 27 [21–35] and a SOFA score of 10 [8–11]. There was a trend of reduction of all cytokines compared to a trend towards increase in the control group without significance. Between groups there was a significant difference in the IL-6 level change and a positive trend in the TNF-alpha change (Figure 1).
Conclusions: The kinetics of proinflammatory cytokines during robot-assisted mobilization showed no change nor a signal of harm compared to standard care.

Figure 1. Dynamics of proinflammatory cytokines in the context of robot-assisted mobilization compared to the standard procedure.

Variable	Intervention* (n = 10)	Control* (n = 10)	p-value
Interleukin 6			
Pre-intervention	75.90 [37.38 – 136.48]	52.90 [28.35 – 194.73]	
Post-intervention	58.75 [23.13 – 120.55]	70.80 [27.13 – 179.90]	
Δ Post-Pre	-4.65 [-13.00 – 3.83]	3.70 [-1.30 – 28.88]	0.049

Combination of an AGTR1 rs275651 polymorphism and plasma angiotensin II level as a pathogenic binary candidate biomarker to predict outcome in sepsis

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001053

Introduction: Dysregulation of blood pressure (BP) significantly impacts the course of a life-threatening septic shock. Octapeptide angiotensin II (AngII), the key player of the renin-angiotensin system, significantly contributes to vasoconstriction, sodium and water retention. These effects are mediated via two distinct types of AngII surface receptors, type 1 (AGTR1) and type 2 (AGTR2) [1]. In a caucasian population, single-nucleotide polymorphism of *AGTR*1 gene T/A in promotor region (rs275651) associates with hypertension and increased promotor activity [2,3]. Recently we have shown that carriage of a minor allele A *AGTR*1 rs275651 in sepsis patients with comorbidity is associated with septic shock development and increased lethality [4]. However, no studies were performed to clarify if polymorphism in Ang II receptor gene and plasma concentration of the receptor ligand, AngII, in combination may affect outcome of sepsis.
Objectives: Determine whether both AngII concentration in plasma and *AGTR*1 polymorphism contribute to sepsis outcome in ICU patients.
Methods: Study cohort included 75 ICU patients diagnosed with sepsis (SEPSIS-3, 2016); 34 patients were diagnosed with type 2 diabetes (T2D), 28 patients had cardiovascular disorders (CVD). Sixty percent of patients had septic shock.The levels of AngII in plasma were determined on admission using enzyme-linked immunosorbent assay. Patient's DNA was isolated from the whole blood using organic solvents. Genetic polymorphism of AGTR1 (rs275651) was studied using tetra primer PCR followed by gel electrophoresis. Means/ SD, medians/ odds ratios (OR), logrank test, Fisher exact test (FET)/Mann–Whitney U test were computed and employed to reveal group differences and their significance at $p < 0.05$.
Results: Plasma Ang II levels were significantly decreased in non-survived patients with sepsis compared to survived patients (Fig., A). However, the significant decrease was evident only in a group of patients with severe comorbidity (T2D and/or CVD). Since our recent study had demonstrated the significantly increased mortality in patients with comorbidity carrying the minor allele of Ang II receptor genetic variant, AGTR1 rs275651 (Fig. B), here we evaluated the contribution of AGTR1 genotype and Ang II levels in plasma to outcome of sepsis patients with and without severe comorbidity. First, we found that carriers with sepsis and genotype TT AGTR1 rs275651 displayed significantly increased levels of Ang II (Fig., C). Second, in sepsis patients, angiotensin II amount in plasma over 200 pg/ml exhibited significant association with favorable outcome ($P = 0.0012$; FET, $OR = 5.1$, 95% CI: 1.9- 13.7, $n = 75$). Logrank test confirmed this evidence, however, a significant link between mortality and Ang II level was revealed only in the group with comorbidity whereas similar trend in patients with sepsis and no comorbidity (no T2D and/or CVD) was not statistically significant (Fig., D). Finally, the association of enhanced survival in sepsis and increased level of AngII in plasma (> 200 ng/ml) was statistically significant only in a group of sepsis patients with the *AGTR*1 TT genotype (Fig., E). Therefore, in homozygous sepsis patients (genotype TT), major allele T in a promotor region of AGTR1 (rs275651) gene associated with the increased transcription of the gene [2,3], contributes to survival of those patients who exhibit increased AngII levels in circulation. We believe that in combination the AGTR1 functional polymorphism and AngII level might represent valuable binary candidate biomarker to stratify sepsis patients with comorbidity for in-time personalized prevention or treatment of septic shock to improve survival. Further studies are needed to reveal if patients with sepsis, D2D and/or CVD, rs275651 TT AGTR1 genotype and low Ang II may represent the targeted candidate cohort to deliver clinical benefit from treatment with AngII.
Conclusions: ICU patients with T2D and/or CVD comorbidity and homozygosity for rs275651 major allele T in *AGTR*1 gene (genotype TT) are most resistant to adverse outcome of sepsis if plasma Ang II levels are high.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001055

Introduction: Catheter Associated Urinary Tract Infection (CAUTI) represents approximately 40% of all Hospital-Acquired Infections (HAI). Approximately 17%–69% of CAUTIs are reported to be preventable (1). A key factor in reducing CAUTI has been described as the assessment of readiness to remove the device (2). At our transplant center, the bundle of CAUTI has been introduced in 2021 and the adherence to preventive measures has been audited in 2022 to assess whether a catheter was promptly removed when appropriate, as per guidelines. The target infection rate for CAUTI was set in 2021 by the hospital acquired infection committee at $\leq 1.8‰$.
Objectives: Evaluate the unnecessary prolonged use of indwelling urinary catheters and the possibility to prompt removal.
Methods: Institutional CAUTI prevention policy based on HICPAC 2009 (3), has been reviewed. A dedicated infection control link nurse retrospectively reviewed 20 patient's charts with a diagnosis of CAUTI from January 2022 to December 2022. The adherence to the prevention bundle was verified. Descriptive statistics and a quality improvement plan are presented. As CDC definitions, infection rate indicator is structured by:
Numerator = Number of CAUTI cases in all units included.
Denominator = Number of catheter (foley) days in all units included $\times$ 1000.
Criterions for foley indication are presented on table 1.
Results: The incidence of CAUTI in 2022 was 1.86‰ with 20 CAUTI events and 10.744 foley days. Incidence in 2022 had an overlapping percentage to 2019 with 1.8‰ incidence and 19 CAUTI over 10.704 foley days. Time frame average between foley insertion and the onset of infection was 21 days with SD $\pm$ 30. The predominant number of CAUTI was sustained by GRAM – bacteria as confirmed in literature, no GRAM + were reported in our surveillance. Details are reported on table 2 (2). Among the 20 CAUTI, N°8 (40%) of the 20 patients developed sepsis. N°10 (50%) were transplanted patients. N°7 (35%) were developed during ICU stay, N°13 (65%) were hospitalized in step down unit. Three of the 7 ICU patients (57,1%) required accurate output measurement, 1 required strict immobilization post-surgery, 1 had urinary incontinence and a sacral wound. In step down unit: 1 of 13 patients (7,69%) had urinary incontinence with a sacral wound, 1 patient had urinary retention, 4 (30,76%) needed accurate output measurement. 9 patients (45%) out of 20 CAUTI cases did not meet the criteria for maintaining indwelling catheter. A multidisciplinary working group with surgeons, nephrologists, anesthesiologists led by Infection Control Nurse called "Nurse Driven Protocol" (NDP) has been discussed; electronic medical documentation has been updated which will allow nurses to remove the device if criterions are met.
Conclusions: Criterion for continuous catheterization and readiness for early removal was not evaluated during the studied time as the taskforce was not active yet, however the analysis shows that 9 patients could have benefited from an early removal of the device.
Findings from literature generally support the acceptability of a NDP (4), particularly in higher-acuity units (5). And implementation of a nurse-driven protocol for the assessment of readiness to remove device as part of a multimodal CAUTI intervention strategy can result in measurable decreases of CAUTI incidence (6).

Table 1 (abstract 001055) Criterions for foley indication

	Criterion	N patient
1	Urinary retention including obstruction and neurogenic bladder	1
2	Short perioperative use in selected surgeries	0
3	Required highly accurate output measurements in ICU	7
4	Placed by urology service	0
5	Assist healing of severe perineal and sacral wounds	2
6	Required strict immobilization for trauma or surgery	1
7	Hospice/comfort care or palliative care	0

Table 2 (abstract 001055) Microorganisms associated with CAUTIs

	fungus	GRAM +	GRAM -	MDR
Klebsiella oxytoca			1	
Enterobacter aerogenes			1	
Pseudomonas Aeruginosa MDR				1
Escherichia Coli ESBL				3
Psedomonas aeruginosa			3	
Candida albicans	1			
Acinetorbacter baumannii MDR				1
CRE - Carbapenem resistent enterobacteriaceae				2

Evolution of intra-ICU infections in a terciary hospital: from the period before COVID-19 to current days

L. Fernandez Ruiz[1], I. Cruz Valero[2], A. Fuentes Calatayud[3]
[1]Hospital Santa Ana de Motril, Intensive care unit, Motril, Spain; [2]Hospital Santa Ana de Motril, Intensive care, Granada, Spain; [3]Hospital Santa Ana de Motril, Intensive care unit, Granada, Spain
Correspondence: L. Fernandez Ruiz
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001057

Introduction: COVID-19 pandemia meant an important increase of intra-ICU infections. After it, the way to work in our ICU is traying to recover its normal activity, committing all the bundles for the prevention of intra-ICU infections in an effort to reach the rates before pandemia.
Objectives: Analize main intra-ICU infection rates in our ICU, stressing on the evolution after the years of highest incidence of COVID-19.
Methods: Prospective, descriptive study, carried out in the ICU of Santa Ana Hospital in Motril in the period from 2019 to 2022. Demographics, severity index SAPS II and APACHE II, and different intra-UCI infections rates were collected.
Results: 857 patients admitted to the ICU at least for 24 h were recruited:398 in 2019, 178 in 2021 and 281 in 2022. 67% were

men, medium age 64 ± 17 years, SAPS II 32,51 ± 17 and APACHE II 11,41 ± 8,1. Medium stay in 2022 was 4,74, vs 7,32 in previous years. In relation to risk factors in 2022 vs previous years: artificial airway 26,33 vs 28,65, urinary catheter 54,80% vs 60,67%, central venous catheter 38,08% vs 42,13% and parenteral nutrition 2,85% vs 2,25%. In ICU 54,8% of patients in 2022 vs 56,18% in previous years, received antibiotics and had received them before the admission 13,17% vs 14,04%. 3,30% vs 1,12% were inmunodeficient and 0,36% vs 0,56% presented neutropenia. Including secondary bacteriemia due to other focus infection, in 2022 the rate of intraUCI infection was 12,90 infections per 1000 days of ICU stay, in front of 321,42 in 2021 and 3,95 in 2019. In 2019 ventilator-associated pneumonia (VAP), urinary infections and Catheter-Related Bloodstream Infection (CRBI) had the same incidence (28,57%). In 2021 VAP supposed 42,86% of infections, urinary infections 22,86% and primary and secondary bacteriemia related to catheter 17,14%. In 2022 NAVM continues to be the main intra-ICU infection, with bigger importance, supposing 76,47%. After it, with same incidence (5,88%) urinary infections related to catheter and bacteriemia.

We present the rates according to location in 2019,2021 and 2022. Ventilator-associted pneumonia (VAP): 3,16 per 1000 days of MV, 23,04 and 17,83. Catheter-Related Bloodstream Infection (CRBI): 1,68 bacteriemia per 1000 days of CV, 4,94 and 1,29. Urinary infections: 1,84 per 1000 days of urinary catheter, 8,65 and 1,56.

In VAP P.aeruginosa was the most frequent isolated in the three periods. In 2021 and 2022 Serratia marcescens was the second microorganism in NAVM. In relation to Catheter-Related Bloodstream Infection (CRBI), in 2022 S.epidermidis caused 100%, while in 2021 the most frequent isolated microorganism was P.aeruginosa(33%) follow by S.epidermidis (33%) and C.albicans (16,67%) and in 2019 only gramnegative bacilli were isolated. Finally, in relation to urinary infections, the most frequent isolated microorganism in 2022 was Serratia marcescens, whereas in 2021 was Candida spp. (33%) follow by Enterococcus faecalis (11,11%) and E.coli (11,11%) and in 2019 100% was caused by P.aeruginosa.

Conclusions: Normalisation of work conditions in ICU, with the decrease of COVID-19 incidence in 2022, has suppose an important decrease of intra-ICU infections rates, far away from previous rates before pandemia yet.

Epidemiological research of Open Chest Management in postoperative management for Congenital Heart Disease—Retrospective observational study at a single institution

T. Tanabe[1], K. Motono[1], T. Kawasaki[1]
[1]Department of Pediatric Critical Care, Shizuoka Children's Hospital, Shizuoka, Japan
Correspondence: T. Tanabe
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001058

Introduction: It has been reported that open chest management (OCM) is useful in management after cardiac surgery. The usefulness of OCM for congenital heart disease (CHD) has also been advocated empirically while OCM is said to carry the risk of infection. But epidemiological studies of OCM in children are limited, and actual management methods vary greatly in different institutions. Furthermore, the details and infection risk have not been revealed.

Objectives: The purpose of this study was to clarify the clinical practice of OCM and to analyze risk factors for the occurrence of infections after OCM.

Methods: Patients who underwent OCM at Shizuoka Children's Hospital were selected. The study period was from January 1, 2011 to December 31, 2022. We assigned patients who underwent OCM after CHD surgery to the extracorporeal membrane oxygenation (ECMO) group and the non-ECMO group. Exclusion criteria were those who underwent slide tracheoplasty, OCM due to mediastinitis, and OCM after the second hospitalization in the same hospital. The primary outcome was the occurrence of surgical site infection (SSI) requiring surgical intervention, ventilator-associated pneumonia, or catheter-related bloodstream infection after OCM management. The secondary outcomes were in-hospital mortality, length of hospital stay and length of ICU stay. In addition, univariate and multivariate analyses were performed to analyze risk factor of any of those serious infections after OCM.

Results: A total of 3419 cardiac surgeries were performed during the study period. 324 cases of OCM were eligible. 69 cases met the exclusion criteria, and 255 cases were included in the study; 35 were assigned to the ECMO group and 220 were assigned to the non-ECMO group. Comparing the interventions during the OCM between the ECMO and non-ECMO groups, median OCM duration was 258 h (IQR 108 to 571 h) vs 188 h (14 to 437 h) ($p < 0.05$); post-OCM infections were 13 (37.1%) vs 38 (17.3%) ($p < 0.05$). In-hospital mortality was higher in ECMO group (13 (37.1%) vs 27 (12.3%) ($p < 0.05$)), and length of ICU stay was longer in ECMO group (57 days (IQR 14 to 415 h) vs 28 days (5 to 409 h) ($p < 0.05$)). In multivariate analysis, only OCM duration over 72 h was significantly associated with post-OCM infection (odds ratio 3.2; 95% confidence interval, 1.26 to 8.12).

Conclusions: Compared with the non-ECMO group, the ECMO group had longer OCM duration and length of ICU stay, and more post-OCM infections and in-hospital deaths. In multivariate analysis, only OCM duration over 72 h was a risk factor for post-OCM infection. Further investigation is required for risk analysis of post-OCM infection.

Delirium and inflammation biomarkers in critically ill covid-19 patients

S. Stauffacher[1], Z. Ltaief[1], J. D. Chiche[1], N. Ben Hamouda[1]
[1]Adult intensive care, CHUV Centre Hospitalier Universitaire Vaudois, Lausanne, Switzerland
Correspondence: N. Ben Hamouda
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001059

Introduction: Delirium in the ICU is common and is associated with increased mortality and length of stay (LOS). In critically ill patients with COVID-19, delirium occurred in more than 50%. Whereas some risk factors have been reported in this population [1], the role of systemic inflammation in the pathogenesis of delirium and acute brain dysfunction has not yet been fully explored in patients with COVID-19.

Objectives: The aim of the study is to investigate the relationship between the advent of delirium and biomarkers of inflammation in critically ill patients with COVID-19.

Methods: We studied critically ill adult patients with confirmed SARS-CoV2 infection admitted to the Centre Hospitalier Universitaire Vaudois (CHUV, Lausanne) between March 2020 and May 2021. Patients with acute brain injury diagnosis on admission or with an ICU Length of stay < 48 h were excluded.

We measured serum cytokines and soluble cytokine receptors (IL-1α, IL-1β, IL-1RA, IL-2, IL-4, IL-5, IL-6, IL-7, IL-9, IL-10, IL-12p70, IL-13, IL-15, IL-17A, IL-18, IL-21, IL-22, IL-23, IL-27, IL-31, IFN-α, IFN-γ and TNF α), chemokines (CCL2, CCL3, CCL4, CCL5, CCL11, CXCL1, CXCL8, CXCL9, CXCL10, CXCL12, CXCL13 and TNF-β) and growth factors (NGF-β, BDNF, EGF, FGF-2, HGF, LIF, PDGF-BB, PlGF-1, SCF, VEGF-A, VEGF-D, BAFF, GM-CSF and G-CSF) by multiplex bead assay as previously described [2]. A positive CAM-ICU during the ICU stay defined the presence of delirium.

Results: 314 patients were enrolled. Mean age was 63 ± 12 years. ARDS was the primary diagnosis in 57% of the population. The incidence of delirium was 35.7% in the cohort and 68% in mechanically ventilated patients. For the immunomodultory drugs, 21% of the patients received tocilizumab (no difference between both groups), and dexamethasone was administered in 70% of the patients included (group delirium- 75% versus group delirium + 60%, p = 0.005).
TNF-β (Tumor necrosis factor), FGF-2 (fibroblast growth factor), BAFF (B-cell activating factor) were not detected in all the patients evaluated. Among all chemokines and cytokines analyzed, CCL11 (C–C motif Chemokine ligand), CCL4, IL-1β, IL-6, IL-15, IL-17A profiles showed an association with the diagnosis of delirium (Figure 1). With regard to growth factors, G-CSF was higher in the delirium group. No association was found between complement and delirium. IBM SPSS 23.0, student's t test, Mann–Whitney U test and Pearson's χ2 tests were used for statistics, level of significance $p < 0.05$.
Conclusions: We have identified in this cohort factors involved in the systemic inflammation and whose levels could be associated with delirium in critically ill patients. These inflammatory factors would be responsible (or partly responsible) for the generation of a neuroinflammation and the activation of the microglia and clinically manifested by the occurrence of a delirium.

Polymicrobial bloodstream infections per se do not increase mortality compared to monomicrobial bloodstream infections: A Korean nationwide sepsis cohort

L. Su Yeon[1], M. H. Park[1], D. K. Oh[1], C. M. Lim[1]
[1]Department of pulmonary and critical care medicine, Asan Medical Center, Seoul, Republic of Korea
Correspondence: L. Su Yeon
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001061

Introduction: It is presumed that polymicrobial bloodstream infections may have worse outcomes than monomicrobial bloodstream infections. But there is limited information about the outcomes of polymicrobial bloodstream infections in sepsis patient. We aimed to investigate outcomes of polymicrobial bloodstream infections compared to monomicrobial bloodstream infections.
Methods: This study used data from the Korean Sepsis Alliance Registry, a nationwide database of prospective observational sepsis cohort. In this registry, adult patients with sepsis from September 2019 to December 2021 at 20 tertiary or university-affiliated hospitals in South Korea were enrolled. Patients with polymicrobial bloodstream infections and those with monomicrobial bloodstream infections were compared in this study.
Results: Among the 3,823 patients with bloodstream infections, 429 of them (11.2%) had polymicrobial bloodstream infections. The crude hospital mortality of patients with sepsis with polymicrobial bloodstream infection and monomicrobial bloodstream infection was 35.7% and 30.1%, respectively ($p = 0.021$). Polymicrobial bloodstream infections per se were not associated with hospital mortality by multivariate cox proportional hazard analysis (HR 1.15, $p = 0.11$). The inappropriate use of antibiotics was associated with increased mortality (HR 1.37 [1.19–1.57], p < 0.001), and source control was associated with decreased mortality (HR 0.51 [0.42–0.62], p < 0.001).
Conclusions: Polymicrobial bloodstream infections per se were not associated with hospital mortality in patients with sepsis as compared to monomicrobial bloodstream infections. The appropriate use of antibiotics and source control were associated with decreased mortality in bloodstream infections regardless of the number of microbial pathogens.

The living experience of surviving out-of-hospital cardiac arrest: a phenomenological study

M. Karanikola[1], M. Aristidou[2], E. Kusi-Appiah[3], A. Koutroubas[1], U. Pant[3], F. Vouzavali[4], E. Lambrinou[1], E. Papathanassoglou[3]
[1]Department of Nursing, Cyprus University of Technology, Vragadinou str-Limassol, Cyprus; [2]Department of Nursing, European University Cyprus, Nicosia, Cyprus; [3]Faculty of Nursing, University of Alberta, Edmonton, Canada; [4]Faculty of Nursing, National and Kapodistrian University of Athens, Athens, Greece
Correspondence: U. Pant
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001063

Introduction: A significant number of out-of-hospital cardiac arrest (OHCA) survivors experience subsequent cognitive, physical, and emotional impairments impacting their quality of life and functionality (Sawyer et al., 2020; Wagner et al., 2021; Yaow et al., 2022). Recognizing the psychosocial and spiritual concerns of surviving out-of-hospital cardiac arrest is important in identifying care priorities, and supporting OHCA survivors and their families to live well. Qualitative studies investigating the experiences of out-of-hospital cardiac arrest survivors illuminated several common themes across cultures (Aristidou et al., 2018), along with variabilities likely due to culture-specific interpretations and language filters (Greyson, 2015; Martial et al., 2019). Therefore, a qualitative exploration to understand how Greek-Cypriot out-of-hospital cardiac arrest survivors make meaning of their experiences can help inform health care.
Objectives: The aim of the study was to understand the meaning of surviving OHCA and its aftereffects among Greek speaking survivors in Cyprys.

Methods: We employed a hermeneutical phenomenological method based on Heidegger's philosophy to inform data collection and analysis. The participants were recruited from the Registry of Cardiac Arrest of a metropolitan General Hospital in Cyprus using purposive sampling. The sample size was based on achievement of a comprehensive description and interpretation of participants' experiences, and thematic saturation. Data were collected through 60–90 min interviews guided by open-ended questions.
Results: Seven males and one female between the ages of 45 and 69 participated. Analysis revealed five themes: "*The unexpected attack*", "*Experiencing a different world*: *Transformation of Body, Time, Emotion and Sensation*", "*Restoration of the re-embodied self*", "*Life transformation*", and "*Personal transformation*". The themes were commensurate with transcultural components of Near-Death Experiences. Surviving out of hospital cardiac arrest was perceived as "a "divine gift" and a chance to continue "living in a more conscious and meaningful way".
Conclusions: Despite participants' physical and psychosocial challenges, our results show that OHCA is experienced as a powerful process of transformation, starting with the cardiac arrest episode itself, and permeating every aspect of survivors' life. A profound transformation of survivors' lives and existence was central in the experience of surviving OHCA, with strong spiritual elements, and themes bearing transcultural components of Near-Death experiences.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001064

Introduction: Predicting patient stability in the ICU is critical for effective patient care as it enables providers to allocate attention to the most critical patients. Recent studies have focused on developing various tools that predict patient deterioration and complications while in the ICU. However, predicting patient stability, i.e., identifying which patients are unlikely to deteriorate, also holds significant value for ICU providers. In this study, we describe the development of a gradient boosting classifier to predict which patients would not require intervention in the next 14 h. We further evaluate the model's performance in prospectively identifying ICU patients at low-risk for respiratory failure or hemodynamic instability.
Methods: The model development study utilized 53,071 patient ICU stays from 7 ICUs within the UMass Memorial Health Care system from 2006 to 2017. The population was divided into three cohorts. The model was trained using 42,737 stays, with hyper-parameter tuning conducted using a validation set of 5,167 stays. The performance of the model was then evaluated using a study set of 5,167 stays.
Following retrospective model development, a prospective, observational study was conducted including all patients admitted to the WakeMed tele-ICU program between May–July 2020. All clinical data, including vital signs, medication records, laboratory data, and all other electronic medical record entries, were prospectively collected and analyzed. Each stay was divided into 1-h evaluation periods, excluding the first 12 h and stays of patients defined as DNI/DNR. Respiratory failure and hemodynamic instability events were prospectively tagged by a senior on-site clinician. The model's performance was evaluated by comparing its ability to predict low risk of deterioration with expert tagging of each period.
Results: Following model training, we demonstrated that at a given moment in time, $38.8 \pm 0.06\%$ of patients across the UMass Memorial system were not in need of intervention within the following 14 h. The model was able to classify these patients as stable with a sensitivity of 0.63, precision of 0.993, and an AUC of 0.83 over the study set of 5,167 stays. The model accurately identified 2,951 twelve-hour shifts that did not require intervention, and 1,659 stays (32% of all stays) that required no significant intervention throughout the entire stay.
Following the retrospective model validation phase, we prospectively evaluated the model performance on 514 adult ICU stays across 3 ICUs covered by the WakeMed tele-ICU program. A total of 21,391 one-hour periods were analyzed. These included 19,375 (90.7%) periods with low risk for deterioration and 1,989 (9.3%) periods of instability, in which the patients experienced either respiratory failure or hemodynamic instability. The model performance in predicting the low-risk periods included a sensitivity, specificity, and PPV of 0.46, 0.97, and 0.99, respectively. Events in which patients deteriorated while the model predicted they were stable were extremely rare, with only 59 (0.27%) mislabeled periods. However, more than 40% of the periods were labeled as stable by the model.
Conclusions: This predictive model successfully identified a significant portion of the ICU patient population as low-risk for significant deterioration both retrospectively and in a real-life prospective environment. Such a prediction can enable providers to focus on the more unstable patients, leading to improved care and better patient outcomes. The model's high sensitivity, specificity, and PPV, with an

extremely low prevalence of mislabeled periods, suggest that it could be a valuable tool in clinical settings. However, further studies are necessary to validate the model's performance and assess its impact on patient outcomes.

Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001065

Introduction: Adrenaline is the first-line medication given in advanced cardiac life support. However, its impact on resuscitation outcome is unclear. Cumulative doses of adrenaline was shown to be associated with unfavourable outcome and increased mortality in patients with non-shockable rhythms. The objective of this study is to investigate the effect of adrenaline doses on return of spontaneous circulation (ROSC) and 30-day survival after an episode of in-hospital cardiac arrest (IHCA).
Methods: This retrospective cohort study collected and analysed 170 patients who suffered from cardiac arrest within a tertiary hospital in Singapore from 1st January 2020 to 31st December 2020. The primary variable was adrenaline doses categorised into quartiles, which was analysed against primary outcome of ROSC and secondary outcome of 30-day survival.
Results: The univariate and multivariate analyses are shown in table 1 for the primary outcome of ROSC. The multivariate analysis showed that patients given more than 5mg of adrenaline had a statistically significant reduced chances of ROSC (adjusted odds ratio (OR) 0.125 (0.03–0.54) and 0.016 (0–0.11) for 3rd and 4th quartile doses). The effect of adrenaline dosage was not found to be statistically significant on 30-day survival post-IHCA.

Table 1 (abstract 001065) Univariate and multivariate analysis on primary outcome of ROSC

PATIENT ROSC	UNIVARIATE		MULTIVARIATE	
	Odds Ratio (95% CI)	***p* value**	**Odds Ratio (95% CI)**	***p* value**
Adrenaline quartile				
1st *(0–3 mg)*				
2nd *(4–5 mg)*	0.339 (0.08–1.49)	0.152	0.321 (0.06–1.65)	0.174
3rd *(6–10 mg)*	0.099 (0.03–0.32)	< 0.05	0.125 (0.03–0.54)	< 0.05
4th *(10–38 mg)*	0.013 (0.00–0.05)	< 0.05	0.016 (0.00–0.11)	< 0.05
Sex				
Female	1.028 (0.54–1.96)	0.934	0.786 (0.31–2.01)	0.615
Age	0.995 (0.97–1.02)	0.720	0.982 (0.95–1.02)	0.339
Initial Rhythm				
Asystole				
Pulseless electrical activity (PEA)	3.097 (1.55–6.17)	0.001	3.353 (1.28–8.78)	0.014
Ventricular fibrillation (VF)	5.322 (1.08–26.24)	0.040	10.295 (1.03–103.08)	0.047
Ventricular tachycardia (VT)	2.129 (0.36–12.46)	0.402	2.489 (0.18–35.16)	0.500
Length of resuscitation (min)	0.950 (0.93–0.97)	< 0.05	0.988 (0.96–1.02)	0.404
Time to 1st adrenaline (min)	0.976 (0.92–1.04)	0.458	0.962 (0.88–1.05)	0.401

Conclusions: The results of the study show that patients that receive more doses of adrenaline (> 5 mg) are less likely to have ROSC.

Antibiotic selection based on microbiology of bile from gallbladder of patients with acute cholangitis

J. Fuss[1], A. Voloboyeva[2], V. Polovyj[3]
[1]Department of Surgery, Regional Hospital of Pustomyty, Lviv, Ukraine; [2]Icu, Communal Municipal Clinical Hospital 8, L'viv, Ukraine; [3]General surgery, Bukovinian State Medical University, Chernivtsi, Ukraine.
Correspondence: J. Fuss
Intensive Care Medicine Experimental 2023, **11(Suppl 1):**001066

Introduction: Acute cholangitis is a life-threatening condition, usually caused by obstruction of the biliary system or/and ascending pathogens due to an incompetent or resected sphincter of Oddi [1, 2]. The early interventional restoration of the bile flow, mostly achieved by endoscopic retrograde cholangiography (ERC), and the early antibiotic therapy are the 2 treatment pillars in the management of acute cholangitis [3–7].
Objectives: This study aimed to provide profiles of microorganisms isolated from bile and antibiotic susceptibility patterns of biliary tract infections (BTIs) in our hospital.
Methods: Patients were included when a bile culture for microbiological assessment was obtained during ERC between January 2018 and December 2022. During this period, bile cultures from 258 patients were available for analysis.
Results: Patients with an age of $\geq$ 65 years were the majority of the participants (198/258; 76.75%). The majority primary diseases were benign (86.4%; n = 223), while 13.6% were malignant. A total of 310 strains of microorganisms were isolated.

Microbial isolates	Total number	%
Gram-negative bacteria		
Escherichia coli	98	31,5
Klebsiella pneumoniae	45	14,5
Pseudomonas aeruginosa	23	7,5
Enterobacter	15	4,9
Acinetobacter baumannii	11	3,5
Proteus mirabilis	9	2,8
Citrobacter freundii	4	1,4
ESBL-producing Klebsiella pneumoniae	3	0,95
Proteus vulgaris	3	0,95
ESBL-producing Klebsiella oxytoca	2	0,7
Stenotrophomonas maltophilia	2	0,7
Aeromonas	2	0,7
C. faecalis	1	0,5
Enterobacter aerogenes	1	0,5
Gram-positive bacteria:		
Enterococcus faecalis	42	13,8
Staphylococcus epidermidis	18	5,8
Streptococcus viridis	12	3,6
MRSE	6	1,7
Streptococcus bovis	6	1,7
Staphylococcus aureus	5	1,6
Enterococcus faecium	2	0,7

Of all isolates, 219 were Gram-negative bacteria (71.1%), 91 were Gram-positive bacteria (28,9%). No anaerobes were detected in our study.
As can be seen from our studies, Escherichia coli were highly sensitive to ertapenem, imipenem and amikacin, with a high sensitivity rate of over 85%.
K.pneumoniae was completely sensitive to ampicillin, and ertapenem, and antibiotics with higher susceptibility rates include imipenem (90%), cefoperazone/sulbactam (98%).

Conclusions: Bacterial resistance increases continuously with the overuse of antibiotics, which make the treatment of BTIs more problematic. Therefore, the rational use and standard management of antibiotics are extremely necessary. Based on the timely drainage and relief of biliary tract obstruction, β-lactamase inhibitors or carbapenems should be given for acute severe BTIs.

Sex differences in the use of mechanical ventilation in a neurointensive care population: a retrospective study

F. Stretti[1], D. Utebay[1], S. Y. Bögli[2], G. Brandi[1]
[1]Intensive Care Medicine, University Hospital of Zürich, Zürich, Switzerland; [2]Neurology, University Hospital of Zürich, Zürich, Switzerland
Correspondence: F. Stretti
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001067

Introduction: Women receive less invasive mechanical ventilation (IMV) 1–4. In neurocritical care, these differences between sexes have been less investigated, but they might contribute to the sex-related differences in mortality5. The aim of this retrospective single center study was to compare the frequency of respiratory support between sexes in a neurocritical care population.

Table 1 (abstract 001067) .

	Total	Male	Female	p-value
n (%)	963	532 (55.2)	431 (44.8)	**0.0013**
Age (years, mean ± SD)	59 ± 17	59 ± 17	60 ± 16	0.379
SAPS (median [IQR])	32 [19, 48]	33 [19, 48]	32 [18, 48]	0.581
Any cerebral hemorrhage	480 (49.8)	245 (46.1)	235 (54.5)	**0.010**
Subarachnoid hemorrhage	280 (29.1)	116 (21.8)	164 (38.1)	**< 0.001**
Traumatic brain injury	23 (2.4)	19 (3.6)	4 (0.9)	**0.009**
Ischemic stroke	164 (17.0)	109 (20.5)	55 (12.8)	**0.002**
Cerebral tumor	126 (13.1)	59 (11.1)	67 (15.5)	**0.044**
Other	223 (23.2)	131 (24.6)	95 (22.0)	0.698
Respiratory comorbidity (n (%))	387 (40.2)	225 (42.3)	162 (37.6)	0.07

Methods: This retrospective study included adults treated at the neurocritical care unit (NCCU) of the University Hospital Zurich between 01.2018 and 08.2021. We collected data on demographics, intubation, re-intubation, tracheotomy, and duration of IMV or other forms of respiratory support from the Swiss ICU registry or medical records. Baseline and outcome characteristics were compared by sex in the whole population and in subgroup analysis (SPSS v. 26).
Results: A total of 963 patients were included. There was no difference in baseline characteristics, except for diagnosis (Table 1). Women had a longer ICU and hospital stay (Table 2). There was no difference between sexes in the provision of IMV but there was a difference in the duration of oxygen support. The subgroup analysis yielded similar results.

Table 2 (abstract 001067) .

	Male	Female	p-value
Reintubation (n (%))	38 (7.1)	20 (4.6)	0.133
Tracheotomy (n (%))	91 (17.1)	68 (15.8)	0.601
Ventilation support (shifts, mean ± SD)	13 ± 21	15 ± 23	0.151
Oxygen support (number of shifts, mean ± SD)	11 ± 12.5	13 ± 13.9	**0.018**
LOS Hospital (days, mean ± SD)	18 ± 13	20 ± 15	**0.010**
LOS ICU (days, mean ± SD)	8 ± 9	10 ± 10	**0.011**
ICU mortality (n (%))	37 (7)	35 (8.1)	0.494

Conclusions: Differences in mechanical ventilation according to sex have been confirmed in a recent metanalysis6, where studies investigating individual diagnostic cohorts were excluded, leading to potential biases. As an example, in the subgroup of sepsis or burn patients, sex had no influence on ICU treatment or mortality 7,8.
In our cohort, women received oxygen supplementation for a longer time. This can be explained with the higher prevalence of SAH in women. In our protocol, we aim for a higher partial pressure of oxygen due to the specific risk of delayed cerebral ischemia.
Women had a significantly longer LOS in the ICU and in the hospital. Again, we can attribute this to the higher prevalence of SAH: these patients are monitored for a longer time due to the risk of vasospasm.
As limitation of the study, it is a single center study in a high-income country. Most data on sex differences in medicine come from higher income countries6, where there could be now more awareness to possible sex-related biases.
In our NCCU population, we found no difference in invasive mechanical ventilation between sexes. Women received a longer duration of other forms of respiratory support (oxygen supplementation through High Flow therapy, mask or nasal cannula) and had a longer length of stay in the ICU and in the hospital, due to the higher prevalence of subarachnoid hemorrhage (SAH).

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001068

Introduction: Early identification and appropriate triaging those patients with severe COVID-19 pneumonia is very crucial in a resource-limited setting.
Objectives: We aimed to validate a simple physiological score, named the National Early Warning Score (NEWS), in its property for discriminating the patients with severe COVID-19 pneumonia from those with non-severe. We also aimed to investigate the performance of the updated NEWS Plus model with common risk factors at time of hospital admission in determining severe cases.
Methods: We retrospectively analyzed all adult patients (age ≥ 18) with COVID-19 infection from the Registry for COVID-19 patients of Chiang Mai, Thailand. The data were collected during the outbreak of COVID-19 between April 2021 and October 2021 from three centers in Chiang Mai including Sansai, Nakornping, and Maharaj Nakorn Chiang Mai hospitals. The patients with severe COVID-19 pneumonia were defined corresponding to the WHO Working Group for COVID-19 infection ordinal scale from six to nine [1]. We used logistic regression analyses to determine risk factors at hospitalization associated with the severe condition and assigned the score corresponding to their coefficient in the logit model. We used the concordance statistic (C-statistic) to analyze the model performance and the Youden index to determine the best cut-off point in identifying severe cases.
Results: A total of 725 adult patients with COVID-19 infection were involved. Of these, 350 (48.3%) patients suffered severe COVID-19 pneumonia. Age and body mass index (BMI) were two significant risk factors associated with severe COVID-19 pneumonia, besides NEWS. We assigned a score of 3 and 4 for an age of 40–59 and ≥ 60,

respectively, and a score of 2 and 4 for a BMI of 25.0–29.9 and ≥ 30.0, respectively. After adding these two variables into the traditional NEWS (maximal score of 20), therefore, the maximal score for the NEWS Plus (NEWS + age + BMI) model would be 27. The use of NEWS showed the C-statistic value of 0.80; 95% CI, 0.77–0.83 in determining the patients with severe COVID-19 pneumonia. While the NEWS Plus model had a better discriminative ability, with the C-statistic of 0.82; 95% CI, 0.79–0.85. It was significantly better in the C-statistic values (p = 0.012) when comparing these two models (Figure 1). The best cut-off point for the traditional NEWS and the NEWS Plus was five and eight scores, respectively. The NEWS Plus model provided slightly higher values of sensitivity and negative predictive value than the traditional NEWS, with the value of 88.0% vs. 83.7% and 84.1% vs. 80.7%, respectively.

Conclusions: The addition of age and BMI into the traditional NEWS provided more satisfaction in discriminating the patients with severe COVID-19 pneumonia from those with non-severe. A score of seven from the NEWS Plus supported physicians for early decision-making since the hospital admission and could deliver an appropriate place for admission in a resource-limited setting.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001069

Introduction: Following traumatic hemorrhagic shock, several physiological mechanisms are involved to maintain blood pressure and organ perfusion. Several hormonal systems contribute to these adaptative mechanisms but remain poorly described yet.

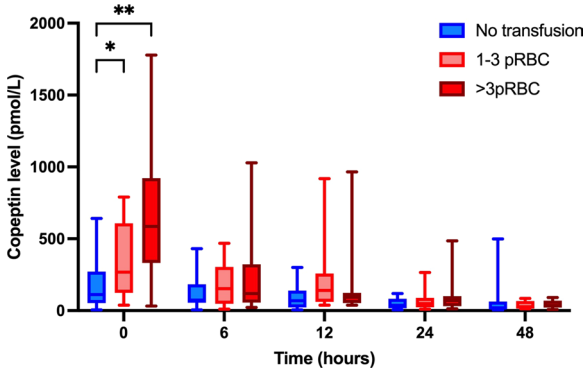

Figure 1 (abstract 001069) Copeptin evolution during the first 48 h of ICU according to the number of pack of red blood cells (pRBC) transfused.

Objectives: The main goal of this study was to explore pituitary and adrenal hormone responses to severe trauma.

Methods: We conducted a prospective and observational study in a French level I trauma center. Patients admitted to the trauma bay following severe trauma with an Injury Severity Score (ISS) > 9 were included. Vasopressin assessed through copeptin secretion, cortisol, renin and aldosterone were measured at intensive care unit (ICU) admission, and at 6-, 12-, 24- and 48-h following ICU admission. Hormone concentrations were compared over the first 48 h of admission between patients transfused with at least one pack of red blood cells (pRBC) and non-transfused patients.

Results: Sixty-six patients were included with a median Injury Severity Score of 25 (19–30). Twenty-eight (43%) patients received at least one pRBC. Evolution of copeptin level was different over the 48 h of admission between transfused and non-transfused patients (p < 0.001). Copeptin was maximum at ICU arrival and was greater in transfused than in non-transfused patients (486 ± 433 pmol/L et 208 ± 206 pmol/L; $p < 0.001$). Copeptin decreased rapidly thereafter, without difference between transfused and non-transfused patients from H6. Admission copeptin was significantly greater in patients receiving higher quantity of pRBC (no transfusion: 208 ± 206 pmol/L vs. 1–3 pRBC: 346 ± 283 pmol/L vs. > 3 pRBC: 606 ± 509 pmol/L, p < 0.001). There was no difference between transfused and non-transfused patients regarding levels of cortisol (p = 0.06), renin (p = 0.3) and aldosterone (p = 0.3) over the first 48 h of admission. Eleven (19%) patients had low cortisol (lower than the lower limit) and 44 (67%) patients presented mineralocorticoid deficiency (renin/aldosterone ≤ 2) over the first 48 h of ICU.

	All patients (n = 66)	Non-transfused patients (n = 38)	Transfused patients (n = 28)	p
Age—years	46 ± 20	47 (20)	46 (21)	0.88
Women—n (%)	18 (27)	10 (26)	8 (29)	0.84
ISS	25 (19–30)	25 (20–32)	25 (18–30)	0.90
Parameters on admission to trauma bay

	All patients (n = 66)	Non-transfused patients (n = 38)	Transfused patients (n = 28)	p
Catecholamine—n (%)	17 (25)	9 (24)	8 (29)	0.65
Evolution				
Fluid balance > 4 L H6	17 (25)	8 (3)	14 (50)	< 0.001*
Hemostatic surgery	20 (30)	2 (5)	18 (64)	0.01*
Embolisation	7 (11)	0 (0)	7 (25)	0.001*
Mortality	14 (21)	10 (26)	4 (14)	0.24

Conclusions: Vasopressin secretion is the predominant and earliest hormonal response to traumatic hemorrhagic shock. Its level is increased in patients requiring transfusion at ICU admission but decreased rapidly in the following hours. Glucocorticoid and mineralocorticoid deficiencies seem common and need further exploration. Hormonal measurement could have a prognostic and therapeutic interest for hemorrhagic shock management in trauma patients.

Surveying satisfaction and the quality of a peer-to-peer tele-medicine service for critical care physicians in Pakistan

M. A. Khan[1], K. Niazi[1], S. Sohani[1], H. Atiq[2], A. Latif[2]
[1]Dean's Office, Aga Khan University, Karachi, Pakistan; [2]Department of Anaesthesiology, Aga Khan University, Karachi, Pakistan

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001070

Introduction: Pakistan has a lack of accredited critical care programs and physicians, a problem which was exacerbated during the COVID-19 pandemic. Many things were done to rapidly expand critical care capacity in the short term, from online seminars to workshops to telemedicine with unknown degrees of effectiveness. In particular, there is a dearth of understanding on physician acceptability of tele-medicine, specifically with regards to peer-to-peer models or its use in critical care settings in low and middle income countries (LMICs).
We established a tele-critical care consultation service to help local providers manage critically ill patients that would not otherwise have access to specialized intensivists. This was set up as a "peer-to-peer" consultation service. We assessed the tele-critical care consultation service for acceptability and satisfaction to help guide future work in this area.
Objectives: Our objective is to assess perceptions of the Tele-ICU service among the physicians that use it using a structured questionnaire. Our secondary objective is to assess the quality of our service and identify areas of improvement.
Methods: We utilize a "hub-and-spoke model" of peer-to-peer telemedicine, in which physicians in ICUs across Pakistan consult critical care experts at our facility. To date, we have treated 1615 patients with 5427 tele-consultations. The study was a cross-sectional survey of end-users of the Tele-ICU project, which were on-site physicians who had utilized the Tele-ICU service at least once in a two year period from April 1st, 2020, to December 31st, 2022.
The survey form captured participants' socio-demographic data and experience in critical care, along with qualitative feedback. Questions regarding the Tele-ICU service were adapted from the guidelines by the American Telemedicine Association and organized in line with its three main themes into clinical, process, and technical. These were answered using a 5-point Likert scale, with the options being "strongly disagree," "disagree," "neutral," "agree," and "strongly agree. These responses were given incremental values from 1–5 respectively, which were then aggregated into scores for each question by calculating the mean of the responses out of 5. A net promoter score was also calculated as a metric for user satisfaction.
Results: The service was used by 360 unique physicians at 48 centers. We had current contact information of 219 total physicians, out of which we received responses from 145 (66.2%) from 39 different facilities. The vast majority of these (63.4%) were between the ages of 25–34, with 33.8% having 1–2 years of experience in critical care and 32.4% having worked for 3–5 years. 43.4% were residents, and 27.6% were medical officers. In terms of specialties, 28.3% were working in anesthesia and 26.2% in internal medicine. 52.4% participated in 1–10 tele-consultations, while 22.8% were involved in 11–20.
The three highest rated aspects of respondents' perception of our service from the clinical section were that working with Tele-ICU physicians added to their medical knowledge (4.64), that it helps them manage difficult/complicated patients (4.63), and they felt that it helped them improve patient outcomes (4.56). With regards to the process section, respondents felt that patient summaries provided by the Tele-ICU were helpful (4.52) and that they were satisfied with the teamwork during tele-consultations (4.37).
24.1% of physicians either disagreed or strongly disagreed that their internet connection was adequate enough for tele-consultations, a finding which varied significantly between provinces on Kruskal–Wallis analysis (p = 0.004) and possibly reflected geographical variation in infrastructure. When asked to qualitatively describe any shortcomings of the service, 10.3% participants felt that the requisite investigations and drugs that were advised for patients were not available. One physician said that the "treatment and management shared by the team is most of the times not available in far-flung areas." When asked if physicians would recommend the Tele-ICU service to their peers, the calculated net promoter score was 59, with 75 promoters, 54 passives, and 16 detractors.
Conclusions: The survey participants were broadly satisfied with the tele-ICU service, attesting that it improved patient care and that it was easy to utilize. Our tele-consultation model can be applied to other LMICs which require bolstering of trained critical care human resources.

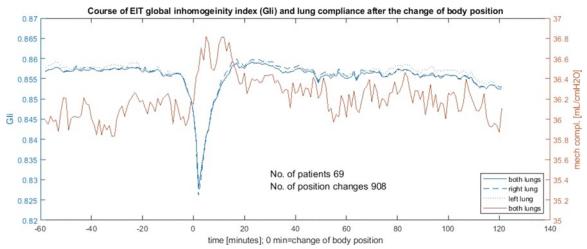
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001071

Introduction: Ventilation management maintaining normoxemia and normocapnia is an important strategy in neurocritical care. Body positioning changes the regional transpulmonary pressures, promotes postural alveolar recruitment which could improve lung ventilation homogeneity and pulmonary blood flow distribution [1].
Objectives: We attempted to quantify the effect of the standard protocol of lateral body position on parameters of lung ventilation homogeneity and compliance obtained by electrical impedance tomography (EIT). Two types of lateral tilting were used: manual positioning of the body by a nurse versus bed tilting (15° lateral tilt, LINET Eleganza 5).
Methods: 69 acute adult mechanically ventilated neurocritical care patients were continuously monitored by EIT over three days on average. We evaluated altogether 908 positions with exact times of tilting manually reviewed. Every two hours the position of the patient was changed ('supine'/'left side'/'supine'/'right side') during which lung ventilation homogeneity was evaluated by Global Inhomogenity index (GIi, [2]). The GIi of both lungs, the left lung, and the right lung was estimated by minute-wise averages, starting 60 min before, and ending 120 min after each position change. We also evaluated the course of mechanical lung compliance, EIT-based regional ventilation delay inhomogeneity index, and electrical lung compliance. SpO2 and EtCO2 parameters were compared before and after each position change (registered hourly).
Results: Tilting our patients transiently decreased the value of GIi and increased the value of lung compliance. The GIi returned to baseline within 20 min after the change of body position ($P < 0.01$), whereas the lung compliance returned to baseline after 50 min on average ($P < 0.05$), showing the dynamics of measured parameters due to the body positioning (see. Figure). SpO2 and EtCO2 parameters measured hourly did not change statistically significantly.
Conclusions: In neurocritical care patients with healthy lungs, the EIT-based lung ventilation inhomogeneity index GIi showed a temporary improvement of lung ventilation homogeneity lasting less than 20 min on average after a body position change. The increase of lung compliance lasted roughly 50 min on average.



Global Inhomogenity index (GIi) and lung compliance.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001072

Introduction: The SARS CoV2 pandemic has been a real challenge for the scientific community facing a disease hitherto unknown. The most severe clinical form of clinical presentation has been the development of severe pneumonia with respiratory distress syndrome, requiring this population admission to the ICU.
Objectives: The aim of this study is to analyze physical and psychological sequelae in patients admitted to the ICU due to severe SARS CoV2 pneumonia.
Methods: Observational, descriptive and qualitative interview study based on the collection of data from patients admitted to the ICU of a community Hospital for SARS-CoV-2 in the period from March 2020 to December 2021. A structured telephone interviews was conducted to know the symptoms and to assess activities of daily living at the time of the assessment. Statistical analysis: Data were analyzed by SPSS 20, quantitative variables were expressed as a mean ± standard deviation and qualitative by percentage.
Results: 106 patients were admitted to the ICU, 16 patients did not respond or could not be located, finally a total of 90 patients were included, 45.6% of whom were in employment. The clinical characteristics of patients are summarized in Table 1. Telephone interview was performed 65 ± 20 weeks after discharge from ICU. 81.11% were found to have some symptoms related to the past infection (Figure 1) while 18.89% reported being asymptomatic. Some degree of dependence or disability to carry out basic activities of daily living was found in 18.8%. Table 2 shows degree of dependence by Rankin scale.

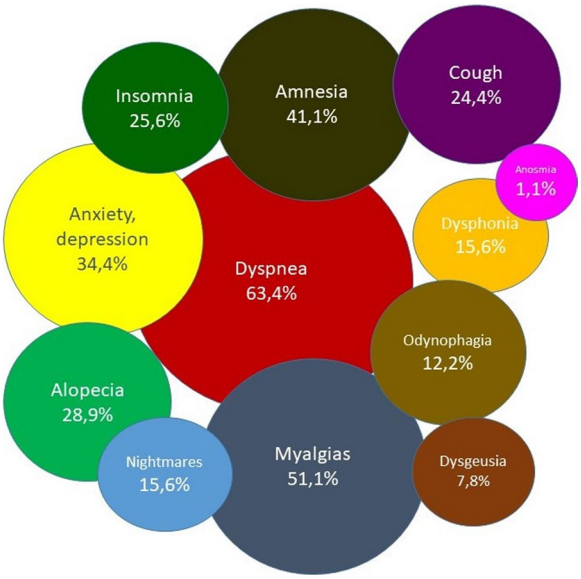
Table 1 (abstract 001072) Clinical characteristics of patients included in the study

Patients discharged from ICU after severe SARS CoV2 Pneumonia. n: 90	
Age (years)	58.9 ± 11.85 years
Gender: Male/ Female	59 (65.6%)/ 31 (34.4%)
Obesity/ Hypertension/Diabetes/Dyslipidemy	22 (24.4%)/50 (55.5%)/ 26 (28.8%)/42 (46.7%)
Heart disease / Respiratory disease/ Chronic Kidney disease	24 (26.7%)/ 11 (12.2%)/6 (6.6%)
Mean length of ICU stay (days)	15.58 ± 15.69
Invasive Mechanical ventilation requirements	56 (62.2%)

Table 2 (abstract 001072) Degree of dependence measured through the Rankin scale

Grade	Frequency	Percentage
No symptoms No significant disability. Able to carry out all usual activities, despite some symptoms	73	81.1%
Slight disability. Able to look after own affairs without assistance, but unable to carry out all previous activities	10	11.1%
Moderate disability. Requires some help, but able to walk unassisted	4	4.4%
Moderately severe disability. Unable to attend to own bodily needs without assistance, and unable to walk unassisted	3	3.3%

Conclusions: Months after admission to the ICU for severe SARS-CoV-2 pneumonia, most patients reported symptoms related to the past infection, with dyspnea, myalgia, amnesia and anxious-depressive mood being the most frequent.



Symptoms after ICU admission due to SARS-CoV2 pneumonia.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**0001073

Introduction: Cerebral hypoxia is a frequent cause of secondary brain injury in patients with acute brain injury 1. Although hypercapnia can increase intracranial pressure, it may have beneficial effects on tissue oxygenation 2. We aimed to assess the effects of hypercapnia on brain tissue oxygenation (PbtO2) 3.
Methods: This single-center retrospective study (November 2014-June 2022) included all patients admitted to the Intensive Care Unit (ICU) at Erasme Hosptial (Bruxelles) after an acute brain injury who required multimodal monitoring including PbtO2 and who underwent induced hypercapnia according to the decision of the treating physician. Patients with imminent brain death were excluded. "Responders" to hypercapnia were defined as an increase of at least 20% in PbtO2 values when compared to baseline levels.
Results: On a total of 163 eligible patients, we identified 23 (14%) patients who underwent induced hypercapnia during the study period; 6 patients had traumatic brain injury (TBI) and 17 subarachnoid hemorrhages (SAH). There was a significant overall increase in the median PtbO2 values from baseline [21 (19–26) to 24 (22–26) mmHg; p = 0.02] after the reduction in minute ventilation There was a small increase (p = 0.63) in ICP after hypercapnia from 8 (7–18) to 10 (8–20) and a non-significant (p = 0.39) reduction in CPP from 113 (99–121) to 106 (88–118). There was no correlation between increases in CO2 (delta CO2) and changes inPbtO2 (delta PbtO2): r spearman − 0.028 (95% CI − 0.0446 to 0.0399). Responders (n = 14/23, 61%) after induced hypercapnia had numerically lower mortality rate than others. [4/14 (29%) vs 3/9 (33.3), p = 0.88].
Conclusions: In this study, a heterogeneous response of brain tissue oxygenation to induced hypercapnia was observed, but without any deleterious elevations of ICP.

Novel extracorporeal therapy device using reactive oxygen species scavenging microbeads for effective sepsis treatment

P. Im[1], D. Kim[2], J. Kim[1], H. G. Jeong[2]
[1]School of Chemical Engineering, Sungkyunkwan University, Suwon-si, Republic of Korea; [2]Division of Neurocritical Care, Departments of Neurosurgery and Neurology, Seoul National University Bundang Hospital, Seongnam-si, Republic of Korea

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**0001074

Introduction: Sepsis is a life-threatening condition that has been challenging to treat. Despite the initial excitement surrounding extracorporeal hemoperfusion devices that remove endotoxin or cytokines, they have ultimately been deemed ineffective and are not recommended for use in guidelines.
Objectives: We aimed to develop an extracorporeal therapy device using microbeads that could effectively treat sepsis by removing excessive reactive oxygen species.
Methods: The mesocellular silica foams (MCF) microbeads were synthesized using a modified template method, while the Ceria nanoparticles (CeNP) were synthesized in an aqueous phase using 6-aminohexanoic acid. CeNP-loaded MCF microbeads (CeMCF) were obtained by mixing CeNPs solution with MCF microbeads, and the resulting product was PEGylated using methoxy PEG-amide-succinimidyl glutarate 5000. The surface morphology, element composition, pore size, pore volume, and surface area of the microbeads were characterized. reactive oxygen species scavenging properties of the microbeads were evaluated in both wells and cartridge systems. Male Sprague–Dawley rats (n = 3; CeMCF, n = 3; control) were used in animal experiments. Rats were anesthetized, intubated, and mechanically ventilated, and cannulation with a 24 gauge catheter was performed in the right common carotid artery, right common femoral artery, and left common femoral vein. An extracorporeal hemoperfusion circuit was set up using tubing, 3-way connectors, a peristaltic pump, and a microbead cartridge connected to the cannula in the common carotid artery and common femoral vein. To induce septic shock, a lethal dose of lipopolysaccharide (20 mg/kg) was intravenously injected. Hemoperfusion was performed for 4 h at a flow rate of 1 to 3 ml/min, and

intravenous norepinephrine was used when hypotension occurred. The serum lactic acid level was measured at the end of hemoperfusion therapy.
Results: MCF with a size of approximately 500 μm and high surface area (244.73 m2/g) and pore volume (0.56 cm3/g) were synthesized. 1 g of MCF was mixed with 5 mg/mL CeNPs, resulting in 100% loading efficiency confirmed by inductively coupled plasma mass spectrometry, scanning electron microscope and energy-dispersive X-ray spectroscopy (Ce 12.54 wt% in CeMCF microbeads). The resulting CeMCF microbeads had sufficient reactive oxygen species scavenging properties in hydrogen peroxide and hydroxyl radical assays, with CeMCF exhibiting up to 90% scavenging efficiency at a concentration of 10 mg. In cartridge system tests, CeMCF microbeads showed significant hydrogen peroxide removal efficiency, with approximately 40% removal after 1 cycle, approximately 50% after 2 cycles, and approximately 70% after 3 cycles, while MCF microbeads showed no significant removal. Hemoperfusion treatment for 4 h in an animal sepsis model using lethal dose of LPS significantly reduced lactic acid levels (4.4 mmol/L in CeMCF microbeads vs. 7.1 mmol/L in the control, $P < 0.01$) and intravenous norepinephrine demand (mean 0.08 ± 0.03 mcg/kg/min in CeMCF microbeads vs. mean 0.49 ± 0.14 mcg/kg/min in the control, $P = 0.02$).
Conclusions: In conclusion, we have developed a novel extracorporeal therapy device using microbeads that effectively scavenges reactive oxygen species and reduces lactic acid levels in a rat sepsis model. Our CeMCF microbeads demonstrated high scavenging efficiency in both well and cartridge system tests, and significantly reduced lactic acid levels and intravenous norepinephrine demand in the animal sepsis model. Our findings suggest that CeMCF microbeads could be a promising therapy option for sepsis treatment, and warrant further investigation for potential clinical applications.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**0001075

Introduction: Cerebral microdialysis (CMD) has become an established bedside monitoring modality 1 but its implementation remains complex and costly and is therefore performed only in a few well-trained academic centres.
Objectives: This study investigated the relationship between cerebrospinal fluid (CSF) and CMD glucose and lactate concentrations 2 -3.
Methods: Two-center retrospective study of prospectively collected data. Consecutive adult (>18 years) acutely brain injured patients admitted to the Intensive Care Unit between 2010 and 2021 were eligible if CSF and CMD glucose and lactate concentrations were concomitantly measured at least once.
Results: Of 113 patients being monitored with an external ventricular drainage and CMD, 49 patients (25 from Innsbruck and 24 from Brussels) were eligible for the final analysis, including a total of 96 measurements. Median CMD glucose and lactate concentrations were 1.15 (0.51–1.57) mmol/L and 3.44 (2.24–5.37) mmol/L, respectively; median CSF glucose and lactate concentrations were 4.67 (4.03–5.34) mmol/L and 3.40 (2.85–4.10) mmol/L, respectively. For the first measurements, no correlation between CSF and CMD glucose concentrations ($R2 < 0.01$; $p = 0.95$) and CSF and CMD lactate concentrations ($R2 = 0.16$; $p = 0.09$) was found. Considering all measurements, the repeated measure correlation analysis showed also no correlation for glucose (rrm = -0.01; 95% Confidence Intervals − 0.306 to 0.281; $p = 0.93$) and lactate (rrm = -0.11; 95% Confidence Intervals − 0.424 to 0.236; $p = 0.55$).
Conclusions: In this study including acute brain injured patients, no correlation between CSF and brain tissue measurements of glucose and lactate was observed. As such, CSF measurements of such metabolites cannot replace CMD findings.

Mechanical ventilation and communication barriers in intensive care units: a qualitative study
S. Brambilla[1], D. Ausili[2], G. Bellani[3], M. Luciani[2]
[1]Scienze infermieristiche, University of Milano Bicocca, Monza, Italy; [2]Department of Medicine and Surgery, University of Milano Bicocca, Monza, Italy; [3]Department of Anesthesia and Intensive Care, University of Trento, Trento, Italy
Correspondence: S. Brambilla
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**0001076

Introduction: Mechanically ventilated patients are unable to verbally communicate due to the presence of the endotracheal tube or the tracheostomy, rendering them temporarily "voiceless" [1]. With the emergence of a new paradigm based on light/no sedation, more and more patients are conscious during mechanical ventilation. Communicating with conscious voiceless patients can be complex and frustrating and lead to negative outcomes and experiences for patients, caregivers, and healthcare professionals [2,3].
Objectives: To explore the negative effects of conscious voiceless patients' inability to communicate verbally in Intensive Care Units (ICUs).
Methods: This qualitative study uses *Interpretive Description* methodology [4]. Semi-structured interviews were conducted with patients, caregivers, nurses, and physicians. Data were collected at two ICUs in Italy from August 2021 to September 2021. Data were analyzed using the *Rapid and Rigorous qualitative data analysis*—RADaR [5].
Results: Forty-three people were interviewed (10 patients, 13 caregivers, 13 nurses, and 7 physicians). Three major themes were identified: "Patient isolation due to lack of interaction", "Inadequate care due to communication barriers: missed care and overtreatment", and "Short- and long-term negative psychological and emotional consequences". The findings indicated that communication difficulties in ICU have negative emotional and psychological consequences for all participants. Most patients reported experiencing fear, anger, irritation, and frustration as a result of continuous communication failures and a lack of understanding of their needs. Such experiences often led patients to isolate themselves and feel disconnected from reality. Healthcare professionals' inability to understand patients and communicate effectively resulted in feelings of inadequacy and impacted patients' care negatively. The study found that healthcare professionals often reported that misunderstandings led to incorrect or unnecessary treatments, especially for patients who were agitated and difficult to interact with. Due to the inability to communicate during

the hospitalization, patients declared to suffer from post-traumatic stress symptoms, that persist beyond discharge from ICU. Patients continue to have nightmares and unpleasant memories for months, which negatively affects their daily lives.
Conclusions: This study confirmed that communication plays a crucial role in patients' care and recovery process, while also affecting caregivers' stress and healthcare professionals' frustration. Our findings emphasized the need to develop new communication methods and tools that can facilitate communication with conscious voiceless patients.

Introduction: Diaphragmatic Ultrasound (DU) became an additionnal tool for monitoring critiaclly ill patients admitted for respiratory failure. Its effectiveness in critical care units (ICU) is widely explained in view of it's a non-invasive technique, easy to use and rapidly available at the bedside.
Objectives: to determine performance of diaphragmatic ultrasound by measuring different parametres (diaphragmatic excursion (DE), inspiratory time (IT), and thickening fraction (TF)) in dyspneic patients admitted to ICU with acute respiratory failure.
Methods: We conducted a prospective observational study from January 1st to March 31th 2023, including non intubated patients admitted with acute respiratory failure in ICU of Zaghouan's regional hospital, Tunisia. DU were performed daily by the same operator by mesearing DE, IT and TF. Measurements were made in a sitting position and were averaged from at least three different respiratory cycles. Subsequently obtained ultrasound measurements and clinical parametres were recorded and analyzed. 2 groups were identified: G1 = patients who need only oxygen support until discharge and G2 = use of invasive mechanical ventilation.
Results: A total of 25 consecutive patients were enrolled, with a total of 70 DU. Median age was 60 years [31–90]. Gender ratio was 4. DU was performed overall on noninvasive ventilation (14 on high flow nasal cannula and 11 on high concentration oxygen mask). Acute respiratory failure were respectively secondary to: community acquired pneumonia (n = 19), acute pulmonary edema (n = 3), pulmonary embolism (n = 2) and post-traumatic pulmonary contusion (n = 1). Eight patients required invasive ventilation (G 2).
In comparaison the 2 groups characteristics at admission we noted that DE was greater in G1 (1.8 cm [1.10–3.6] vs 1.42 cm [0.8–2.00], $P = 0.14$) and IT was longer in group 1 (0.7 s [0.40–1.18] vs 0.55 s [0.35–0.70] with no significant difference. TF were similar in both groups (25.75% vs 25.50%). In group 1, repeated DU revealed a progressive improvement of the DE and a lengthening of the IT without modification of the TF (Table 1).
Conclusions: In non intubated adult patients admitted with acute respiratory failure, the use of ultrasonographic assessement of DE, IT and TF seems to be feasable, useful and an accurate tool to detect and monitor respiratory function. Further studies are needed to evaluate its impact on clinical practice.

Table 1 (abstract 001078) .

Time / Groups	Day 1			Day 2			Day 3			Day 4		
	DE cm	IT s	TF %	DE cm	IT s	TF %	DE cm	IT s	TF %	DE cm	IT s	TF %
Group1	1.8	0.70	25.75	1.78	0.73	31	2	0.71	25.7	1.96	0.77	31.5

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001079

Introduction: One of the determining factors for the COVID-19 course of treatment is disease severity. Medical imaging, particularly CT scans and X-rays, is frequently used in this assessment. However, these methods have significant downsides. Lung ultrasound has recently gained recognition as an alternative to CT scans and X-rays due to the advantages presented by the exam. Lung ultrasounds are cost-effective, portable, fast, non-invasive, easily repeatable, and do not expose patients to radiation. These aspects are particularly relevant in the context of low-resource healthcare providers.
Objectives: This study proposes a framework for automated severity analysis of COVID-19 lung ultrasounds, intended to detect frames presenting alterations indicative of the disease and provide its subsequent severity classification.
Methods: The process included two approaches for dimensionality reduction. One combined the use of IPCA (Incremental Principal Component Analysis) and UMAP (Uniform Manifold Approximation and Projection), and the other explored the usage of an autoencoder. The lower dimensional representations obtained were then clustered using the K-Means and GMM (Gaussian Mixture Models) algorithms. According to the pipeline, the obtained clusters would be tested on their ability to improve classification performance. However, since such evaluation isn't possible, the process was carried out to demonstrate the concept.
Results: The elected Pleura, B-Lines, Subpleural Consolidation, and Lobar Consolidation classifiers achieved very high evaluation metrics. The Pleura classifier obtained an accuracy of 99% and an average F1-Score of 99%. The B-Lines model attained an accuracy of 96% and an average F1-Score of 96.5%. The Subpleural Consolidation achieved an accuracy of 99% and an average F1-Score of 96.5%. Finally, the Lobar Consolidation classifier achieved perfect metrics, obtaining perfect accuracy and an F1-Score score. These results prove that having pre-selected informative frames makes it possible to train a classifier to reproduce the doctor-attributed scores.
Conclusions: Based on these findings, the study concluded that by having pre-selected informative frames, it's possible to train a classifier to reproduce the doctor-attributed scores, which could ease the learning process of healthcare providers and enable them to obtain expert-level LUS severity assessments even in low-resource situations.

Introduction: Laryngotracheal injuries are a common cause of disability following invasive mechanical ventilation in intensive care units (ICUs). Its incidence is underestimated specially if symptoms occur after discharge from ICU.
Objectives: In this study, we investigated the rate of laryngotracheal complications in patients discharged from ICU after orotracheal intubation (OTI).
Methods: It was a prospective observational follow-up study. Patients who were treated with endotracheal intubation, in the ICU of Zaghouan's regional hospital between November 2021 and November 2022, and who underwent systematic laryngotracheal evaluation using a flexible endoscope after extubation or tracheostomy by otolaryngologists, were included in this study. Clinical data, conditions of intubation as well as the characteristics stay in ICU were recorded.
Results: During the study period, 77 patients were intubated,43 of them were discharged and 34 died. Thirty-two patients met the inclusion criteria. Mean age was 41.5 years ± 21 [15–80] and sex ratio was 3.5. Mean SAPS II and APACHE II scores were respectively 34.4 ± 15.6 and 15.3 ± 10. Mainly reason for OTI was neurologic distress in 19 patients, respiratory failure in 8 cases and hemodynamic failure in 5 cases. Chronic obstructive pulmonary disease, diabetes mellitus and hypertension were the most frequent comorbidities. Six patients had a medical history of anterior OTI. At admission, OTI was performed with video-laryngoscopy in 11 cases. Immediate complications of IOT were: esophageal intubation (n = 4), oral injuries (n = 7), two or more failed attempts (n = 5) barotrauma (n = 1). Means duration of OTI and ICU length of stay were respectively 10 [1–28] and 20 days [2–84]. Two patients required orotracheal reintubation during hospital stay. Self extubation Occurred in 5 patients. Five patients had undergone tracheostomy and were discharged with.
Otorinolaryngology examination was performed in patients approximately 3 weeks after extubation. Of the total number of patients examined (n = 27), Adverse consequences were found in 11 patients. It was laryngotracheal stenosis in 6 patients, Unilateral vocal fold immobility in 3 cases, laryngeal oedema and tracheomalacia in one case each. only one tracheotomized patient devolopped tracheal stenosis.
Following factors presenting statistical significance for the development of laryngotracheal injuries: duration of OTI (P = 0.004), mallampati class III and IV (P = 0.008), esophageal intubation (P = 0.02), dysphonia developped after extubation (P = 0.03), swallowing disorder (P = 0.026).
Outcome was favorable in 27 patients, four patients still tracheotomized and only one patient died.
Multivariate analysis showed that duration of OTI ≥ 10 days was independent risk factor of larayngotracheal injuries.
Conclusions: Post-intubation laryngotracheal damage was frequent and of poor prognosis despite systematic and early diagnosis. Systematic follow-up after discharge and patient education is essential.

Introduction: Healthcare-associated infections (HAIs), especially in critically ill, are related to an increased length of hospitalization and significant increases in morbidity, mortality, and economic costs [1]. The incidence of HAIs in the intensive care units (ICU) is reported to be around 22% [2], while a higher proportion of multidrug-resistant (MDR) strains is also documented here [3]. Although most HAIs are of endogenous origin, bacteria can be also transmitted between patients either through droplets, contaminated objects, or the hands of staff and cause HAIs exogenously. Monitoring the spread of identical bacterial clones on wards is an important component in the prevention of HAIs. Early detection of the spread of MDR strains can prevent an infectious outbreak and help to guide antibiotic stewardship.
We present our experience with the McRAPD (Melting curve of Random Amplified Polymorphic DNA) typing technique based on combination of two previously described methods (see also www.typingforlife.cz) at the Department of Anaesthesiology, Resuscitation and Intensive Care (KARIM), University Hospital Olomouc, Czech Republic. We believe the technique has the potential to become a fast and relatively cheap screening tool for identification of suspected bacterial clones and it can prevent the emerging outbreaks. Based on the results obtained, system gaps or non-adherence to the epidemiological regimes can be detected and their correction can be carried out.
Methods: All isolates of gram-negative bacteria obtained as part of routine microbiological diagnostics between March and December 2022 from KARIM patients were identified using MALDI-TOF MS. The first isolate of each species detected from each patient was included in weekly strain typing. Authorized workers from KARIM and the Department of Hospital Hygiene received the results in the form of a regular report.
Results: At KARIM, the most significant pathogens identified were *Klebsiella pneumoniae* and *Klebsiella variicola*. During the 6 months of the project 55% of all cases of *K. pneumoniae/variicola* colonization or infection at KARIM were caused by clonal isolates of these two closely related species, of which in 61% patients multiresistant clones—ESBL + or AmpC + were detected.
The highest proportion of clonal spread was found in *Burkholderia multivorans* showing the clonal spread in all cases, but two. Two

clones were identified. One dominant (32 patients) and one minor (7 patients).
Conclusions: During the monitoring a high rate of clonal spread of bacteria was noted at KARIM; e.g. transfer between neighbouring patients, a succession of beds or during transfer of patients between units. The information obtained was used to revise the hygienic-epidemiological regimes and for evaluation of compliance with local guidelines. From our observation it seems that most of the clonal spread goes unnoticed and is not recorded by traditional methods of surveillance.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001082

Introduction: Indirect calorimetry (IC) is considered the gold standard for measuring resting energy expenditure (REE) in critically ill patients and has shown to significantly reduce short-term mortality (1). Recent guidelines have therefore strongly recommended its use over predictive methods (2). However, IC has several limitations and is not always feasible. Furthermore, there are no validated protocols for its use, and those existing are guided mainly by expert opinions.
Objectives: We sought to confirm the hypothesis that REE in critically ill patients measured by IC significantly differed from that estimated by predictive methods. We then aimed to identify factors associated with resting energy expenditure variability and with the postulated inaccuracy of predictive methods.
Methods: Retrospective cross-sectional cohort study in a level 3 ICU. All valid IC measurements performed from October 2022 to April 2023 were included. IC was performed in invasively ventilated patients with an expected length of stay > 72 h using Q-NRG + device. Exclusion criteria were FiO2 > 70%, PEEP > 10 mmHg, air-trapping, air-leak, ECMO or CRRT. REE was measured by IC and simultaneously estimated using both weight based predictive method (25 kcal/kg/24 h) and Mifflin-St Jeor predictive equation (MSJ). Significant difference between measured and estimated REE was defined as a ± 10% difference from IC. Statistical analysis was performed using Qui-square, T-student and Mann–Whitney U tests. Correlations were evaluated using Pearson or Spearman tests.
Results: A total of 45 IC measurements were performed in 29 patients (maximum 3 per patient) and were included in the study. REE estimated by weight based predictive method and MSJ equation was accurate in only 31.1% and 20% of measurements respectively. Mean measured REE was 20.1 (± 6.2) Kcal/kg/24 h and was significantly lower in patients with body mass index (BMI) > 30 (17.5 vs 21.4, $p < 0.05$). Measured REE (Kcal/kg/24 h) was positively correlated with day of ICU stay ($r = 0.305$, $p < 0.05$) and negatively correlated with age ($r = -0.484$, $p < 0.001$) and ideal body weight ($r = -0.376$, $p < 0.05$). Weight based predictive method performed worse at estimating REE in obese patients ($p < 0.001$) and in the early phases of ICU stay (6.3th vs 10.4th day of ICU stay, $p = 0.005$). REE estimated by MSJ equation was inaccurate across all tested variables.
Conclusions: IC should be performed to measure REE whenever possible in critically ill patients to guide energy delivery, as recommended by recent guidelines, given the variability and consequent inaccuracy of currently available predictive methods. Our study confirmed that this is particularly relevant in obese patients and in the early phases of critical illness, where estimated REE by weight based predictive method (25 kcal/kg/24 h) performs worse. A valid method for predicting REE in critically ill patients whenever IC is either unfeasible or unavailable is urgently needed.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001083

Introduction: Acute Kidney Injury (AKI) is a clinical condition that develops in more than 40% of patients after cardiac arrest (CA). Few studies have evaluated the role of urinary electrolytes on the recurrence of AKI after CA.
Objectives: To assess whether urinary chloride levels as well as chloride load and balance are associated with the development of AKI in CA patients.
Methods: Retrospective single center study including all comatose adult patients admitted to the Intensive Care Unit (ICU) after cardiac arrest (CA) from January 2007 to December 2014. Inclusion criteria were: age ≥ 18; non-traumatic arrest; complete data available on serum and urinary samples for at least 3 days; survival ≥ 24 h after admission. Patients with previous AKI, anuria and on chronic haemodialysis were excluded.
We collected chloride levels on daily serum (SCl) and urinary (UCl) analyses; chloride load (Clload) was calculated by considering the amount of chloride present in the IV fluids and nutrition administered daily to the patient, while chloride balance (Clbalance) was calculated as: Clload—Cloutput, where Cloutput is UCl × daily urine output. AKI was defined according to the latest AKIN criteria.
Results: Of the 404 eligible patients, 165 met the inclusion criteria and were analyzed. Out of CA occurred in 102 (62%) patients, median time to ROSC was 15 [10–25] minutes, 74 (45%) patients had a shockable initial rhythm. ICU mortality was 48% (n = 80). Patients with favorable outcome (CPC 1–2) at 3 months were 75 (45%). 70 patients (42%) developed AKI after a median of 2 [2–3] days since admission; 20 of them (12%) also needed continuous renal replacement therapy. No differences in the daily fluid balance was observed between AKI and non-AKI patients, however, despite a similar Clload, patients with AKI had a lower Cloutput (43 [12–142] vs. 177 [72–292] mmol; $p < 0.001$) and UCl (66 [32—92] vs. 102 [60–137] mEq/L; $p < 0.001$) than others. This resulted in a higher serum chloride levels in the AKI group. These differences were maintained during the first five days of ICU stay.

Conclusions: After CA, AKI occurred in 42% of patients and was associated with a significant difference in renal chloride elimination, already on admission.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001084

Introduction: A crucial step in the transition from mechanical ventilation (MV) to extubation is the successful performance of a spontaneous breathing trial. Successful weaning from MV depends on the patient's ability to cough efficiently. Evaluation of cough strength via objective measures using peak expiratory flow rate is a non-invasive and easily reproducible way that may predict extubation failure.
Objectives: We aimed to predict extubation outcome using an overall model, including cough performance with a cough peak expiratory flow (PEF) measurement assessed by a ventilator flow meter.
Methods: A prospective observational study was conducted from January 2018 to December 2019. After a successful spontaneous breathing trial, subjects were encouraged to cough as strongly as possible before freezing the ventilator screen to assess cough peak measurement. Epidemiological, clinical, biological, and therapeutic data were captured from medical records.
Results: During the study period, we enrolled 43 patients. The mean age was 61.8 ± 15 years and the sex-ratio was 1.88. The mean IGSII and APACHE II scores were respectively 39.5 ± 13.8 and 17.1 ± 6.15. The most prevalent morbidities were chronic obstructive pulimonary disease (46.5%) and asthma (9.3%). All patients required extubation after a mean duration of MV of 24.4 ± 29 days and mean duration of volume-controlled assisted ventilation mode was 15.9 ± 30 days. The mean number of weaning trials was 1.42 ± 0.7 [1–4] carried out by Tpiece weaning trial in 76.9%. Reintubation was noted in 26.8% of cases and the mortality was 16.7%.
The mean of PEF was 63.2 [35–120] l/min and it was correlated with the extubation failure ($p = 0.03$). The mean PEF in the sub group of extubation filure was 53.1 ± 16. A cut-off value of 45 l/min was identified as a predictive value of extubation failure (sensibility 96.7% and 54,5% of specificity and area under the curve ROC = 0.703) (Figure 1).
Conclusions: PEF measured using the flow meter of an ICU ventilator above 45 l/min was able to predict extubation outcome with very high sensibility. External validation of this value is mandatory.

Who cares for those who care? Burnout in a tertiary ICU—results from pilot study

G. C. Almeida[1], M. P. Vidal[1], J. E. Mateus[1], I. Santos[1], A. Martinho[1], A. Catarino[1], M. Simões[1], P. Martins[1]
[1]Intensive Care Unit, Centro Hospitalar e Universitário de Coimbra, Coimbra, Portugal

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001085

Introduction: Continued confrontation with persistent and often silent professional stressors can lead to burnout syndrome, despite ineffective coping attempts. Burnout is a psychological syndrome, characterized by high emotional exhaustion, high depersonalization and low professional achievement, which leads to the erosion of personal, professional and health values. An estimated 15% of working-age adults have a mental disorder at any point in time and the health sector is particularly affected by this.
Individuals with burnout generally have a reduction in the quality of professional performance, with a higher probability of medical error, higher rates of absenteeism, less commitment to the function and to the employer, decreased job satisfaction, higher occurrence of medical leave, greater personal distress and increased interpersonal conflicts involving bosses, colleagues, and family, alcohol and other psychotropic abuse, and lower levels of physical exercise or other healthy lifestyle activities.
Intensive care physicians are a group very susceptible to this disorder, especially due to the complexity and severity of patients, excessive workload, high technical demand, advanced communication skills and management of strong emotions.

Objectives: The aim of this study was to evaluate the levels of burnout among physicians in the intensive care unit of a tertiary hospital in Portugal and to investigate related risk factors and consequences of this syndrome.
Methods: An online questionnaire was sent for voluntary and anonymous completion to all physicians working in the hospital's intensive care unit. Sociodemographic characterization questions, including risk factors for burnout, assessment of the incidence of burnout and professional and personal consequences were asked. The last part of the questions aimed at collecting suggestions and wishes for improvement of mental health in the professionals surveyed. The Maslach Burnout Inventory—Human Services Survey (MBI-HSS) was used in its validated translation for Portuguese as an objective measure in quantifying the prevalence of burnout, consisting of 22 items that involve the three dimensions of this syndrome: emotional exhaustion, disbelief/depersonalization and professional achievement. Each item was classified on a numerical scale between 0 (never) and 6 (every day). For each category, the sums of the scores were calculated and classified as low, intermediate or high risk.
Results: A total of 32 responses were obtained. 6 (18,8%) physicians scored Low Risk in the 3 components, especially specialist physicians (5/6), male and with less time working in this intensive care unit. Only one (3,1%) doctor scored High Risk for the 3 categories of burnout and three for at least two of them. The decrease in professional achievement was the one that most often scored as High Risk in the variables analyzed. In terms of the consequences of burnout, most respondents revealed that working in the intensive care unit has an impact on their health (physical and/or mental), on their family relationships and even on the appearance of medical error in their professional practice.
Conclusions: Among physicians working in this intensive care unit, the prevalence of burnout can be considered relevant. Regular measures to identify, prevent and resolve this syndrome should be implemented to increase the personal and professional fulfillment of these workers and reduce the possible consequences (personal and organizational).
In the future we expect to increase research in this area and make a comparison with other units of other national hospitals.

Introduction: SARS-CoV2 infection is a systemic infection in which the development of a severe form is thought to be related to an imbalance in the innate and adaptive immune response. Neutrophil-to-lymphocyte (NLR) ratio is a strong indicator for the early detection of patients at risk of developing a severe form. Its contribution in critically ill patients admitted to the ICU remains controversial.
Objectives: The aim of our work was to study the kinetics of NLR and its impact on mortality.
Methods: This was a descriptive, retrospective, single-center study conducted from March 2020 to December 2021. Patients over 18 years old hospitalized with confirmed severe COVID-19 pneumonia were included. Two groups of patients were identified (dead and survivors). A study of NLR kinetics during ICU stay and a comparison between the two groups were performed.
Results: The study included 460 patients with 198 survivors. Dead patients (n = 262) were older, had more comorbidities and more severe clinical presentation of the disease. The mean time to admission to the ICU was comparable and the medical treatment was standardized.
The NLR was significantly higher in the dead group at almost every control point (Figure 1). In the survivor group, the NLR decreased since admission. In the dead group, the elevation of NLR at the beginning of the stay was significantly higher with a peak at Day10. The comparison between the two groups identified four factors associated with mortality. These were NLR D0, NLR D3-5, NLR D10 and Delta NLR D3-5. On multivariate analysis, only an NLR at D10 ≥ 8 (OR = 10.14; CI95% [(5.46–18.84]; p < 10–3) was independently associated with an increased risk of death.
Conclusions: Our study confirm that baseline NLR and its kinetics are surrogate marker of increased mortality in critically ill COVID-19 patients.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001087

Introduction: Sepsis is the most common trigger of severe acute kidney injury (AKI) in critically ill patients. Few data are available on the changes of urinary chloride and their association with AKI in septic patients.
Objectives: To assess whether chloride serum and urinary levels as well as chloride load and balance are associated with the development of AKI in septic patients.
Methods: Retrospective analysis of an institutional database including all patients admitted to the Intensive Care Unit (ICU) for sepsis and septic shock from January 2011 to June 2015. Inclusion criteria were length of stay in the ICU > 48 h and complete data available on serum and urinary samples for at least for 2 days. Patients were excluded if

they had anuria on ICU admission, continuous bladder irrigation, if they were on haemodialysis (chronic or of recent onset) and if they were kidney transplanted. We collected chloride levels on daily serum (SCl) and urinary (UCl) analyses; chloride load (Clload) was calculated by considering the amount of chloride present in the IV fluids and nutrition administered daily to the patient, while chloride balance (Clbalance) was calculated as: Clload—Cloutput, where Cloutput is UCl × daily urine output. UCl was measured on 24-h urinary collection. AKI was defined according to the latest AKIN criteria.
Results: 339 eligible patients met the inclusion criteria. Median SOFA score on ICU admission was 7 [5–10]; ICU mortality was 29% (n = 99). 298 patients (88%) developed AKI after a median of 0 [0–0] days since admission; 81 of them (24%) also needed continuous renal replacement therapy. No significant difference in fluid balance over the first five days was observed between AKI and non-AKI groups; despite a similar Clload on admission, patients with AKI had a lower Cloutput (32 [12–75] vs. 80 [38–158] mmol; p < 0.001) and lower UCl (34 [20–60] vs. 54 [23–91] mEq/L; p = 0.004) than patients without AKI, resulting in higher serum chloride levels. These findings were observed during the first five days of ICU stay.
Conclusions: AKI occurred in almost 90% of septic patients; urinary excretion of chloride is reduced in these patients.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001088

Introduction: Outcome prediction after out-of-hospital cardiac arrest (OHCA) is difficult and identification of risk factors associated with poor outcome could help clinicians in making decisions about post-resuscitation management. Among these, early predictors, and in particular those eventually available before recommended neuroprognostication indexes, may help to identify patients with the highest probability of poor outcome in early course of post-resuscitation care1,2.
Objectives: We aimed to examine predictive ability of demographical, clinical, and peri-arrest variables with the adjunct of data from Blood Gas Analysis (BGA) taken in the first 24 h after OHCA, to find out risk factors of poor outcome before starting of neuroprognostication.
Methods: A prospective observational study was conducted from January 2019 to December 2022 in a large academic hospital, including all consecutive adult patients (> 18 years old) admitted to our Intensive Care Unit (ICU) with diagnosis of OHCA. Demographical and clinical variables regarding pre-existing conditions and medications, and data from BGA at Emergency Department (ED) arrival, ICU admission and at 24 h were collected. Outcome was evaluated at ICU discharge by Cerebral Performance Category (CPC) scale (range 1–5). A CPC score ≥ 3 was considered as poor outcome. Univariate logistic regression was used to examine the association between ICU outcome and different demographical and early clinical variables. Clinical reasonable variables were tested into a multivariable logistic regression. Independent predictors of the multivariable models were considered in the presence of a p-value < 0.05.
Results: 90 patients were enrolled in the study period. Survival rate was 44.44%, and 25 patients had a good neurological outcome at discharge (27.78% of OHCA).ICU outcome was associated with low flow time (p = 0.03), mechanical CPR (p = 0.03), rhythm of presentation (p = 0.007), ACC location (p = 0.022), chronic therapy with P2Y12-inhibitors (p = 0.023) and ACE-inhibitors (p = 0.032), serum lactate at the ED presentation (p < 0.001), at ICU admission (p = 0.048) and in the first ICU day (p < 0.001). In a multivariable analysis taking into account age, biological gender, low-flow time and lactate levels at the ED presentation, only low-flow time was independently associated to poor outcome (OR 0.96 for each minute of low flow time, IC95% 0.92–0.99). **Figure 1 shows adjusted probability of good outcome for increasing low-flow time.
Conclusions: In this prospective evaluation, low-flow time was an independent predictor of poor ICU outcome, in accordance with international literature, with no association found with age and gender. We found a univariate association between outcome and BGA variables collected in the first 24 h from cardiac arrest, as is reported in previous studies. The independent predictive value of lactate levels must be evaluated in a larger population.

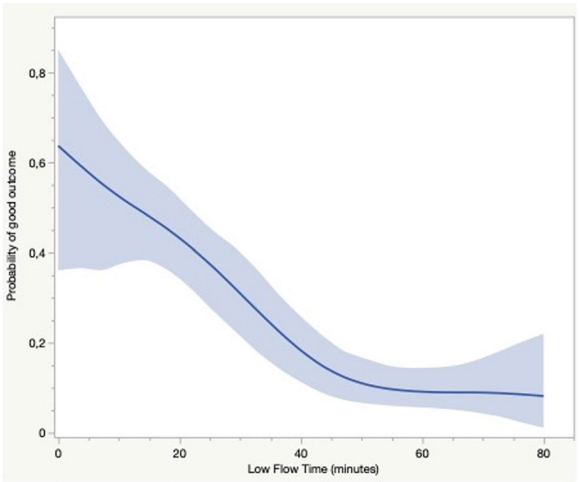

Figure 1 (abstract 001088) Adjusted probability of good outcome according to low flow time

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001089

Introduction: Prediction of volume responsiveness in mechanically ventilated patients with hemodynamic instability remains challenging especially in conditions where usability of standard dynamic tests is significantly limited due to irregular heart rhythm.
Objectives: The aim of our study was to assess relationship between the values of dynamic arterial elastance (Eadyn) and hemodynamic response to leg raise test in patients with circulatory shock and irregular heart rhythm.
Methods: Mechanically ventilated patients with combined cardiogenic and septic shock treated with vasopressors (norepinephrine and/or vasopressin) and inotropes (dobutamine and/or milrinone) and irregular heart rhythm were eligible for the study. Pulse pressure variation (PPV), stroke volume variation (SVV), Eadyn, cardiac output (CO), stroke volume (SV) and mean arterial pressure (MAP) were continuously monitored from pulse wave analysis. The values of PPV, SVV and Eadyn were recorded before standard passive led raise test (LRT) and analyzed for correlation with the change (after LRT—before LRT) in CO (dCO), SV (dSV) and MAP (dMAP).
Results: Eighteen hemodynamically unstable patients were enrolled (mean age 63 years, females 6/18). Irregular heart rhythm was caused by atrial fibrillation (12/18) or frequent premature complexes (6/18). Admission diagnoses were cardiac arrest (8/18), acute myocardial infarction (4/18), aortic stenosis (2/18), pulmonary embolism (2/18), COVID-19 (1/18), and cardiac tamponade (1/18). All were treated with inotropes and vasopressors. A significant correlation was observed between Eadyn and dCO (Spearman $r=0.691$, $P=0.004$) as well as between Eadyn and dSV ($r=0.734$, $P=0.002$) but not between Eadyn and dMAP ($P=0.437$). The values of PPV and SVV did not correlate with any of the changes.
Conclusions: Our results indicate that Eadyn could be used as a predictor of volume responsiveness in mechanically ventilated patients with circulatory shock and irregular heart rhythm.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001090

Introduction: SARS-CoV2 infection is a systemic infection in which the development of a severe form is thought to be related to an imbalance in the innate and adaptive immune response. Lymphopenia is a cardinal hematological finding and an indicator for the early detection of patients at risk of developing a severe form.
Objectives: The aim of our work was to study the kinetics of lymphocytes and its impact on mortality in critically ill patients.
Methods: This was a descriptive, retrospective, single-center, prognostic study conducted from March 2020 to December 2021. Patients over 18 years old hospitalized with confirmed severe COVID-19 pneumonia were included. Two groups of patients were identified (dead and survivors). A study of lymphocyte kinetics during the ICU stay and an analysis of both groups were performed. Lymphopenia was defined as a lymphocyte count less than 1500/mm3.
Results: The study included 460 patients with198 survivors. Dead patients ($n=262$) were older, had more comorbidities and a more severe clinical presentation of the disease. The mean time to admission to the ICU was comparable and the medical treatment was standardized.
The lymphocyte count at admission was comparable in both groups. Lymphopenia was present in both groups. Throughout the ICU stay, dead patients had a lower lymphocyte count compared to the survivors, but the difference was significant only at D30 (2300 [1370–2830] /mm3 in the survivors' group versus 1315 [762–1722] /mm3 in the dead group with $p=0.002$).
Lymphocyte kinetics were comparable between the two groups with a progressive and less important increase in the dead group (Figure 1). A greater regeneration of lymphocytes in the survive group was observed between D25 and D30 with $p=0.037$.
Conclusions: Our study did not show any association between lymphocytes kinetics and mortality in critically ill COVID-19 patients. However, it suggests that lymphocyte regeneration may reflect a favorable disease course.

Correspondence: A. Cuadra-Calahorra
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001091

Introduction: The coronavirus disease (COVID-19) pandemic has been a real challenge for resource management in intensive care units (ICU). The burden of critical care experienced in several periods of the pandemic may influence the long-term outcomes of the survivors.
Objectives: To analyze whether the care overload suffered in the first waves of the COVID-19 pandemic had an impact on the quality of life of patients admitted to a critical care unit compared to those who were admitted in waves with less care overload.
Methods: This cross-sectional study among critical ill COVID-19 survivors at 1-year of intensive care unit (ICU) discharge, who were admitted during the periods of higher demand (HD) (1st, 2nd, 3rd wave of the pandemic) and lowest demand (LD) (4th, 5th and 6th wave) for critical care resources (CCR). Quality of life (QoL) was assessed by the EQ-5D-5L tool and the euroQoL visual analog scale through phone-based questionnaires. Mental health was assessed through medical records and a validated instrument was used: the Post-Traumatic Stress Disorder (PTSD) Checklist-5 (PCL-5), based on the Diagnostic and Statistical Manual of Mental Disorders (DSM-5) for screening PTSD using a cut-point score of 31–33. Categorical variables are expressed as counts and percentages and were compared using the $\chi 2$ test and Fisher test; continuous variables are expressed as medians and interquartile range (IQR) and were compared using Mann–Whitney U test. A two-sided level of significance of 5% was used. Data analysis was performed using STATA version 13 ® (StataCorp LCC).
Results: A total of 270 patients 1-year after ICU discharge were analyzed. The majority were men (69.01%) with no differences between groups, the median age was higher in the group of HD-CCR (62 [53–68] vs 54 [44,62] years old; $p < 0.001$). Patients in the period of HD-CCR had a higher PTSD prevalence (12,56 vs 1,41%; $p = 0.036$) with a higher Score PCL-5 (8 [2–19] pts vs 6 [0–14]; $p < 0.001$). The consumption of psychopharmacological drugs during the month prior to the interview was similar in both groups. There were no differences in the perception of their health status as estimated by the EuroQOL Thermometer (70 [50–90] vs 75 [60–90]; $p = 0.249$) neither did the level sum score (LSS) (15 [5–40] vs 10 [0–30]; $p = 0.055$). The EQ-5D-5L questionnaire showed that patients from HD-CCR period had greater problems for self-care (31,7 vs 15,49%; $p = 0.048$) and for the development of usual activities (50,25 vs 32,39%; $p = 0.039$); there were no differences in mobility problems, pain/discomfort and anxiety/depression.
Conclusions: Periods of higher demand for critical care resources had significantly greater impact on the development of PTSD, self-care and the performance of usual activities problems, among critical ill COVID-19 survivors at 1-year after ICU discharge. However, the ICU burden did not impact the perception of health status or in the disease severity index estimated by LSS.

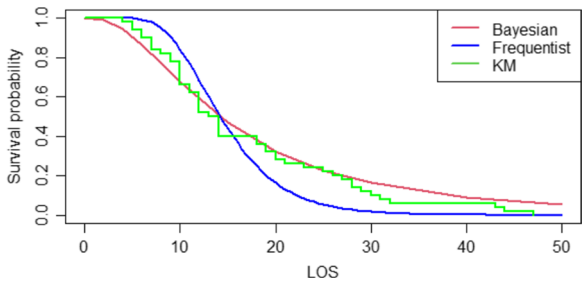
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001092

Introduction: COVID-19 is a rapidly expanding disease caused by the virus SARS-COV-2. As a new disease, its poor understanding can result in delayed identification and treatment. Thus, during the COVID-19 pandemic, it is crucial to understand the factors that may influence the Length of Stay (LOS) for hospitalized patients. The hospital LOS refers to the number of days a patient stays there. In addition, comprehending those factors is important for planning the allocation of medical resources.
Objectives: To study the risk factors that influence the hospital LOS variationfor COVID-19 patients using multiple statistical approaches.
Methods: This study has access to information on 50 COVID-19 patients after being hospitalised in the Hospital García da Orta in Almada. The data set contains 45 explanatory variables, including information about patients' demographic characteristics and clinical indicators regarding inflammation and renal, liver, heart and lung

functions. A survival analysis approach is used to achieve that goal since, when modelling the LOS, the observations may be censored. Two survival analysis approaches are employed, the semiparametric approach, where Cox proportional hazards model is used, and the parametric approach, by fitting an Accelerated Failure Time (AFT) model.
Results: Results show that having hypertension and higher levels of haemoglobin, neutrophils, fibrinogen, D-dimer, atrial fibrillation, HCO3, and troponin lead to less time in the hospital. In addition, patients with DM, AKI, and having higher levels of INR, pH, pCO2, FiO2 and FC tend to stay longer in the hospital. The comparison between statistical approaches was done, analysing the variables that are relevant for each model and which ones are kept in all of them, and plotting the survival curves of each model for both approaches by adding the KM estimate. The variables pCO2, FiO2 and FC were the only ones to be kept in all models. Thus, it is possible to believe those indicators are strongly related to the LOS variation.
Conclusions: To our knowledge, the effect of the levels of pCO2, FiO2 and heart rate on LOS variation never appeared in the literature. Understanding the risk factors associated with the variation of the hospital LOS will provide useful information for planning the allocation of medical resources and improving hospital management and patient quality of care.



Best model for each approach.; Frequentist approach is the lognormalmodel; Bayesian approach is the log-logistic model.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001093

Introduction: Presenting rhythm has been widely reported as a prognostic factor in cardiac arrest, having the non-shockable rhythm a worst survival prognosis.
Objectives: Primary objective: to know the prevalence of cardiac arrest in Pontevedra and O Salnés Health Area.
Secondary objective: to analyze possible differences, in terms of vital prognosis, related to the first documented rhythm.
Methods: Descriptive and retrospective study carried out between January 2017 and December 2022 in patients with cardiac arrest whose cardiopulmonary resuscitation (CPR) was performed by intensivists from Hospital Universitario in Pontevedra. All emergency calls for cardiac arrest during this period were included. Patients whose stay in ICU was considered as non-beneficial, due to their previous serious clinical condition or preexisting comorbidities, were excluded.
Results: Over the six-year period, 168 cardiac arrests were collected. The first documented rhythm was non-shockable in 112 of them (66.7%). Of those, 63% presented asystole and 42.8% pulseless electrical activity (PEA). Shockable rhythm was documented in 46 patients (27.4%), being ventricular fibrillation (84.8%) more frequently found than pulseless ventricular tachycardia. In patients with non-shockable rhythm, the most common underlying cause of cardiac arrest was respiratory, whilst cardiac was the main cause in patients presenting shockable rhythm. Survival rate was higher among patients with shockable rhythm (52.2% at hospital discharge and 47.9% at 12-month follow-up) compared to those presenting non-shockable rhythm (34.8% at hospital discharge and 33.6% at 12-month follow-up). Of all variables investigated as prognostic factors, elevated lactate level was the only one to be found as statistically significant predictor for mortality (p-value = 0.011, OR 3.75 and CI 95% (1.92–5.58) in non-shockable rhythms and p-value = 0.001, OR 3.06, CI 95% (1.71–4.42) in shockable).
Conclusions: In our area, data were similar to the previously described in literature, with mortality rate as 3.75 times higher (1.92–5.58) in non-shockable rhythms and 3.06 times (1.71–4.42) in shockable.

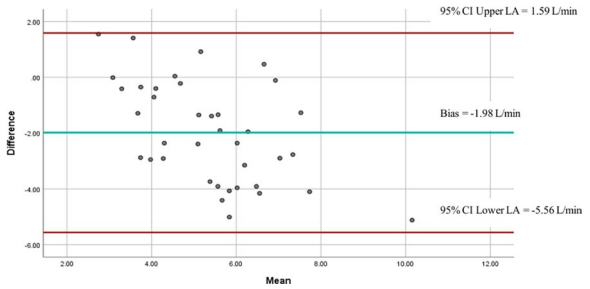
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001094

Introduction: Coronary artery bypass surgery is associated with significant hemodynamic variability. Accurate and continuous hemodynamic monitoring is recommended for early diagnosis of changes in organ function and timely intervention.
Objectives: The purpose of this study is to evaluate the correlation of the measured hemodynamic parameters obtained from estimated continuous Cardiac Output (esCCO) based on pulse wave transit time and thermodilution in post coronary artery bypass patients.
Methods: This prospective cross-sectional study included 39 patients who had coronary artery bypass surgery. Reference hemodynamic parameters were obtained from intermittent bolus thermodilution using a pulmonary artery catheter at 3 different time points postoperatively. Simultaneous hemodynamic measurement was obtained using the esCCO monitoring system. Using arterial blood gas from the arterial line and venous blood gas from the pulmonary artery, and indirect Fick method of hemodynamic monitoring was also performed. Differences with the absolute values of the hemodynamic parameters obtained from the 3 methods were compared. Bland–Altman analysis was used to determine bias and the limit of agreement.
Results: The absolute values of hemodynamic parameters from the different methods differ significantly at each time point. When compared to the gold standard thermodilution, esCCO measurements were significantly higher at all time intervals, while SVR was lower. Between between esCCO and TD CO the bias was -1.98 L/min, and the SD bias was ± 1.83 L/min; 95% CI of the limits of agreement ranges from -5.56 L/min to 1.59 L/min.
Conclusions: The absolute values of hemodynamic parameters obtained from the non-invasive esCCO did not correlate accurately to the measured parameters from the gold standard thermodilution.

Variations in SVR, which are common in patients after coronary artery bypass grafting, appear to influence the accuracy of esCCO, as seen by wide ranges of agreement between esCCO and TD. Further refinement of this technology is warranted.



Bland–Altman plot for repeated measurements between cardiac output (CO) measurements obtained with estimated continuous cardiac output (esCCO) and thermodilution cardiac output. The green lines correspond to the mean difference (bias), the red lines correspond to 95% confidence interval of the upper and lower Limits of agreement.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001095

Introduction: According to the literature, in-hospital cardiac arrest is still associated with high mortality rates (around 75% had occurred by 12 months).
Objectives: Primary objective: to describe and compare the demographic data and survival rate of our Unit with those published.
Secondary objetive: to evaluate prognostic factors described in literature as predictors of survival from in-hospital cardiac arrest (IHCA).
Methods: Descriptive and retrospective study of IHCA patients admittted to our Intensive Care Unit (ICU) from all wards of our University Hospital in Pontevedra from January 2017 to December 2022. All emergency calls for cardiac arrest and cardiopulmonary resuscitation (CPR) performed by intensivists, successful or not, were included. Patients whose stay in ICU was considered as non-beneficial, due to their previous serious clinical condition or comorbidities, were excluded and CPR was not performed.
Results: During the six-year period, 98 patients with IHCA were admitted, 52% from A&E. Mainly male (67.3%), with a mean age of 72.37 years old (59.22–85.52), and 87.7% were older than 60 years old. Focusing on main cardiovascular risk factors, prevalence of hypertension (70%), diabetes (39.8%) and smoking (47%) was found. Return of spontaneous circulation was achieved in 72.4% of the patients and the survival rate to hospital discharge was 46.9%. Mortality at 12-month follow-up period was 58.2%, being the first days after cardiac arrest the period with higher mortality rate.
The cause of the cardiac arrest was most often cardiac (38.8%) followed by respiratory (30.6%), being most often nonshockable (69.4%) versus shockable (30.6%) as the presenting rhythm. The mean time from event onset to initiation of CPR, whether it was performed by witnesses or hospital staff, was 0.83 min, and the average duration of CPR lasted 7.87 min.
In cardiac arrest, mean ph value was 7.20 and lactate level was 7.24 (statistically significant for mortality with p-value 0.001, OR 3.45 and CI 95% (1.54–5.37)). Neuron-specific enolase (NSE) levels were assessed at 24 and 72 h, being a significant predictor of mortality those levels recorded at 24 h (p-value 0.018, CI 9.04–83.72).
Conclusions: Similarly to what has been described in literature, mortality rate in our hospital was 60%. Consistent with the results of other studies, higher lactate levels and NSE levels sampled at 24 h after cardiac arrest were associated with higher mortality rates in our population.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001098

Introduction: Sleep disorders in the intensive care unit (ICU) are associated with increased incidence of delirium, changes in the immune system, neuroendocrine dysfunction, and abnormalities associated with cardiovascular diseases, neuropsychiatric diseases, and mortality. Poor sleep quality in critically ill patients may be related to factors related to critical illness or healthcare-related factors. Single-center studies have shown that it is possible to improve healthcare-related factors, resulting in subjective sleep quality improvement, with some studies showing benefits in the medium and long term. The present study aims to evaluate whether the implementation of a package of measures with multidisciplinary interventions can improve the sleep quality of critically ill patients admitted to ICUs.
Objectives: To demonstrate an improvement in sleep quality in critically ill patients by reducing the Richards-Campbell Sleep Questionnaire (RCSQ) score after the implementation of a structured package of evidence-based measures to improve sleep in critically ill patients.
Methods: Multicenter clinical trial with quasi-experimental design. The first step consists of evaluating the sleep quality in sequential patients admitted to the ICU and characterizing the disruptive elements. Twenty-five consecutive patients will be allocated, and demographic data will be collected, and RCSQ will be administered for three consecutive days in patients included in the study, starting from the first day when clinical conditions allow. On the day of ICU discharge or the subsequent day, the Sleep in the Intensive Care Unit Questionnaire (SICUQ) will be administered to assess the disruptive elements of sleep. The second step will involve sensitizing and training at least 75%

of the multidisciplinary team about the importance of sleep for critically ill patients and training them for the implementation of a Multidisciplinary Protocol for Sleep Improvement in Critically Ill Patients. Once the protocol is implemented, it will be followed for a period of 30 days to ensure adequate adherence from the team's perspective. After this period, data collection will be done again from a sample of 25 consecutive patients, and demographic data and sleep questionnaires will be administered as in the initial phase. Based on previous studies, a sample size calculation estimated 50 patients in each group (pre- and post-intervention) to detect a difference of 15 points in the mean RCSQ score with 80% power and alpha of 5%.
Results: We hope that the implementation of a package of measures with multidisciplinary interventions can improve the quality of sleep of critically ill patients admitted to ICUs.
Conclusions: The conclusions will be postponed after the elucidation of the results.

Mortality in the first 24 h after ICU admission—an audit to improve care

R. Pinto Medeiros[1], R. Pereira[1], M. Bourbon Ruao[1], C. M. Teixeira[1]
[1]Departamento de Anestesia e Cuidados Intensivos-CHUdSA, Hospital Geral de Santo António, Porto, Portugal
Correspondence: R. Pinto Medeiros
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001101

Introduction: Intensive care unit (ICU) admissions have increased considerably in the last decade [1]. A group of patients that remains poorly characterized are the ones who die within the first 24 h following ICU admission. Prior studies suggested that 20% of all deaths in a mixed ICU population, may occur within the first 24 h [2]. Given the significant resources involved in the admission to an ICU, death within the first day, theoretically represents a high cost to benefit ratio [3]. Thus, a better understanding of this population may lead to insights on how to improve the process of ICU triage and admission, as well as improved outcomes.
Objectives: To describe patients who died within 24 h of admission in a Portuguese university hospital polyvalent ICU.
Methods: Monocentric descriptive observational study. Demographic and clinical data from 1st January to 31st December 2022 were registered.
Results: 105 (23.8%) patients died in the ICU out of a total of 442 patients admitted; 7.7% (n = 34) of patients died within the first 24 h. 23 (67.6%) were men, average age of 70.9 years. SOFA (9.9 ± 3.8); SAPS II (69.6 ± 19.2). As demonstrated on Figure 1, the average Clinical Frailty Score of the studied population was 4. Most patients were admitted from the emergency room (n = 17). Main cause of admission was cardiovascular pathology regarding shock state (n = 13) and the main cause of death was refractory shock (n = 23). The average time from admission until time of death was 12.6 h. Thirty-three patients had a decision of withdraw (n = 17) or withhold therapeutic measures and only 1 patient died despite advanced life support.
Conclusions: Despite growing demand and utilization of ICU, our current understanding of the demographics, case-mix and circumstances surrounding early deaths is limited. Therefore, a better knowledge regarding our ICU population is crucial in order to deliver high quality care.

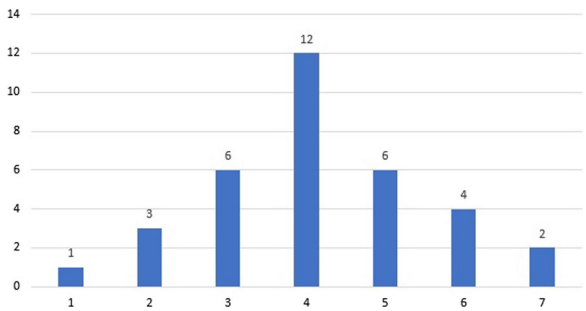

Figure 1 (abstract 001101) Clinical Frailty Score of the study population

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001102

Introduction: High blood endotoxin levels in sepsis have been associated with its severity and outcome. APAD (GPN00068) (Grandpharma, Wuhan, China) is a new chemical compound invented as a multiple PAMPs (Pathogen Associated Molecular Patterns) antagonist. Our hypothesis was that APAD administration in a clinically relevant septic shock large animal model may improve outcome.
Methods: Sepsis was induced through fecal peritonitis in 24 mechanically ventilated, hemodynamically monitored female sheep. Animals were randomized to three groups of 8: control, concurrent treatment (CuT), and post treatment (4 h later, PT). APAD was given as a bolus (0.2 mg/kg) followed by a continuous infusion (0.03 mg/kg/h). During the first 4 h, fluid was maintained at 2 ml/kg/h; then, fluid resuscitation was individualized to maintain pulse pressure variation $\leq$13%, antibiotics were given and peritoneal lavage was administrated. Norepinephrine was added to maintain mean arterial blood pressure $\geq$65 mmHg if necessary. The experiment lasted 24 h. 99mTc (Technetium) labeled albumin was utilized to measure kidney cortex, medulla and intestine perfusion at the end of experiment.
Results: CuT & PT groups had a higher cardiac index than the control group. A decreased capillary leakage was suggested in these groups by higher total protein concentrations. At autopsy, wet/dry ratio of the right lung middle lobe was lower in the CuT group than in the control group. The PT group tended to require less vasopressors ($p=0.18$) and have a higher kidney cortex perfusion ($p=0.14$) assessed by Tc99m activity at the end of experiment than the other groups. Survival tended to be longer in the two treatment groups ($p=0.08$) (Figure 1).
Conclusions: In this model of sepsis induced by fecal peritonitis, endotoxin neutralization with APAD resulted in higher cardiac index, tended to decrease vasopressor requirement and improve survival. Higher blood protein concentrations and less pulmonary edema at autopsy also suggested a protective effect of vascular permeability. These changes were still observed when the APAD administration took place 4 h after the onset of sepsis.

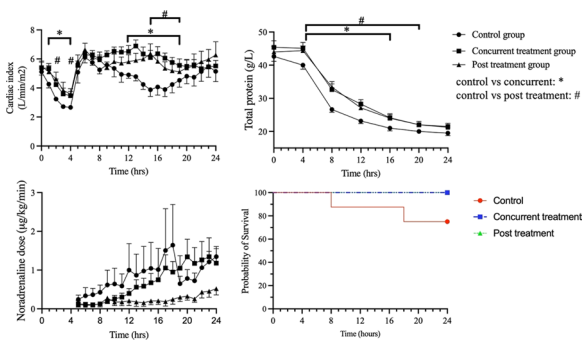

Figure 1 (abstract 001102) Evolution of cardiac index, total protein concentration, noradrenaline dose and probability of survival in the CuT/PT/control groups during the experiment

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001103

Introduction: It is now well established that sleep quality of critically ill patients is poor. Although sleep quantity might be normal, sleep is highly fragmented by arousals and brief awakenings. These sleep disruptions have been associated with prolonged weaning duration and mortality.
Quantifying sleep in sleep ICU patients is challenging. Polysomnography (PSG) offer the advantages to measure sleep continuity, a recent parameter which has been associated with outcome in patients treated with non-invasive ventilation (1). However, performing PSG in the critically ill is very challenging, requiring dedicated sleep technicians and sleep experts familiar with specific sleep scoring rules. Then, we elaborated an automated sleep scoring algorithm measuring sleep continuity by processing one single EEG channel.
Richards-Campbell sleep questionnaire (RCSQ) is a validated questionnaire to assess sleep quality in ICU patients. However, RCSQ is difficult to administrate in patients who are not fully awake and a more simple numeric visual analog scale have been proposed as an alternative.
Objectives: We investigated the relationship between sleep continuity measured with our automated scoring algorithm and patient-reported sleep quality.
Methods: We analyzed retrospectively 52 polysomnographies previously recorded in non-sedated and conscious ICU patients. Patients sleep was recorded the night after extubation. For each patient, one EEG channel (C3-A1) was processed, providing automated sleep hypnogram. Sleep continuity was measured using this automated scoring as previously described. Patients-reported sleep quality was assessed using Richards Campbell Sleep Questionnaire (score 0 to 100) and by using a visual analog scale (score 0 to 10), graduated from 0 "very poor sleep quality" to 100 "excellent sleep quality". We search for a correlation between patient reported sleep quality and sleep continuity.
Results: Sleep continuity could be calculated on 29 PSG (age: 68y [58–77], median [25th–75th]). Richards-Campbell sleep questionnaire (62 [48–72]) and visual analog scale (5.5 [4.0–7.0]) have been obtained in 18 patients and 29 patients, respectively. Among the 29 patients, 5 (17%) had a positive delirium scale.
Our results show a significant correlation between automated sleep continuity and visual analog scale ($p<0.008$, $Rho=0.46$; $n=29$; Spearman correlation test). In contrast, no correlation existed between sleep continuity and RCSQ score ($p=0.66$, $n=18$; Spearman correlation test).
Conclusions: Self-reported sleep quality using a simple VAS can be easily administered in ICU patients. Sleep continuity measured by an automated algorithm may capture a large part of sleep perception and might be a mean to quantify sleep quality.

Detecting non-convulsive seizures—delays and obstacles to EEG

J. Urquidi Ferreira[1], W. Ellis[1], H. Holmes[1], M. Spivey[1]
[1]Critical Care, Royal Cornwall Hospital, Truro, United Kingdom
Correspondence: J. Urquidi Ferreira, W. Ellis
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001104

Introduction: Non-convulsive seizures (NCS) occur in about 50% of patients with coma or convulsive status epilepticus (Herman et al., 2015). NCS/NCSE is well known to be underdiagnosed and in sedated patients depends on EEG. Research shows that prolonged NCS/NCSE is associated with increased mortality and worsened neurologic outcome. Access to EEG is limited by availability of technicians and clinicians, amongst other factors.
Methods: We performed an audit of patients admitted with a primary diagnosis of convulsive status epilepticus (CSE) into our 19 bed ICU/HDU. In 2017–2018, there were 29 individuals (5 neonatal, 2 paediatric, 22 adults). We collected data on initial treatment, when and if patients underwent EEG and whether treatment was escalated beyond this.
Results: Over 90% of patients required escalation to general anaesthesia and intubation for termination of seizure, airway protection and to facilitate imaging. There was an average unit stay of 2.7 days (SD 3.3) and only one death. Formal data on performance status was not available. One third of these patients (10/29) underwent EEG within the first 48 h of admission. Those admitted over weekends were the least likely to undergo EEG. No burst activity or NCSE was detected in any EEGs. In addition to this, formal EEG reports were frequently delayed by over 72 h from the time of recording. Data on performance status on discharge was not available.
Conclusions: There is a significant delay in obtaining standard EEG to confirm the absence of NCS/NCSE. This infers a high risk of underdiagnosing NCS/NCSE. Use of continuous EEG at the bedside pending formal EEG may aid in confirming burst suppression and the absence of ongoing seizure activity, bypassing service limitations and bringing practice in-line with both NICE and EMSIC guidelines (Friedman et al. 2009, Herman et al., 2015). Establishment of cEEG in our service could also optimise care for a much broader patient population. This will require further audit cycles and has its own implementation challenges which must be identified.

Introduction: The coronavirus disease 2019 (COVID-19) has been related with long-term impact in physical and psychological aspects (1). The use of invasive mechanical ventilation (IMV) was needed if severe respiratory failure was not responding to non-invasive respiratory support. This study aimed to describe the long-term impact influenced by IMV in COVID-19 patients survivors.
Objectives: To analyze the long-term impact of the need of invasive mechanical ventilation in COVID-19 patients survivors.
Methods: This cross-sectional study among critical ill mechanically ventilated COVID-19 survivors at 1-year of intensive care unit (ICU) discharge. Quality of life (QoL) was assessed by the EQ-5D-5L tool and the euroQoL visual analog scale through phone-based questionnaires. Mental health was assessed through medical records and a validated instrument: the Post-Traumatic Stress Disorder (PTSD) Checklist-5 (PCL-5), based on the Diagnostic and Statistical Manual of Mental Disorders (DSM-5). The PCL-5 can determine a provisional diagnosis of PTSD using a cut-point score of 31–33. Categorical variables are expressed as counts and percentages and were compared using the $\chi 2$ test and Fisher test; continuous variables are expressed as medians and interquartile range (IQR) and were compared using Mann–Whitney U test. A two-sided level of significance of 5% was used. Data analysis was performed using STATA version 13 ® (StataCorp LCC).
Results: A total of 549 COVID-19 patients were admitted to the ICU and received IMV. Of them, 7 patients were lost because relocation to another hospital before weaning, 208 died (global mortality of 38,38%) and 214 agreed and were available to answer the phone survey. The 27% needed IMV for less or 7 days while the 73% needed it for more than 7 days. Those who needed IMV for more than 7 days have an increased in hospital length of stay (42,5 Vs 21 days; $p = 0$) and ICU length of stay (25 Vs 9 days; $p = 0$). There were not significant differences in the demographics baseline. Treatment with psychotropic drugs (antidepressants, benzodiazepines, neuroleptics and opioids) was collected before ICU-admission and after 1 year from ICU discharge, there were not differences between both groups. Patients with more than 7 days of IMV went more often to the emergency department (1 Vs 0 times; $p = 0.0$) and required more rehabilitation (62% Vs 45%; $p = 0,02$), comparing with those who needed IMV for less or 7 days. With respect to functional limitations, mental health, reduced physical performance and impaired health-related quality of life, we were not able to find significant differences comparing both groups. All the information is summarized in Table 1 and 2.
Conclusions: COVID-19 survivors who required IMV for more than 7 days went more often to the emergency department and were more likely to require further rehabilitation than those with IMV less or 7 days. We did not find differences in functional limitations, mental health, reduced physical performance and impaired health-related quality of life.

Table 1 (abstract 001105) Summary of baseline characteristics and other outcomes. BMI (Body Mass Index). CFS (Clinical Frailty Score). EuroQoL (EuroQuality of Life). PCL-5 (Post-Traumatic Stress Disorder Checklist-5). PTSD (Post-Traumatic Stress Disorder).

	IMV ≤ 7 days n = 58 (27,1%)	IMV > 7 days n = 156 (72,9%)	p =
Women (%)	26/58 (44,8%)	58/156 (37,1%)	p = 0.35
Man (%)	32/58 (55,1%)	98/156 (62,8%)	p = 0.30
Age (years) [IQR]	57,5 (49-63)	61 (52-69)	p = 0.58
BMI [IQR]	29,1 (26-31)	29,9 (26,7-34,6)	p = 0.30
Charlson (median) [IQR]	2 (1-3)	2 (1-3)	p = 0.70
Frailty (CFS) [IQR]	3 (2-3)	2 (2-3)	p = 0.37

Introduction: Microcirculation plays a crucial role in tissue metabolism. It is a composition of capillaries and endothelial glycocalyx (EG) which covers inner surface of endothelial cells and makes a biological interface where many important interactions happen. EG is a sugar based endothelial lining involved in the physiology of capillary wall and pathogenesis of many diseases associated with endothelial functions.
Microcirculation is available for in vivo microscopic evaluation at the sublingual mucosa. EG disintegration in disease is evaluated mostly by concentration of its shed products, especially syndecan-1. Sulodexide is a glycosaminoglycan-based drug prescribed in patients with angiopathy proved to be effective.
Objectives: We aimed to investigate whether sulodexide positively modulates EG and microcirculation on a porcine model of EG enzymatic damage.
Methods: Eight piglets were induced EG damage by hyaluronan III and heparanase I given intravenously. Four animals received sulodexide 600 IU intravenously prior to the enzymes (protection group) and four animals after the enzymes (treatment group). Sublingual microcirculation by Side-stream Dark Field imaging and plasmatic concentration of syndecan-1 by ELISA were measured at baseline, 20 min after intervention, at 40th, 60th and 90th minute onwards.
Results: All animals finished the protocol. Neither the analysis of sublingual microcirculation nor syndecan-1 showed any statistically significant results based on 2way ANOVA for inter group difference and unpaired Student's t-test for time point analysis. On the other hand, we noticed a positive trend toward lower values of syndecan-1 and better profile of sublingual microcirculation in the protection group.
Conclusions: Sulodexide might be more effective as a pre-treatment of pre-conditioning before the insult. Our results might have impact into the clinical practice in vascular surgery patients who are exposed to ischemia–reperfusion injury.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001107

Introduction: Post-extubation dysphagia (PED) can lead to serious health problems in vulnerable critically ill patients, yet routine bedside screening may be lacking in many Intensive Care Units (ICUs), possibly due to limited awareness for this condition.
Objectives: The present study aimed to establish baseline data on the current approaches, the status of perceived best practices to PED management and treatment, as well as to assess awareness of PED and its consequences. The questionnaire was completed by a designated clinician, after consultation with the ICU team.
Methods: A nationwide cross-sectional, online survey was conducted of all adult ICUs (n = 14; response rate 100%) in the Republic of Cyprus.
Results: None of the included ICUs had a dedicated speech and language pathologist/ therapist (SLP/SLT). More than 85% of ICUs reported that there was no standard protocol indicating which patients should be screened for PED. Cough reflex testing and water

swallow test were the most commonly reported assessment methods used to confirm the presence of PED. In the majority of ICUs (64.3%), nurses and intensivists were responsible to assess PED as well as SLP/SLTs. Muscle strengthening exercises without swallowing and swallowing exercises were mostly used to treat dysphagia. Of the ICUs, 71.4% reported the need for standard protocols for PED screening. Overall, 28.6% of the ICUs agreed that PED was common in their unit.
Conclusions: We identified gaps in Greek Cypriot ICUs awareness and practice regarding PED management, treatment, and consequences. Comprehensive unit-based dysphagia education programs must be urgently implemented. Interdisciplinary and collaborative work between nurses, intensivists and SLPs is needed to improve the quality of care provided.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001108

Introduction: In Portugal, the use of non-heart beating donors has a low expression in the total number of transplants performed. Most organ donors are brain-dead patients with central nervous system injuries. (1) There is a clear limitation on obtaining organs, so the use of "old" donors could be a viable alternative. However, it is questionable whether the survival of these grafts is similar to that of newer organs.
Objectives: The authors intend to evaluate the 4-year survival of patients undergoing liver transplantation with organs from donors over 70 years old.
Methods: Retrospective study including all patients undergoing liver transplantation at a transplant center in Lisbon, over a period of two years (2017 to 2018). A review of the clinical processes of hospitalizations and transplant *follow- up* appointments was carried out over a 4-year period. Data collection maintained the patients anonymity. Comparison was made between the 2 groups (patients transplanted with new organs versus those with old organs) regarding patient mortality at 4 years and graft loss requiring retransplantation.
Results: In the 2-year period analyzed, 187 patients underwent surgery, with 10 patients being excluded due to abandonment of the centre. 59 liver transplants were performed with livers from donors aged over 70 years. Most donors died of cerebrovascular disease (60%) followed by traumatic brain injury (34%). The cold ischemia time of these grafts was 399 min and the warm ischemia time was 39 min. The 4-year graft survival is 83% and the 4-year mortality rate is 10%. The transplants of new grafts corresponded to 118. Most donors died of cerebrovascular disease (67%) followed by traumatic brain injury (24%). The cold ischemia time of these grafts was 417 min and the warm ischemia time was 38 min. The 4-year graft survival is 86% and the 4-year mortality rate is 9%.
Conclusions: When we analyze graft survival and mortality rate at 4 years, there is no significant difference between old grafts and new grafts.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001109

Introduction: Aortic stenosis is one of the most frequent causes of heart failure and might lead to cardiogenic shock. The presence oh hemodynamic instability and the comorbidities of our patients makes surgical manegement prohibitive. For this reason, the utilization of emergency transcatheter aortic valve implantation (eTAVI) is considered in these selected cases as a therapeutic implement.
Objectives: To describe clínical clinical characteristics of patients undergoing eTAVI, evaluation of clinical course and most frequent complications related to the procedure.
Methods: Observational, retrospective study from January 2021 to December 2022 in an Intensive Care Unit (ICU) of a tertiary care hospital. Patients undergoing eTAVIwere included. Demographic variables, admission to ICU, surgical risk (Euroscore II), left ventricular ejection fraction (LVEF) before and after procedure, clinical course and complications were collected. Qualitative variables were described by frequencies; quantitative by mean and interquartile range (IR).
Results: A total of 4 patients were included, 100% male, with a mean age of 65 years (61–85). The main reason for ICU admission was acute valvular heart disease due to severe Aortic stenosis (50%).
The mean ICU stay was 6.50 days (0.9–13.9) and the total hospital stay was 13,50 days (2.58–33.91). The mean Euroscore II was 14,06% (5.03–23.08), reason for which the surgical intervention was rejected in all the cases.
Only de 25% of our cohort needed required mechanical ventilation before the procedure with a favorable weaning in the first 8 days postprocedure. One patient (25%) developed an acute kidney failure requiring continuous renal replacement therapy (CRRT). We notice an only case of cardiac arrythmia after TAVI were performed. In our cohort we observed a significant improvement of LVEF after procedure with statistical significance level $p < 0.27$ (IC 3.71–31.28).

Table 1 (abstract 001109) Demographic data and clinical curse

Clinical features	N = 4
Male, n (%)	4 (100%)
Age, mean (IR)	65 (61.75–80.25)
ICU admission	
Decompensated heart failure, n (%)	1 (25%)
Miocardial acute infarction killip 3, n (%)	1 (25%)
Symptomatic acute severe aortic stenosis, n (%)	2 (50%)

Clinical features	N = 4
Euroscore II % (IR)	14.06 (5.03–23.08)
Mellitus diabetes II, n (%)	3 (75%)
Arterial hypertension, n (%)	3 (75%)
Chronic kidney disease, n (%)	2 (50%)
Chronic ischemic heart disease, n (%)	1 (25%)
LVEF before TAVI, mean (RI)	15 (11.25–26.25)
LVEF after; mean (RI)	38 (36.50–47)
Arrythmias; n (%)	1 (25%)
Mechanical ventilation, n (%)	2 (50%)
Vasoactive amines, n (%)	3 (75%)
CRRT, n (%)	1 (25%)
ICU length of stay, mean (RI)	6.50 (0.9–13.9)
Hospital length of stay, mean (RI)	13.5 (2.58–33.99)

Conclusions: In our study we observed a significant clinical and statistical improvement of LVEF after procedure which is related to a recovery of functional class of our patients. Most frequents complications described in bibliography such as acute kidney injurie and cardiac arrythmias appeared in some of our cases. Despite the limitation of the simple size, we notice favorable results, although more studies are required to endorse this procedure.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001110

Introduction: Early and precise prognosis determination in cardiac arrest survivors remains challenging despite multimodal approach. Currently, the only guidelines-recommended biomarker for early prognostication is neuron-specific enolase (NSE).
Objectives: The aim of our study was to compare prognostic values of NSE with novel biomarkers serum tau protein (Tau), neuro-filament light chain (Nfl) and Galectin-3 (Gal) at different timepoints after cardiac arrest and with combination of all four biomarkers.
Methods: Eligible subjects for this single-center prospective study were out-of-hospital cardiac arrest survivors. All patients were treated with targeted temperature management (33 °C for 24 h) using an endovascular device. Blood samples for the measurements of NSE, Tau, Nfl and Gal levels were drawn at 24 h (D1), 48 h (D2), 72 h (D3), and 96 h (D4) after hospital admission. Thirty-day neurological outcomes according to the Modified Rankin Scale (mRS) were evaluated as clinical endpoints, poor outcome was defined as mRS 4–6. Prognostic values of NSE, Tau, Nfl and Gal for the prediction of poor outcomes were determined using ROC analysis.
Results: A total of 43 cardiac arrest survivors (mean age 64.2 years) were enrolled in the present study. The area under the ROC curve (AUC) for NSE was 0.776, P<0.001 at D1, 0.911, P<0.001 at D2, 0.982, P<0.001 at D3, and 1.0, P<0.001 at D4. The AUC for Tau was 0.823, P<0.001 at D1, 0.893, P<0.001 at D2, 0.938, P<0.001 at D3, and 0.980, P<0.001 at D4. The AUC for Nfl was 0.614, P = 0.232 at D1, 0.782, P = 0.001 at D2, 0.969, P<0.001 at D3, and 0.990, P<0.001 at D4. The AUC for Gal was 0.675, P = 0.048 at D1 and not significant for D2-4. The comparison of ROC curves revealed significantly lower AUC for Gal in comparison to other biomarkers at D2-4; a trend to lower AUC was detected for Nfl at D1 in comparison to NSE (P = 0.151) and Tau (P = 0.077) with comparable values at D2, D3 and D4. Numerically, the highest AUC at D1 was observed for Tau and at D2, D3 and D4 for NSE. The highest sensitivity for the prediction of poor prognosis with 100% specificity was detected for Tau values at D1 (33.3%) or D2 (70.0%) and for NSE values at D3 (92.9%) or D4 (100%). Multiple logistic regression revealed that combination of all four biomarkers may predict poor prognosis already at D1 with 100% specificity and 53% sensitivity (AUC 0.888, P<0.001).
Conclusions: Our results indicate that the novel biomarkers Tau and Nfl have comparable predictive value for clinical outcomes as NSE at 48 to 96 h after cardiac arrest. At the first day after admission the highest predictive value has Tau followed by NSE, whereas Nfl is not significantly associated with outcomes at this timepoint. Gal values predict outcomes only at 24 h.
Combination of all four biomarkers could improve prognosis prediction with high predictive value already the first day.

Long-term survival after mechanical support with VA ECMO

M. Mendoza-Prieto[1], N. Palomo-López[2], L. Martin Villen[1], I. Espinosa Rueda[1], J. Navarro-Rodriguez[1]
[1]Critical Care Unit, Hospital Universitario Virgen del Rocío, Sevilla, Spain; [2]Critical Care Unit, Virgen del Rocío University Hospital, Sevilla, Spain
Correspondence: I. Espinosa Rueda
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001112

Introduction: At the present time the use of VA ECMO as a treatment for refractory cardiogenic shock of any etiology has increased. Although its use is on the upswing, the mortality associated to it remains high. There are few studies that describe the progress, as well as the complications, quiality of life and mortality of patients who requiered VA ECMO once they are discharged from the ICU (intensive Care Unit).
Objectives: To describe the characteristics and short and long term outcome of shock cardiogenic patient on VA ECMO in a tertiary hospital.

Methods: Observational and retrospective study, in which patients with cardiogenic shock requiring ECMO between January 2013 and September 2022 were collected. All those patients discharged from hospital were followed up until December 2022.
Demographic variables, outcome, complications, and ECMO-related variables were collected. Qualitative variables were described by median and interquartile range. X2 test was performed for qualitative variables and U Mann Whitney for quantitative variables. Survival was represented by Kaplan–Meier. Statistical significance was considered when $p < 0.05$.
Results: A total of 135 patients were obtained, whose 96 (71,1%) were decannulated successfully. Hospital mortality for those who were decannulated was 31,25%. 66 patients were discharged from hospital, whose 95,3% were alive at 6 months. The demographic variables, survival and those variables related to ECMO are described in the Table 1.

Variables n (%) / Median (IR)	**Hospital survival N = 66**
Male	39 (59.1)
Age	52.50 (39.50. 60)
Chronic Kidney Failure	3 (4.5)
BMI > 30	7 (10.61)
Cardiogenic shock aetiology n (%)	
Postcardiotomy shock	23 (34.8)
Acute myocardial infarction	21 (31.8)
Acute myocarditis	7 (10.6)
Primary graft failure	6 (9.1)
Right ventricular failure	6 (9.1)
Survival after ECMO withdrawal	
6 months	95.53%
12 months	87.5%
60 months	83.33%
Days on VA ECMO	5.0 (3.0;8.0)
Days on mechanical ventilation	11.0 (6.5;46.5)
Peripheral neuropathy	27 (40.91)
Anxiety depressive syndrome	10 (15.15)
Kidney Failure	9 (13.63)
Surgical wound infection	8 (12.12)
Causes of mortality; n (%)	
Pneumonia	1 (25)
Hemorrhagic stroke	1 (25)
NYHA classification at 12 months	
I	36 (54.54)
II	20 (30.0)
III	9 (13.64)
IV	1 (1.51)

Conclusions: VA ECMO is postulated as an useful implement in the management of patients in refractory cardiogenic shock. In our cohort, it is associated with raised early mortality, although after hospital stay the survival of these patients remains high.

Topic: Cardiovascular issues in ICU

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001114

Introduction: Covid-19 can be complicated by pneumonia of varying severity up to acute respiratory distress syndrome (C-ARDS).
Objectives: The study aim was to describe the clinical, paraclinical and evolutionary data of C-ARDS according to the severity.
Methods: We conducted a retrospective study between March 2020 and February 2021 including all patients hospitalized for C-ARDS (according to the Berlin criteria with a positive virological test). We included patients hospitalized via the hospital emergency department for C-ARDS. Patients who died within 48 h of admission and those admitted from another hospital were not included in the study. Patients without C-ARDS and those with ARDS of other etiologies were excluded. We compared the initial clinical and paraclinical data and patients outcomes according to the severity of the ARDS.
Results: We enrolled 215 patients with a mean age of 66 ± 12 years and a sex ratio of 1.38. The main comorbidities were hypertension (55.8%) and diabetes (45.1%). The median consultation time was seven days and was shorter in mild C-ARDS (5 days). Oxygen saturation was lower in severe and moderate C-ARDS (80 and 84% respectively) than in mild C-ARDS (88%). Lung injury extension was < 10% in four cases (1.9%), 10 to 25% in 29 cases (13.5%), 25 to 50% in 67 cases (31.2%), 50 to 75% in 83 cases (38.6%à) and > 75% in 32 cases (14.9%). C-ARDS was mild in 121 cases (56.3%), moderate in 84 cases (39.1%) and severe in 10 cases (4.7%). Demographic characteristics, comorbidities, initial biological and CT data were comparable between the different severity stages of C-ARDS. Non-invasive ventilation was the most commonly used oxygenation modality; indicated in 204 cases (94.9%) alternating with High- flow nasal cannula (HFNC) oxygen therapy in 30 cases. It was more indicated in mild (98.3%) and moderate (91.7%) ARDS than in severe ARDS (80%). Invasive ventilation was indicated in 28.8% of cases (n = 62) and 80% of severe ARDS; after a median delay of five days [2–10]. Ventilation was performed in the prone position in 81 patients (37.7%), 76 of whom received spontaneous ventilation. ICU length of stay was comparable between the three stages of C- ARDS. The mortality rate was 34.9% (n = 75); higher in severe C-ARDS.
Conclusions: Patients with C-ARDS have a mean age of 66 years. Oxygen saturation and lung injury extension define the C-ARDS severity. The most frequent modes needed in C-ARDS are non-invasive ventilation. The use of invasive ventilation and mortality are high in severe forms.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001115

Introduction: Cardiac arrest (CA) represents the extreme of critical illness; survivors predominantly die as a result of the deconstructive processes affecting the nervous system. While temperature control (TC) is routinely practiced, recent evidence indicate that cooling to a hypothermic target fails to demonstrate either survival or neurological benefit (1,2). We hypothesized this may relate to the rapidity and degree of target achievement.
Objectives: To examine the published literature to identify the impact of early versus delayed initiation of TC on the rate of survival and neurological outcomes in CA victims. We further assessed the type of cooling method utilised.
Methods: A systematic search was conducted using the following databases: PubMed, Cochrane Library and U.S National Library of Medicine. Only prospective, randomised, controlled trials were included. A meta-analysis was performed using Review Manager software version 5.4.
Results: The search yielded 11,678 citations of which 11 (ten out-of-hospital) met the inclusion criteria. 4922 participants were included in the analysis. Three methods were utilised to initiate cooling (cold fluid, trans-nasal evaporative, and pharyngeal cooling). In six studies cooling was commenced during cardiopulmonary resuscitation (CPR), and in the remaining five after restoration of spontaneous circulation. Survival rates were similar in both groups (RR 1.01; 95%CI 0.92 to 1.11; I2 = 0%, p = 0.79). Early cooling also failed to improve neurological function (RR 1.01; 95%CI 0.93 to 1.14 I2 = 0%, p = 0.51). However, a sub-analysis of two studies comprising 310 patients presenting with shockable rhythms suggested early nasal evaporative cooling was beneficial (3.4). In six studies, administration of cold fluid during CPR was associated with re-arrest occurrence. All ten out-of-hospital studies failed to reach the target temperature range of 32–34 °C at hospital admission.
Conclusions: Early initiation of TC failed to show any survival or neurological benefit in cardiac arrest survivors though target temperatures were not attained. Patients presenting with shockable rhythms may benefit from nasal evaporative cooling though larger confirmatory studies are needed.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001116

Introduction: Acute bacterial meningitis is a medical emergency that often requires thepatient to be admitted to the ICU. The severity of the disease is frequently associatedwith significant morbidity and mortality. Identifying predicting factors associated withmore adverse clinical outcomes is important, in order to optimize care and ultimatelythe prognosis of these patients.
Objectives: We aimed to study a cohort of patients admitted to our ICU in the last 10 years and do an exploratory analysis to identify factors associated with a worse diagnosis.
Methods: We performed a retrospective analysis during a 10-year period of patients older than 18 years, admitted to a polyvalent ICU due to acute bacterial meningitis. Demographic, clinical and outcome data were collected from medical records in the electronic clinical file. Categorical data is presented as frequency (percentage). We performed a descriptive analysis. In addition, we performed logistic regression models adjusted to age when considered relevant. Statistical significance was set at $p < 0.05$.
Results: We identified 49 patients with the diagnosis of acute bacterial meningitis. Two thirds of the patients were male and the mean age was 54.8 years (std 17.6). The mortality during the ICU stay was 10.2%, the 28-day and 3-month mortality was 16.3% and 20.4%, respectively, and the 6-month mortality was 24.5%.
On univariate analysis, age and Charlson scale were the only variables associated with mortality. On binary logistic regression adjusted to age, Charlson scale was the only tool that could predict mortality at 1 year (OR: 1.550, 95%CI = [1.025, 2.346], p = 0.038), with statistical significance. Neither APACHE II (OR = 0.993, 95%CI = [0.867, 1.136] p = 0.913), SAPS II (OR = 1.118, 95%CI = [0.967, 1.292] p = 0.132), SAPS 3 (OR = 1.177, 95%CI = [0.935, 1.481] p = 0.164) nor SOFA score at admission (OR = 1.095, 95%CI = [0.822, 1.457] p = 0.536) could predict mortality. The same trend was observed to mortality at 28 days, 3 months and 6 months.
During the stay at the ICU, 42.9% of the patients had secondary seizures and 22.7% had secondary hydrocephalus prompting the need to place an external ventricular drain.
The patients registered significant morbidity levels in the following months with 38.9% having a score of 3 or less in the Glasgow Outcome Scale.
Conclusions: In our study, age and higher score at Charlson Scale were associated with higher mortality. Also, significant neurological disability was observed in the following months, as measured by the Glasgow Outcome Scale.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001117

Introduction: Patients with acute brain injury who require mechanical ventilation (MV) after an urgent intubation are at increased risk for ventilator-associated pneumonia (VAP). The benefit of a short course of antibiotics in preventing early-onset VAP has been shown in previous studies, but uncertainty remains.
Objectives: To evaluate the association of early antibiotic exposure at the time of ICU admission for other medical reasons with development of VAP within 7 days of mechanical ventilation (early-onset VAP) in patients with acute brain injury after an urgent intubation.
Methods: Prospective cohort of patients admitted to a specialized trauma and neurocritical ICU, from January, 2019 to December, 2022, in a tertiary hospital in São Paulo, Brazil. The analysis included patients with an acute brain injury due to traumatic brain injury, ischemic or hemorrhagic stroke or aneurismatic subarachnoid hemorrhage; older than 18 years old; who required urgent intubation performed in prehospital setting or emergency department; and that required MV for at least 48 h. Patients were excluded if they were using antibiotics as treatment for an infection at the time of ICU admission and if they were submitted to a considered non-urgent intubation in the operating room. We performed an inverse probability weighted analysis adjusting for baseline confounders to evaluate the association between exposure to an early antibiotic course for 48 h for other medical reasons, mostly antibiotic prophylaxis for open fractures and cerebral spinal fluid fistulas according to hospital guidelines, with development of VAP up to 28 days, early-onset ($\leq$ 7 days) VAP and late-onset (> 7 days but < 28 days) VAP.
Results: A total of 697 patients with acute brain injury were admitted to the ICU in the period. Of those, 433 received MV for at least 48 h following an urgent intubation (Table 1). Early-onset VAP occurred in 45 patients (10.4%) and late-onset VAP in 34 (7.9%) patients (Table 2). In the weighted pseudopopulation, antibiotic exposure within 48 h of intubation was associated with decreased odds of VAP (OR = 0.48, 95% CI 0.27–0.84, p = 0.010). The exposure was associated with less early-onset VAP (OR = 0.41, 95% CI 0.20–0.82, p = 0.011), but not with late-onset VAP (OR = 0.68, 95% CI 0.30–1.53, p = 0.35). Antibiotics exposure was not associated with neither lower ICU (p = 0.34) nor hospital mortality (p = 0.85), but it was associated with more ventilator-free days (median difference = 7 days, 95% CI 1.05–12.95, p = 0.021, Figure 1).
Conclusions: Antibiotic exposure within 48 h was associated with a reduction in early VAP in patients with acute brain injuries intubated in an urgent setting.

CSF-LDH as a potential prognostic marker in acute bacterial meningitis

A. R. Nogueira[1], J. E. Mateus[1], J. Rua[1], L. Linhares[1], M. Simões[1], P. Martins[1]
[1]Intensive Care Unit, Centro Hospitalar e Universitário de Coimbra, Coimbra, Portugal
Correspondence: J.E. Mateus
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001118

Introduction: Acute bacterial meningitis is a medical emergency that often requires the patient to be admitted to the ICU. Ensuring a timely diagnosis and an adequate management is important to reduce mortality and to improve the neurological outcome. Lumbar puncture is paramount in the diagnosis and treatment of acute meningitis. Increase in spinal fluid LDH level is an indication of either neuronal or glial cell injury.
Objectives: We aimed to characterize the patients with acute bacterial meningitis within an ICU setting and study the role of CSF leukocyte count, CSF glucose, CSF proteins and CSF-LDH in the prognosis of these patients.
Methods: We performed a retrospective analysis during a 10-year period of patients older than 18 years, admitted to a polyvalent ICU due to acute bacterial meningitis. Demographic, clinical and outcome data were collected from medical records in the electronic clinical file. Categorical data is presented as frequency (percentage). We performed a descriptive analysis. Continuous variables were correlated by Spearman correlations. Comparisons were made through Mann–Whitney tests. Statistical significance was set at $p < 0.05$.
Results: We identified 49 patients with the diagnosis of acute bacterial meningitis. Two thirds of the patients were male and the mean age was 54.8 years (std 17.6). The mortality during the ICU stay was 10.2%, the 28-day and 3-month mortality was 16.3% and 20.4%, respectively, and the 6-month mortality was 24.5%.
A definite microbiological diagnosis was achieved in 61.2% of the patients. *Lysteria monocytogenes* and *Streptococcus pneumonia* were the most common agents, accounting for 42.9% of the total cases.
CSF LDH was associated with increased leukocyte count ($r = 0.69$, $p < 0.001$), CSF proteins ($r = 0.44$, $p = 0.030$) and the need to perform External Ventricular Drainage (non EVD: 225.4 ± 393.6 vs. EVD: 683.5 ± 580.2, $p = 0.009$). Although CSF-LDH is higher in patients who died in the follow-up, we found no statistically significant association with mortality.
Conclusions: CSF-LDH seems to have a role as a measure of assessment of severity of acute bacterial meningitis and the need for external ventricular drainage placement. Prospective studies could clarify its role as a potential prognostic marker.

Status epilepticus: a life-threatening condition in the ICU

P. Matía Almudévar[1], A. C. S.[1], M. S. N.[1], P. R. M.[1], B. I. E.[1], C. R. M[1]
[1]Intensive Care, Puerta de Hierro Majadahonda University Hospital, Majadahonda, Spain

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001119

Introduction: Status epilepticus (SE) is a prevalent condition which requires prompt and adequate identification and treatment to prevent excessive morbidity and mortality. This assertion become even more challenging when we refer to nonconvulsive status epilepticus (NCSE) which is a frequent form of seizures in the ICU.
Refractory status epilepticus (RSE) accounts for 12–48% of all status epilepticus in general population (1), but this number increases amongst ICU patients; furthermore, some of them will progress to super-refractory status epilepticus (SRSE).
Objectives: To describe our experience in SE management and prognosis, focusing on RSE, SRSE and NCSE.
Methods: Retrospective, observational study from January 2020 until December 2022 of all patients diagnose of SE upon ICU admission or who developed it during ICU stay in a Spanish tertiary hospital.
Results: During the period studied 18 SE were diagnosed in our ICU. Fourteen were RSE with nine progressing to SRSE (64) and nearly one third (5) were non-convulsive status epilepticus (NCSE).
In this group of patients, mean age was 52 ± 19 years old. 55% (10) were women. Mean APACHE II score was 18 ± 5. Median ICU length of stay was 11 (2–30.5) days, median hospital length of stay was 19,5 (10.75–53.5) days.
Seventeen of them had at least one risk factor for developing SE: previous history of epilepsy (7), acute structural brain insult (6), lowering seizure threshold drugs (2), metabolic abnormalities (2), alcohol withdrawal syndrome (1) and longstanding structural brain injury (1).
Regarding treatment, the antiseizure medication (ASM) of choice in the ICU was levetiracetam, used in more than 85% of the cases (16), followed by lacosamide (13), valproate (9), perampanel (8), clonazepam (7), and phenytoin (2).
Alongside with antiepileptic drugs, all of our patients but one received continuous IV sedation. Our first choice was the combination of propofol + remifentanil (16), adding midazolam (9) ± ketamine (6). There was also one patient who received thiopental and one who received sevoflurane. Nearly two out of three (11) patients required two IV sedation drugs at the same time.
The median time among survivors to achieve adequate seizure control was 1 (0–11) days, and to fulfil IV sedation tapering, eleven patients (61%) received three or more AMS simultaneously.
Mean predicted mortality rate as given by APACHE II score was 29.1%, whereas mortality among RSE and SRSE in our cohort was 43% (6 out of 14) and 67% (6 out of 9) respectively, and it was even higher in NCSE patients, 80% (4 out of 5).
The main cause of death was withdrawal of life sustaining treatment due to grim neurological prognosis.
Conclusions: Non-convulsive status epilepticus, as well as refractory and super-refractory status epilepticus are neurological emergencies that increase mortality in ICU patients. Early identification and adequate treatment are of the utmost importance.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001120

Introduction: Monitoring cardiac output (CO) and tissue oxygenation is part of the comprehensive management of critically ill patients in the Intensive Care Unit (ICU), especially those in shock. Cardiac output is the amount of blood flow ejected by the left (or right) ventricle in a unit of time, expressed in liters per minute and is the product of heart rate per stroke volume.
CO (l/min) = heart rate (beating/minute) x stroke volume (liters).
Traditionally cardiac output has been measured by thermodilution with a pulmonary artery flotation catheter (PAC) or Swan-Ganz catheter. The availability of newer, less invasive cardiac output devices has decreased the widespread use of the PAC.
The main ways of measuring cardiac output are: Fick's principle, Dilution techniques, Arterial wave analysis techniques, Ultrasound by Doppler principle.
Objectives: Research question: Is there a difference in the measurement of cardiac output reported by minimally invasive monitoring compared to cardiac output measured by ultrasonography?
General Objective: To compare the measurement of cardiac output measured through minimally invasive continuous monitoring compared with cardiac output measured by ultrasonography.
Methods: Type of study: Transversal, Observational, Prospective, Analytical—correlational.
Population: Patients admitted to the adult intensive care service of Hospital Juárez de México, from 18 to 85 years, who have minimally invasive cardiac output monitoring and cardiac window for ultrasonographic evaluation.
Resources: Minimally invasive continuous cardiac output monitor (Flotrac—Edwards Lifesciences™) & VENUE Ultrasound from General Electric ™
Results: A total of 18 patients were studied, of which the mean age was 37.3 (± 8.2), the female gender was 16 patients (88.9%), 2 patients male (11.1%), the mean BMI 29.6 (± 5.9), SOFA mean 11.2 (± 3.1), APACHE II median was 17 (range 9–28), SAPS mean was 38.2 (± 13.9). The EV1000 values, the mean of SV was 73.8 (± 19), the mean of GC 7.26 (± 2.5), the mean of SVR 792 (range 629–1202). The measurements by ECOTT, the SV mean was 51.2 (± 14.8), the GC mean was 4.5 (± 1.6), the SVR mean 1291.7 (± 498), more details in Table 1.
Finally, given the only variable that showed significance, the CG was entered into a regression model resulting in an R 0.472 (47%) association, however, a squared or adjusted R2 was performed, leaving R2 0.225 (22%). of association between the CG measured by EV1000 against the CG measured by ECOTT, which explains a weak association, the other variables did not show significance. Figure 1.
Conclusions: Cardiac output measurement using a minimally invasive monitor (by arterial pulse wave analysis) and the one obtained by transthoracic ultrasound do not correlate with each other in critically ill patients.
The measurement of central venous pressure by a pressure transducer and the one estimated by abdominal ultrasound in the subxiphoid window, have adequate correlation with each other, with statistical significance. However, the sample used in the study is a small population, so it deserves further study to obtain more data in this regard.

Table 1. General characteristics of the population.

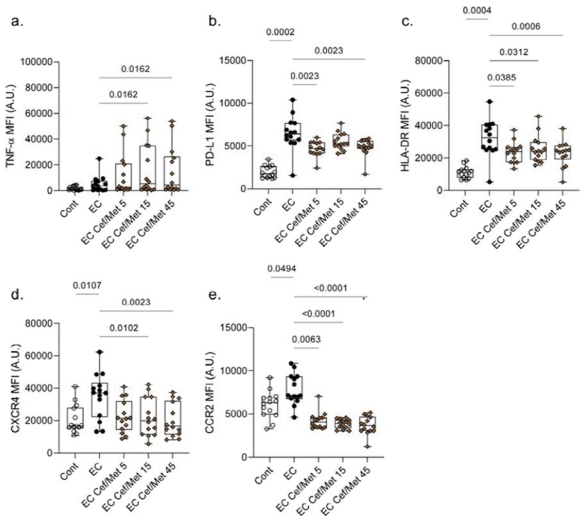
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001122

Introduction: Sterile inflammation induced by major surgery results in simultaneous activation of the immune system. Antibiotics are often prescribed following sterile surgery to reduce the risk of post-operative infections. Antibiotics are known to modulate the immune system. We hypothesised that antibiotics often used for prophylaxis following surgery result in impaired immune response to a bacterial stimulus, which may paradoxically increase the risk of late post-operative infections.
Objectives: Identify if amoxicillin, cefuroxime and metronidazole impair the innate immune (monocyte and granulocyte) response to a bacterial stimulus in vitro.
Methods: Healthy volunteer (n = 16) whole blood was incubated in vitro with heat-killed E. coli (HKB) and antibiotics for 6 h. Amoxicillin, cefuroxime, metronidazole, and combined cefuroxime-metronidazole were used at concentrations of 5, 15 and 45mcg/ml to represent, sub-clinical, clinical, and supra-clinically relevant concentrations respectively.
Flow cytometry was used to assess markers of granulocyte (migration (CXCR4), activation (CD16, CD66b, CD86), cytokines (IL-1ß, IL-6, and TNF-α)) and monocyte (antigen presentation (HLA-DR, and CD86), chemotaxis (CCR2 and CXCR4), cytokines (IL-1ß, IL-6, and TNF-α), T-cell suppression (PD-L1)) function.
Results: Each antibiotic in isolation resulted in minimal or no alterations to markers of immune function. However, cefuroxime and metronidazole in combination caused an increase in granulocyte TNF-α (a), and in monocytes decreased PD-L1, HLA-DR, CXCR4, and CCR2 expression (b–e).
Conclusions: Commonly prescribed surgical antimicrobial prophylaxis induce features of impaired immune function, particularly monocyte chemotaxis and antigen presentation (HLA-DR). It needs to be evaluated if lymphocytes are affected, if similar changes occur in patients, and the clinical consequences.



Data presented as individual data points (n = 16), horizontal line (median), box (interquartile range) and whisker (range). Difference between Control (Cont) and E. coli (EC) compared using Wilcoxon test, and between EC and all doses of cefuroxime (Cef) with metronidazole (Met) with E. coli using Friedman test without post-hoc correction. Only p-values < 0.05 shown.

Introduction: Among resuscitative interventions for patients with septic shock and persistent hypoperfusion signals (capillary refill time > 3 s or serum lactate > 2 mmol/L) after adequate fluid administration, increasing mean arterial pressure (MAP) from 65 to 85 mmHg in previously hypertensive patients could improve end-organ perfusion. However, vasopressor titration (either increasing norepinephrine dose or adding vasopressin) could also deteriorate cardiac performance, splanchnic artery resistance or renal function, leading to worse clinical outcomes.
Objectives: We report the initial results of an ongoing physiologic randomized controlled study comparing vasopressin vs placebo to target a higher MAP in septic shock patients. However, the aim of this one is to assess the multidimensional impact of vasopressor titration to achieve a MAP of 85 mmHg on cardiovascular performance, tissue perfusion, splanchnic artery flow, venous return, and renal function in mechanically ventilated, fluid-unresponsive patients with septic shock who had a history of hypertension.
Methods: We increased the MAP from 65 to 85 mmHg in patients who continued to experience hypoperfusion despite achieving adequate fluid resuscitation and a MAP of 65 mmHg. MAP was increased either with norepinephrine alone or by adding vasopressin (0.03 UI/min) to achieve the MAP target of 85 mmHg for 24 h. We conducted a comprehensive ultrasound assessment. Echocardiography, Doppler resistance index of the liver, spleen, and kidneys, capillary refill time (CRT) and lactate levels were assessed at baseline, after 1 h of achieving the new MAP target (85 mmHg), and again at 24 h. Renal and cardiac biomarkers were assessed at baseline and at 24 h after achieving the MAP target. Statistical analysis was performed using the SPSS. A p-value < 0.05 was considered significant. This study was supported by FONDECYT 11201220.
Results: Fourteen patients (age 69 ± 11 yr, 50% female) were included in this preliminary report. At baseline the APACHE II score was 20 ± 7 and SOFA score was 9 ± 3. Norepinephrine was used as the only vasopressor in 8/14 (57%) patients, while in the remaining 6 (43%) patients, vasopressin was added to norepinephrine as indicated. The main cardiovascular performance parameters, splanchnic perfusion parameters, and biomarkers are presented in Table 1. After 1-h, systolic volume increased by more than 10% in 7/14 (50%) patients, showed no change in 5/14 (35%) patients, and decreased in 2 (14%) patients. Splanchnic artery resistance did not change significantly, whereas portal venous velocity increased significantly due to splanchnic venous return. Capillary refill time improved in 5/6 patients (83%) who previously had an abnormal value (6.5 s [IQR 4.4–10] vs 3.7 s [IQR 2.6–6], p = 0.026) and did not change in 8 patients who were within normal range. In 5/9 (55%) patients with increased lactate improved at least 10% in 1-h and increased in 2/5 (40%) patients who had a normal lactate level. Tissue perfusion improved in 7/14 (50%) patients, did not change in 2/14 (14%) patients, and deteriorated in 5/14 (36%) patients at 24 h. Acute kidney injury was present in eight patients (57%). Renal support therapy was initiated in 3 (21%) patients. The ICU mortality was 42%, 5 out of 6 non-survivors did not improve tissue perfusion at 24 h.
Conclusions: In mechanically ventilated patients with septic shock who exhibited persistent hypoperfusion despite achieving adequate fluid resuscitation and a MAP of 65 mmHg, and history of previous hypertension, increasing the MAP from 65 to 85 mmHg improved tissue perfusion in most cases. Despite this significant increase in vasoconstriction, cardiac performance and markers of regional perfusion and biomarkers of organ function did not worsen, showing the safety of this strategy. The final results of the study will further increase our understanding of improving tissue perfusion by manipulating MAP.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001124

Introduction: Respiratory quotient (RQ) is the ratio of carbon dioxide production (VCO_2) to oxygen consumption (VO_2). Under aerobic conditions, it is primarily determined by energy sources. In anaerobic conditions, there are sharp increases in the RQ related to anaerobic VCO_2. RQ is measured by analysis of expired gases through a metabolic chart, which is not usually available in the ICU. It has been proposed that the ratio of venoarterial PCO_2 difference to arteriovenous oxygen content difference ($Pv–aCO_2/Ca–vO_2$) could be used as a surrogate for RQ. In observational studies, a value higher than 1.4 has been associated with hyperlactatemia and outcome (1). Since metabolic acidosis and hemodilution are strong predictors of $Pv–aCO_2/Ca–vO_2$, this relationship does not reflect anaerobic metabolism (2). In experimental studies, the correlation between RQ and $Pv–aCO_2/Ca–vO_2$ is only poor. To the best of our knowledge, these variables have not been compared in critically ill patients.
Objectives: To compare the respiratory quotient measured by indirect calorimetry with $Pv–aCO_2/Ca–vO_2$. We hypothesized that the variables were not interchangeable.
Methods: Septic shock patients (n = 47) undergoing mechanical ventilation with stable hemodynamic and respiratory conditions were recruited from two surgical/medical ICU. VO_2, VCO_2 and RQ were recorded breath-by-breath using an indirect calorimeter over a 30-min period.

In arterial and central venous blood samples, drawn at the end of this period, we measured gases, O_2Hb and hemoglobin to calculate Pv–aCO_2/Ca–vO_2. Oxygen contents were calculated using standard formulae.
The relationship between RQ and Pv–aCO_2/Ca–vO_2 was assessed using Pearson's correlation and Bland–Altman analysis. Bivariate linear regression analysis with Pv–aCO_2/Ca–vO_2 as the outcome variable was conducted, and variables showing a P value < 0.30 were entered into a multiple linear regression model, looking for its determinants.
Results: No correlation was found between the RQ measured by indirect calorimetry and Pv–aCO_2/Ca–vO_2 (r = -0.10, P = 0.50) (Figure 1). The bias between both variables was 1.09, and the 95% limits of agreement were -1.10–3.27.
The multiple linear regression model showed that Hb, venous PCO_2, and venous O_2Hb as Pv–aCO_2/Ca–vO_2 determinants ($R^2 = 0.36$, $P = 0.0007$).
Conclusions: This is the first study performed in critically ill patients, comparing RQ and Pv–aCO_2/Ca–vO_2. Neither variable was correlated and showed unacceptable-wide limits of agreement. The Haldane effect and Hb levels, but not the RQ, are determinants of Pv–aCO_2/Ca–vO_2.
Our data showed that Pv–aCO_2/Ca–vO_2 is a poor surrogate for RQ and raises concerns regarding its use for the assessment of tissue oxygenation.

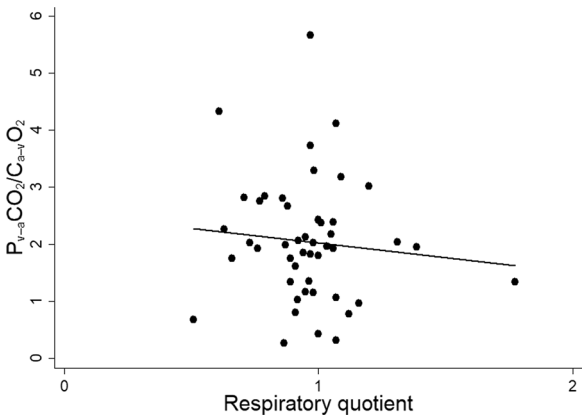

Figure 1 (abstract 001124) Scatter plot between the RQ measured by indirect calorimetry and Pv–aCO?/Ca–vO?

Development of a VR-simulation, a UCD mixed method study

K. Hoek[1], N. Groeneveld[2]
[1]Intensive Care, LUMC, Leiden, France; [2]Intensive care, Leiden University Medical Center (LUMC), Leiden, Netherlands

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001126

Introduction: Simulation training in medical settings is becoming a cornerstone of clinical training (Anthony, 1996; Yunoki & Sakai, 2018). Virtual reality (VR) is a new method of delivering simulation offering several potential benefits for trainer and trainees as an alternative to full-body mannequins based training. Through the Proteus effect trainees can feel present while being fully immersed in a virtual world (Bian et al., 2015; Navarro et al., 2022). VR simulation may affect attitudes, perception and behaviour enhancing active learning. VR-simulation can generate personalised scenario's effective for differentiated learning, as it enables practicing situational awareness, decision making, triages of possible actions and other multitiered response systems in a highly stressful, but safe environment.
Objectives: The main objective of this study was to develop and evaluate a VR-scenario training program for anaesthesiologist-intensivists tailored to the needs and experience of the trainees and simulation trainers with a multidisciplinary expert team involved throughout the development process to guide all design decisions. Physiological features of the patient were adaptable by the trainer via a trainer dashboard to be able to induce stress amongst trainees and train performance and crisis resource management under pressure. The VR-simulation was built for multiplayer use.
The authors explored user experiences of trainees and a trainer during a final evaluation of the VR-simulation. They identified a workflow for all basic components of the VR application for further development and extension of the VR-simulation.
Methods: This user-centered design (UCD) used an iterative design process to develop a VRsimulation for anaesthesiologist-intensivists. The protocol was approved by the Institutional Science Committee and received a certificate of no rejection from the Institutional Review Ethics Committee. The multidisciplinary expert team consisted of one anesthesiologist, one intensivist, one resident, and two VR-developers. The authors adapted the Failure Modes and Effects Analysis (FMEA) as it identifies possible system failures and vulnerabilities in complex processes (Ashley et al., 2010; Davis et al., 2008). The authors assessed content validity and face validity through a final evaluation. Quantitative outcome measures included the Virtual Embodiment Questionnaire and the Multimodal Presence Scale, expressed in frequencies and percentages. Qualitative outcome measures with focus group interviews were analysed adapting a thematic analysis framework.
Results: Three simulation prototype iterations were made, each evaluated with a simulation setting, debriefing and FMEA with the multidisciplinary expert team. After every simulation, feedback was provided to the mechanical engineering team, designs iterations were made and the modified prototype was tested and adapted until thematic saturation was achieved. Five trainees and one trainer were included in the final evaluation of the VR-simulation. Quantitative outcome measures and qualitative outcome measures reported potency of the VR-simulation with sentiment of *presence* and effective *immersion*. No serious adverse events were reported.
Conclusions: This study elaborated on the development of a VR-scenario training program with the potency of experimental learning with VR. It may contribute to further research and healthcare educational programs avid to use immersive simulation learning with VR.

Novel staging system (AVEX stage) predicts survival in patients with severe COVID-19 who received ECMO: analysis of the Japanese national registry

S. Ohshimo[1], S. Takaki[2], N. Shime[1], K. Liu[2], T. Ogura[2], K. Shimizu[2], S. Kushimoto[2], S. Hashimoto[2], Y. Fujino[2], S. Takeda[2]

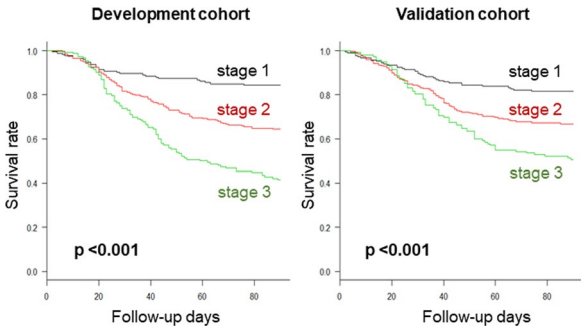
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001127

Introduction: A staging system to predict the survival of severe coronavirus disease 2019 (COVID-19) could be useful for the appropriate allocation of medical resources. However, appropriate systems to predict survival of severe COVID-19 patients receiving ECMO were not well established.
Objectives: To develop a novel staging system to predict survival of patients with severe COVID-19 receiving ECMO.
Methods: We developed a prospective national registry covering > 80% of intensive care units in Japan. Patients with severe COVID-19 who received ECMO were divided into two groups: a development cohort and a validation cohort. Using variables identified by a Cox proportional hazards model associated with survival in patients with severe COVID-19 who received ECMO, AVEX score (Age, Ventilator days before starting ECMO and institutional EXperience of ECMO for COVID-19) was developed. Each score was defined as follows and a total score of 0 to 5 was calculated: age ≥ 59 years, 2 points; age < 59 years, 0 points; ventilator days before starting ECMO ≥ 2 days, 2 points; ventilator days < 2 days, 0 points; institutional ECMO experience for COVID-19 < 10 cases, 1 point; experience ≥ 10 cases, 0 points. According to the AVEX score, AVEX stages were defined as follows: 0–1 points were defined as stage 1, 2–3 points as stage 2 and 4–5 points as stage 3. The association between AVEX stage and survival was analyzed using the Kaplan–Meier method.
Results: A total of 9,745 patients received mechanical ventilation, of whom 1,214 (12%) received ECMO between January 2020 and October 2021. The overall survival rate of patients who received ECMO was 64%. The number of patients in the development cohort with AVEX scores of 0, 1, 2, 3, 4 and 5 points was 95 (16%), 78 (13%), 149 (25%), 133 (22%), 72 (12%) and 80 (13%), respectively. The number of patients in the development cohort with AVEX stages 1, 2 and 3 were 173 (29%), 282 (46%) and 152 (25%), respectively. The 90-day survival rates were 84%, 64% and 41%, respectively. AVEX stage was significantly associated with survival ($p < 0.001$).
The number of patients in the validation cohort with AVEX stages 1, 2 and 3 were 185 (30%), 280 (46%) and 142 (23%), respectively. The 90-day survival rates were 82%, 67% and 51%, respectively. We confirmed that the AVEX stage was significantly associated with survival in the validation cohort ($p < 0.001$).
Conclusions: AVEX staging system significantly predicted 90-day survival in patients with severe COVID-19 who received ECMO.



Kaplan–Meier curves showing the association between a novel staging system (AVEX stage) and survival in severe COVID-19 patients who received ECMO. Kaplan–Meier curves for (A) the development cohort and (B) the validation cohort.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001128

Introduction: Ultrasonic parameters like the diaphragm thickness (DT) and diaphragmatic excursion (DE) are being increasingly used to measure diaphragmatic function during mechanical ventilation. Advanced doppler modes like Pulse wave Tissue Doppler imaging (PW-TDI) can be used to quantify the peak velocity of the diaphragm which reflects the diaphragmatic strength. However, TDI of the diaphragm has been scarcely used to assess the characteristics of diaphragmatic contraction and relaxation. We hypothesize that, diaphragmatic TDI can help predict weaning in critically ill mechanical ventilated patients.
Objectives: To determine the diagnostic accuracy of diaphragmatic PW-TDI parameters in predicting weaning outcomes in critically ill mechanically ventilated patients. We also compare the performance of TDI derived parameters with that of conventional ultrasound-based parameters for prediction of weaning and outcomes.
Methods: Forty mechanically ventilated patients eligible for spontaneous breathing trial (SBT) after a minimum 48 h of mechanical ventilation were included in the study. Conventional 2D parameters {DE, DT, Diaphragmatic Thickening Fraction (DTF), DE time index (DETI) & Diaphragmatic Rapid Shallow Breathing Index (RSBI)} & Tissue Doppler parameters {peak contraction velocity, peak relaxation velocity, inspiratory velocity time integral (VTI) and expiratory VTI} were measured at end of SBT. Patients were classified as weaning success (WS) or weaning failure (WF) depending on requirement of respiratory support within 48 h of extubation.

Results: Half of the patients had successful weaning and extubation. The PW-TDI parameters: contraction velocity, relaxation velocity, inspiratory VTI and expiratory VTI; were found to have low sensitivity (50%, 45%, 50% & 55% respectively) and high specificity (100%, 100%, 95% & 90% respectively) for prediction of successful weaning. Among all parameters, contraction velocity was found to the independent predictor of successful weaning, from logistic regression analysis and the inspiratory VTI had the best discriminating ability with a AUC 0.985, 95% CI 0.884–0.993. The AUC curves of all the parameters of PW-TDI were better than that of RSBI. The AUC curves of the two models using 2D and PW-TDI parameters were found to be comparable (0.86 vs. 0.87) and both are similar in predicting outcomes.
Conclusions: PW-TDI measurement of diaphragm during weaning is a promising new tool in predicting weaning outcomes. All TDI parameters performed better than RSBI for prediction of successful weaning and are found to be comparable to the conventional 2D diaphragm measurements.

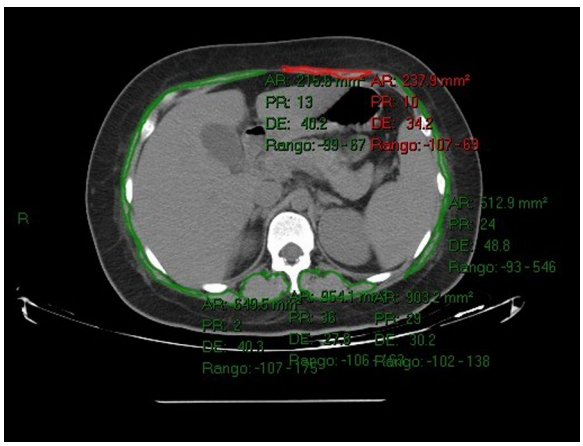
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001130

Introduction: Sarcopenic obesity is defined as the presence of disfunction and low muscle mass, its associated with higher mortality and complications in critically ill patients, Low muscle mass, a component of sarcopenia, is proposed as an independent predictor of poor outcome including fewer ventilator-free days, longer ICU stay, hospitalization, and higher mortality.
Despite de gold standard of muscle mass measurement with CT scan is at L3 level, the measurement of T12 level has proven to be equally valid.
SMI (Skeletal Muscle Index) values of < 46.2 cm^2/m^2 (men), < 30.6 cm2/m2 (women) established as a component of the diagnosis of sarcopenia.
In concern to measurement tools, are proposed methods such as MRI, densitometry, bioimpedance, which are complex to implement in critically ill patients and hospitals with limited resources. Most patients admitted to ICU have chest CT scan as an ordinary study. The measurement of muscle mass at the t12 level could be useful to diagnose low muscle mass and this could be a predictive factor of complications.
Objectives: Primary outcome: Determine if obese patients with low muscle mass have greater mortality during their admission to ICU.
Secondary Outcomes: Determine if obese patients with low muscle mass have more complications such as, higher days of mechanical ventilation, ICU stay length, acute kidney injury, renal replacement, vasopressor use and intrahospital infections.
Methods: Cross-sectional study, Observational, Descriptive, retrospective
The total number of patients with Obesity were diagnosed by BMI greater than 30 who were admitted to the ICU of the Hospital Juárez de México from October 2022 to February 2023, including patients who had chest CT scan in the first 4 days of hospital admission It was performed Imaging measurements of the muscle area at the T12 level, defining the paraspinal, transverse, oblique, and rectus abdominis muscles. A review of the files of these patients was carried out to determine and record their clinical evolution.
Results: The data collected statistically evaluated with the statistical program SPSS v23
Of the twenty initial patients included, seven were discarded, obtaining an N of thirteen patients, with average age of 44 years, average BMI of 34.1, 61.5% women, 38.5% men, SMI mean of 22; a 100% of the patients had low muscular mass, 38.4% result on death during ICU stay. The OR was not significant for predicting mortality risk associated with low muscle mass. OR de 0.222 IC (0.020–2.451).
Conclusions: We cannot compare the groups of obese patients with low muscular mass and mean muscular mass because all patients had low muscular mass, we had non significative -statistical data about mortality, ICU stay length, mechanical ventilation length, Acute Kidney Injury, Metabolic control, or prognosis association with SOFA, APACHE, SAPS or NUTRIC Score; a bigger sample group is a required to obtain more significative results.



Measurement of muscle mass at the level of T12

Early mobilization of the most critically ill and mechanically ventilated patients in the intensive care unit—is it possible in clinical practice?

K. O. Poulsen[1], J. Bruun Frandsen[2], E. Laerkner[2], T. Strøm[1]
[1]Department of anesthesiology and intensive care, Odense University Hospital, Odense, Denmark; [2]Department of anaesthesiology & intensive care, Odense University Hospital, Odense, Denmark

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001136

Introduction: During the first week of critical illness in the Intensive Care Unit (ICU), massive loss of muscle strength occur. Multiple organ failures and deep sedation relates to a lower degree of mobilization. Immobilization is a risk factor for developing Intensive Care Unit Acquired Weakness (ICU-AW) (1–6).
Early mobilization (EM) and rehabilitation may improve patient mobility during ICU and hospital admission, reduce the incidence of delirium and increase the number of days alive after hospital stay (7).
Several publications report different types of barriers to early mobilization. One type of barriers are physiological. These barriers are hemodynamic and respiratory instability and the use of continuous renal replacement therapy (CRRT).
Examples of recommendations from safety protocols regarding EM, are the level of Fraction of Inspired Oxygen (FiO2) below 0,6, level of Positive End Expiratory Pressure (PEEP) below 10 cm H2O during Mechanical Ventilation (MV), no vasoactive drugs or no increase in vasopressor in the past 2 h and the presence of CRRT (8–9).
The general ICU at Odense University Hospital is a 27-bed ICU with more than 20 years of practice with a no-sedation strategy. In our daily care, nurses and physiotherapists assess the patient in collaboration during daytime to explore the possibility for EM. In the evening, the nurses assess the patient. Our unit has a 1:1 patient-nurse ratio.
Objectives: To explore the practice regarding EM in our unit.
Inclusion criteria: Adults from both medical and surgical specialties with at least 24 h of admission.
Inclusion dates from 1/1 2021–31/12 2022.
Only patients undergoing MV from these groups is included:
PEEP > 10 cm H2O or FiO2 > 0,6
Noradrenaline infusion.
CRRT
EM is defined as mobilization during the first 7 days of admission in the ICU.
Methods: A retrospective, quantitative study.
Data is extracted from Critical Information System, CIS via the HealthQ system. Data is extracted anonymously.
Results: From 1/1 2021 to 31/12 2022, a total of 3257 adult patients was admitted to our general ICU. 1124 of these underwent mechanical ventilation. Preliminary data analysis shows, that:

- 463 patients had a PEEP of 10 cm H2O or more. 148 (32%) patients were mobilized. A total of 474 mobilizations was registered.
- 825 patients had a FiO2 of 60% or more. 78 (11%) patients was mobilized. 216 mobilizations was registered.
- 86 patients underwent CRRT. 14 (16%) was mobilized. A total of 21 mobilizations was registered.

Further results will be presented at the conference.

Conclusions: Data from a period of two years show, that EM of the most critically ill and mechanically ventilated patients in our ICU was possible during the first 7 days after admission. EM occured in 32% of patients with a PEEP of 10 cm H2O or more, 11% of patients with a FiO2 of 60 or more and 16% of patients undergoing CRRT.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001137

Introduction: Subarachnoid hemorrhage (SAH) is frequent among neurocritical patients and is related to disability and mortality. Through several specific scores and scales at the admission in Intesive Care Unit (ICU), it has been estimated morbidity and mortality in this group of patients.
Objectives: To analyze prognostic factors related to severe disability or mortality in patients with subarachnoid hemorrhage admitted to ICU.
Methods: Retrospective, observational study performed on patients with SAH admitted to ICU of HGU Greogrio Marañon between 2021 and 2022 years. Epidemiological data, cardiovascular risk factors, Charlson comorbidity index, organic support, intraventricular hemorrhage (IVH), type of aneurysm treatment, ciruculation affected by the aneurysm, presence of vasoespasm and patient clinical characteristics were collected during ICU stay. The prognostic scores and scales collected were: SOFA, APACHE II scores, modified Fisher, Hunt & Hess (H&H) and World Federation

of Neurosurgical Societies scale (WFNS). Severe disability or mortality was defined by the modified Rankin scale (mRS) (unfavorable mRS: 4–5-6).
Descriptive data were expressed as means with standard deviation for normally distributed continous variables, medians with interquartile range (IQR), for non-normally distributed variables, and percentages for categorical data. Chi-square (RR) for the qualitative variables, and t student for the quantitative variables performed for the univariate analysis. The prognostic factors of severe disability or mortality in SAH were obtained by multiple logistic regression analysis.
Results: Fifty two patients were included. 78.8% were female, mean age was 57 ± 12 years and Charlson comorbidity index 0 pts (0–1). 38.5% smoking, 34.6% Hypertension, 21.2% dislypidemia, 11.5% Mellitus Diabetes. Intracranial aneurysm location: Anterior communicatig artery 30.8%, Middle cerebral artery 26.9% (80.8% anterior circulation) and 19.2% vertebrobasilar. Intracranial aneurysms were treated in 84.6% (endovascular 55.8% and surgical treatment 28.8%). 71.2% of patients had IVH and the 50% needed external ventricular drainage. Vasoespasm during ICU stay was 48.1%. Severity scores: APACHE II (11 ± 7), SOFA (5 ± 5), GCS (10 ± 5). The 59.6% of patients needed mechanical ventilation, 32.7% needed tracheostomy for weaning. SAH specific scales: Modified Fisher (3 ± 1), WFNS (3 ± 2) and H&H (3 ± 2). The mRS unfavorable was observed in 31% and the In-hosital mortality was 23%
In the univariate analysis, the variables related to unfavorable mRS were: age (66 ± 15 vs 54 ± 10; p = 0.003), WFNS (OR 2.49; 95% CI 1.58–3.93), H&H (OR 2.71; 95% CI 1.66–4.44), intraventricular hemorrhage (RR 1.48; 95% CI 1.18–1.85), mechanical ventilation (RR 11; 95% CI 1.29–93.39), APACHE II (OR 1.19; 95% CI 1.08–1.31) and Glasgow scale at the admission in ICU (OR 0.75; 95% CI 0.65–0.87).
In the multivariate analysis, on a máximum model including the previously described, the age (OR 1.19; 95% CI 1.09–1.31) and H&H scale (OR 2.71; 95% CI 1.66–4.44) were the only variables independently associated with unfavorable mRS in patients with SAH.
Conclusions: In our experience, the only factors independently associated with severe disability and mortality in patients with SAH admitted to ICU were the age and the Hunt & Hess scale.

Following up chest X-rays in critical care: are we meeting national standards?

E. Smith[1], K. Puxty[2], A. Puxty[3]
[1]Intensive Care, Glasgow Royal Infirmary, Glasgow, United Kingdom; [2]Intensive Care Unit, Glasgow Royal Infirmary, Glasgow, United Kingdom; [3]Intensive Care Unit, NHS GGC, Glasgow, United Kingdom
Correspondence: E. Smith
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001139

Introduction: Chest X-rays (CXR) are a common imaging investigation in Critical Care. Guidance from the British Thoracic Society (BTS) (1) suggests that those with an abnormal CXR should have follow up imaging in 6 weeks if they have a higher risk of malignancy (age > 50 or smoker), or persisting symptoms/signs. We reviewed our compliance with this recommendation.
Objectives: To assess whether patients who met criteria for follow up CXRs after discharge from critical care were being followed up with surveillance imaging as per the BTS guidelines.
Methods: Ethical approval was considered but deemed not to be required as this project was an audit against of practice versus a gold standard. A search was made of the Scottish Intensive Care Society Audit Group (SICSAG) Database "Wardwatcher" for all admissions to our unit over a 5-year period from January 2018 until February 2023. Participants were included on the basis of either a SICSAG or APACHE II diagnosis of pneumonia of any cause. Patient notes were then reviewed to assess whether a follow up CXR was necessary and, if so, whether one was carried out. We included those who underwent cross sectional imaging as having had appropriate follow up on the basis that this is a more sensitive test than CXR.
Results: 199 patients were found to meet criteria for inclusion. Of these, 21 did not require a follow up CXR and 1 left the area before follow up. A further 43 patients died within the 6 week follow up period. Of the remaining, 134 patients met criteria for requiring a follow up CXR after 6 weeks. 63 patients (47%) within this group did not have follow up imaging.
Conclusions: We are currently not meeting the standard set out by the BTS and we aim to review our processes and assess how we can improve this. However, discharge from Critical Care, and subsequently hospital, is a complex process involving multiple specialties and disciplines from both primary and secondary care. Governance of follow up is a challenging issue and one that will require careful consideration as we consider how best to alter our processes to meet this standard.

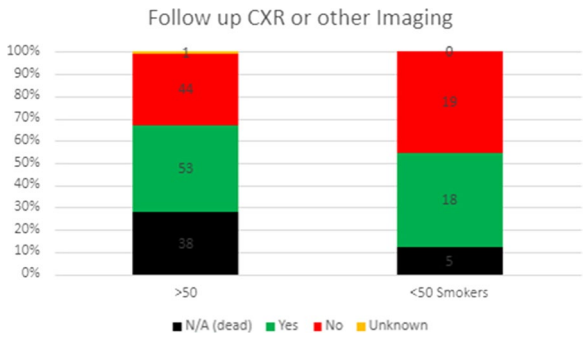

Chart 1 (abstract 001139) Follow up on basis of high-risk criteria—over 50s and under 50 but smoker

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001140

Introduction: Traumatic brain injury (TBI) is associated with death and life-changing long-term disability. TBI may occur alongside polytrauma, which can further complicate its care. Patients with TBI are often transferred to specialized neuro-surgical centres as part of their care but this does not always happen due to resource limitation and type/severity of injury.
Objectives: The objective of the study was to compare demographics, injury characteristics and outcomes of TBI patients who were transferred to a neurosurgical centre with TBI patients who remained in a regional trauma unit (RTU) without neurosurgical support, as protocol development for the management of TBI in patients in regional trauma units.
Methods: This was a retrospective observational study of patients presenting between Jan 2010 and Jan 2020 to a regional trauma unit critical care with TBI. Exclusion criteria were hanging injuries and unknown outcomes of interest. Data collected included demographics, length of stay, transfer, ASA physical classification, mechanism of injury, trauma type (isolated TBI (iTBI) or polytrauma and traumatic brain injury (pTBI)), injury severity score (ISS) and GCS. The Adapted Clavien Dindo in Trauma (ACDiT) score > 2 and mortality were recorded in 30 days, 90 days and 1 year. Patients were stratified based on transfer and trauma status.
Results: A total of 202 patients were included in the study, of which 38 (18.8%) were transferred to a neurosurgical centre and 164 (81.2%) were managed in the regional trauma unit (Table 1). The overall mortality rate at 1 year was significantly higher in patients with iTBI compared to pTBI (41% vs. 23%,p = 0.009). This was also significantly higher for patients who were not transferred compared to those who did (35% vs. 13%, P = 0.016). However, when transferring status was subgrouped by polytrauma there was no statistical significance for iTBI or pTBI (p = 0.085 and p = 0.09 respectively). There was no difference between patients with an ACDiT score > 2 in those who were transferred (44.7% vs. 39.6%, p = 0.694) or who had iTBI vs. pTBI (47% vs. 35.9%, p = 0.15). Predictors of significance of ACDiT > 2 were age > 65, ASA grade 4 and severe TBI (Severe TBI OR 19, p. value < 0.005).
.

Table 1 (abstract 001140) Demographics, injury characteristics and outcomes based on transfer (T), pTBI or iTBI

		iTBI-RTU (70)	iTBI-T (15)	pTBI-RTU (94)	pTBI-T (23)	P value
Age		57.4 (19.7)	51.8 (21.4)	49.3 (20.9)	43.0 (20.2)	0.014
Gender (% female)		18 (25.7%)	3 (20.0%)	21 (22.3%)	5 (21.7%)	0.958
ASA	1	15 (21.4%)	5 (33.3%)	37 (39.4%)	13 (56.5%)	0.004
	2	16 (22.9%)	3 (20.0%)	34 (36.2%)	5 (21.7%)	
	3	31 (44.3%)	5 (33.3%)	20 (21.3%)	4 (17.4%)

	9–12	12 (17.1%)	2 (13.3%)	9 (9.57%)	5 (21.7%)	
	13–15	28 (40.0%)	7 (46.7%)	47 (50.0%)	13 (56.5%)	
Lenth of stay		2.46[1.66;4.03]	1.71[0.39;10.4]	4.74[2.00;11.7]	2.44[0.54;8.96]	0.008
ACDiT > 2		33 (47.1%)	7 (46.7%)	32 (34.0%)	10 (43.5%)	0.358
Mortality	30days	30 (42.9%)	3 (20.0%)	23 (24.5%)	1 (4.35%)	0.001
	90days	32 (45.7%)	3 (20.0%)	24 (25.5%)	2 (8.70%)	0.002
	1 year	32 (45.7%)	3 (20.0%)	25 (26.6%)	2 (8.70%)	0.002

Conclusions: Patients with TBI who are not transferred to a neurosurgical unit have increased mortality rates. Age > 65 and severe TBI are strong predictors of mortality. These findings highlight the need for early recognition and management of TBI patients to improve their chances of survival and develop specific guidelines for the peri-transfer period.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001142

Introduction: Delirium is an acute physiologic disruption of brain networks experienced by 10–50% of hospitalized and 30–60% of critical care patients, leading to increased mortality and morbidity. Evidence exists to detect, prevent, and treat delirium. The worldwide extent of delirium management structures and processes in clinical practice remains unknown.
Objectives: To assess the delirium practice and delirium prevalence in wards and units caring for pediatric and adult hospitalized patients.
Methods: This was a non-funded, prospective, cross-sectional, survey study across 44 countries completed on World Delirium Awareness Day, March 15th, 2023. A 39-question survey was available on 3/15/23 for participating clinicians to complete via SurveyMonkey. The primary outcome is the prevalence of delirium in present patients in the morning (8 a.m.) and in the evening (8 p.m.), each ± 4 h. Secondary outcomes included the use of pharmacological and non-pharmacological interventions, use of protocols and education, and priorities for future care and research. Descriptive statistics was performed for demographic and clinical characteristics. The primary outcome was compared across age groups and settings.
Results: In total, data from 44 countries (all continents, n = 1,714 wards/units, n = 37,395 inpatients) were collected. The delirium assessment rate in the morning was 69.6% (26,033/37,395) and in the evening was 68.8% (23,305/33,891). Validated assessment tools were used in 66.2% (n = 1,134 wards/units) of wards/units, compared to 22.8% (n = 391) non-valid tools such as personal judgement, and other tools (11%, n = 189); the most frequently reported validated tool was the CAM-ICU (20.2%, n = 347/1,698). In total 15,774 patients were assessed with a validated assessment tool, of those were 18.2% (2873/12901) delirium positive in the morning and 17.9% (2503/11460) were delirium positive in the evening. In wards/units with valid delirium assessments, delirium prevalence was significant different between continents, age groups, disciplines, and ward/unit types (all $p < 0.001$). The most frequently reported prevention measures were pain management (90.4%, n = 1,462), mobilization (86%, n = 1,390), and adequate fluids (84.1%, n = 1,360). The most frequently reported pharmacologic interventions were Haloperidol (51.9%, n = 787), Quetiapine (42.8%, n = 649), and reducing delirogenic drugs (33.7%, n = 511). Shortage of staff (58.4%, n = 930), lack of time to educate staff (52.4%, n = 834), and missing knowledge about delirium (40.4%, n = 644) were the most reported barriers.
Conclusions: Delirium is a worldwide problem. In this cross-sectional prevalence study, every fifth to sixth inpatient was assessed as being delirious. Findings from this study can inform future quality improvement projects. The developed research infrastructure can be used to evaluate efforts to improve delirium detection and prevention on World Delirium Awareness Day 2024.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001143

Introduction: Traumatic spinal injury (TSI) has important physical, social and emotional consequences for the patients. Surgical stabilization and decompression plays an important part in its management but the best timing is still not fully understood.
Methods: To evaluate the impact of two different surgical timing strategies [early (< 48 h) vs. late (> 48 h)] in major TSI, we performed a retrospective single centre study of all patients consecutively admitted to an ICU of a University Hospital from 2019 to 2021. Besides demographic data, TSI characteristics, organ support, ICU and hospital length of stay (LOS) and short- (ICU and hospital) and long-term (1 year) mortality were collected.
Results: Of the 99 patients with TSI (15.1% of all trauma admissions), 63 (63.6%) had major TSI. Most of them were male (76.2%) with a median age of 56 years and a median SAPSII score of 26. At least one comorbidity was present in 61.9% of the patients. According to the AO Spine Classification, 30 were type A (47.6%), 7 were type B (11.1%) and C were 24 (38.1%). Regarding the level of fractures, 19.0% had subaxial TSI, 44.4% had cervical TSI and 63.5% dorsolumbar injury. Isolated TSI was only documented in 8 patients (12.6%). Invasive and non-invasive mechanical ventilation were used in 27 (42.8%) and 14 (22.2%) patients, respectively. 44.4% needed vasopressor support. Tracheostomy was done in 5 patients (7.9%). ICU, hospital and 1 year mortality were 9.5%, 14.3% and 19% respectively.
No statistically significant differences were observed between patients submitted (n = 38; 60.3%) or not (n = 25; 39.7%) to surgical intervention, regarding baseline characteristics, organ support and both short- and long-term mortality.
Early surgical treatment (EST) was performed in 18 patients (47.4%). Compared to late intervention, no differences wereobserved regarding demographic data, general and specific severitytrauma scores, AO Spine classification, mono vs. polytrauma, need and duration of mechanical ventilation or tracheostomy and rate of nosocomial infections. Duration of vasopressor support was lower in EST group (3 vs. 8.5 days; $p = 0.007$). Although not statistically significant, time to rehabilitation was also shorter in EST (5 vs. 13.5 days; $p = 0.1$). ICU LOS was shorter in EST group (4.5 vs. 11 days; $p = 0.049$) but no differences were found in terms of hospital LOS. ICU and hospital mortality were similar, but one-year mortality was significantly lower in EST group (0% vs 20%; $p = 0.048$).
Conclusions: In major TSI, surgical treatment was not associated with a worse outcome. If performed in the 1st 48 h, it allowed earlier rehabilitation and was associated with a lower ICU LOS and lower 1 year mortality.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001144

Introduction: Risk prediction of morbimortality through the use of scoring systems and specific scales in the intensive care unit (ICU) is important in subarachnoid hemorrhage (SAH).
Objectives: The purpose of this study was to assess the predictive prognosis value of the different severity scoring systems used in the ICU and the specific scales for patients with SAH.
Methods: Retrospective study performed of patients with subarachnoid hemorrhage admitted to ICU of HGU Greogrio Marañon in 2021 and 2022 years. Epidemiological data and patient clinical characteristics were collected. Scoring systems and specific scales for SAH were SOFA, APACHE II, modified Fisher, Hunt & Hess (H&H) and World Federation of Neurosurgical Societies scale (WFNS). The prognostic of the patients was assessed by the modified Rankin scale (mRS), considering unfavorable mRS 4–5-6 (moderate-severe).
Descriptive statistics were expressed as mean ± SD or median (interquartile range) for continous variables and percentage for categorical data. The ability of the scoring systems to discriminate prognosis was assessed using the area under the receiver operating characteristic curve (AUROC). Estimation of their calibration was established through Hosmer–Lemeshow goodness of fit test.
Results: Fifty two patients were included. 78.8% were female, mean age was 57 ± 12 years and Charlson comorbidity index 0 pts (0–1). Severity scores: APACHE II (11 ± 7), SOFA (5 ± 5). Specific scales: Modified Fisher (3 ± 1), WFNS (3 ± 2) and H&H (3 ± 2). The unfavorable mRS was 31%. Length of stay in hospital was 41 ± 29 days and mortality 23%.
It was confirmed that severity scores and specific scales were predictor of severe disability or mortalitiy (unfavorable mRS), except Modified Fisher scale: APACHE II (OR 1.19; 95% CI 1.09–1.31), SOFA (OR 1.22; 95% CI 1.06–1.40), WFNS (OR 2.49; 95% CI 1.58–3.93) and H&H (OR 2.71; 95% CI 1.66–4.44).
Using the AUROC curves (Table 1), H&H score on admission was found to be the most reliable scoring system to discriminate unfavorable mRS (AUROC 0.86, CI 0.76–0.96) with a good calibration ability (Chi-squared 1.42, p = 0.70), followed by the APACHE II score (AUROC 0.83, CI 0.72–0.94) with good calibration ability too (Chi-squared 3.99, p = 0.86). However, there were no significant differences in the ability to discriminate between the scales analyzed (Figure 1) (Table 2).
Conclusions: Our data show that the specific scales for subarachnoid hemorrhage were not superior to the standard scoring systems used in critically ill patients. Of all the severity scores analysed, the greatest discriminatory power was observed in the Hunt & Hess scale.

Table 1 (abstract 001144) .

	DISCRIMINATION		CALIBRATION	
	AUROC	CI 95%	Chi-squared	Sig
APACHE II	0.83	0.72-0.94	3.99	0.86

Social and health support for critically ill COVID-19 survivors

M. Márquez Doblas[1], G. Morales Varas[1], P. Rodríguez Villamizar[1], G. Alonso Gómez[1], P. Carneiro Pereda[1], A. Cuadra-Calahorra[1], J. Guerra Cuervo[1], M. Vecino Montoya[1], E. Alonso Ciria[1], V. Pais Sánchez-Malingre[1]
[1]Critical Care Unit, Hospital General Universitario de Toledo, Toledo, Spain

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001145

Introduction: Critical illness and ICU treatment, can cause physical, mental and cognitive symptoms (which we know as post-intensive care syndrome (PICS)). These symptoms are associated with increased mortality, higher health care costs, and lower quality of life. The COVID-19 pandemic has led to an increase in the number of critically ill patients who required ICU treatment, with many survivors at risk of experiencing PICS.
Objectives: To evaluate the socio-health care and support provided by the National Health System after one year of survival of critically ill patients by COVID-19.
Methods: This cross-sectional study among critical ill COVID-19 survivors aged 18 years and above one year after ICU discharge through phone-based questionnaire and the medical record was reviewed to assess the use of health resources. Categorical variables are expressed as counts and percentages and were compared using the $\chi 2$ test and Fisher test; continuous variables are expressed as medians and interquartile range (IQR) and were compared using Mann–Whitney U test. A two-sided level of significance of 5% was used. Data analysis was performed using STATA version 13 ® (StataCorp LCC).
Results: A total of 388 survivors at ICU discharge were surveyed, 8 rejected the survey (2,88%) and 278 responded to the survey. The demographic characteristics and evolution in the ICU are summarized in Table 1. Return to normal activity was lower in women than in men at 6 months (42% vs 54%; $p = 0.074$) and at one year (58% vs 70%; $p = 0.045$). Self-assessment of health status with the EuroQOL Thermometer (100 being the best possible health status, and 0 the worst health status) was lower in women than in men (70 (50–85) vs 80 (55–90); $p = 0.016$). There were no differences in emergency visits (37% of patients), hospitalizations (19%), surgical interventions (16%), or rehabilitation (48%) [Table 2]. In the comparison of age groups, no statistically significant differences were observed, except that younger patients felt less accompanied by the Health System (46% [under 40 years] vs 66% [41 to 65 years] vs 74% [over 65 years]; $p = 0.030$).
Conclusions: The majority of COVID 19 critical illness survivors felt supported by the health care system at the one-year follow-up. The use of health resources was important, in contrast to social support. Women had a higher consumption of psychotropic drugs and a lower return to normal activity.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001146

Introduction: Nosocomial infections are frequent in ECMO patients and are probably associated with increased in-hospital mortality. The most known risk factor is the length of the ECMO run. Although there are modifiable factors, it is challenging to specify which actions to underline to control infections. One of these factors might be the interhospital transfer. Despite infection control best practices, nosocomial infections with antibiotic-resistant organisms are associated with interhospital transfer. It may be due to mobile devices, such as ventilators. ECMO support in adult patients has subsequently increased interhospital transfer under this kind of support. The evidence shows that larger centers have better outcomes for patients on ECMO, so there may be an increase in the transport of patients receiving ECMO. It is necessary to clarify the risk of nosocomial infection related to interhospital transfer. With the extra personnel and the problem of keeping infection control methods in numerous conditions, we hypothesized that interhospital transfer might be associated with more nosocomial infections. Our ECMo team is the reference center for a large population area. If necessary, we help other hospitals and activate our ECMO mobile team for cannulating patients who need extracorporeal support and whose clinical status is too severe for a conventional interhospital transfer.
Objectives: We aim to compare the frequency of positive microbiological results in the culture of ECMO cannulas from patients cannulated within our facility and those cannulated in other centers by our ECMO team. After initiating ECMO support, the patients cannulated at other centers were transported primarily or secondarily to our hospital.
Methods: We present a retrospective observational analytical study. We included two hundred ninety-two patients on VV, or VA ECMO, admitted to the Vall d'Hebron University Hospital (HUVH) in Barcelona between January 2016 and July 2022. Antibiotic prophylaxis with daptomycin or vancomycin was employed in 95% of patients. During decannulation, we sectioned the distal 5 cm of both cannulas aseptically, sending the samples to the Microbiology laboratory for processing by Maki-type culture. We conducted a descriptive study of the sample by calculating frequencies and percentages for the qualitative variables. We calculated the odds ratio (OR), the relative and absolute increase in risk (ARR and AAR, respectively), and the number needed to harm (NNH) with their corresponding confidence intervals (CI) for hypothesis testing.
Results: One hundred thirty patients (44%) of the 292 admitted were cannulated in other healthcare centers and transported to the HUVH jointly with the multidisciplinary team of the High Complexity Unit of the Emergency Medical System (SEM) of Catalonia. Of these, 36 patients (27% of transported patients) had at least one positive result for one of the cannula cultures; 17 were positive in both the drainage and return cannula. Of the 162 patients cannulated within the HUVH (56%), at least 24 (14% of the patients cannulated within the hospital) tested positive for at least one cannula. Almost 50% of these 24 patients (13) were positive for both cannula cultures (drainage and return). The calculated OR was 1.64, CI (0.9;2.9). The ARR 0.5, CI (-0.06, 1.39). AAR 0.07, CI (-0.01, 0.15). The NNH 14, CI (-6; 92).
Conclusions: The risk of suffering an infection from the ECMO cannulas does not present statistically significant differences in the group of patients cannulated within our center compared to those cannulated outside. An expert team must transport patients on ECMO and follow a structured and protocolized process. New prospective studies are needed to confirm these findings and an evidence-based definition of colonization and infection of ECMO support devices.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001148

Introduction: Coronavirus disease (COVID-19) presents different levels of severity that may require admission to an intensive care unit (ICU) and different organ support. The care of critically ill patients with COVID-19 has been a real challenge for ICU staff. Long-term outcomes help to define the burden of disease in critically ill patients with COVID-19.
Objectives: To analyze the impact on long-term outcomes of critical illness due to COVID-19 through mortality estimation, years of life lost (YLLs), quality-adjusted life years (QALYs).
Methods: Patients were evaluated at 1-year of those who required ICU admission during the first two years of the pandemic. Medical records were reviewed and Quality of life (QoL) was assessed by the EQ-5D-5L tool and the euroQoL visual analog scale through phone-based questionnaires. 1-year mortality, YLLs, QALYs and aspects of QoL and health status perception as defined by the EuroQoL thermometer and Severity index were evaluated. Categorical variables are expressed as counts and percentages and were compared using the $\chi 2$ test and Fisher test; continuous variables are expressed as medians and interquartile range (IQR) and were compared using Mann–Whitney U and Kruskal–Wallis test. A two-sided level of significance of 5% was used. Data analysis was performed using STATA version 13 ® (StataCorp LCC).
Results: A total of 652 ICU admissions were analyzed, of which 60 were not reviewed or interviewed. The median age was 62 (53–69) years and 66.22% (392/592) were male. 1-year mortality was 38.51% (228/593), of which 34.45% (204/592) died in hospital and of the 388 survivors, 24 (6.18%) died during the year of follow-up. Mortality was higher in older patients ($p < 0.001$); in the first 3 waves of the pandemic ($p < 0.001$); in the most fragile patients ($p < 0.001$); with greater severity of Acute respiratory distress syndrome (ARDS) ($p < 0001$); in who required invasive mechanical ventilation (IMV) ($p < 0.001$) and who had who had more IMV days ($p = 0.012$). Women had higher YLLs (18.8 [13.8–26.8] vs 13.2 [7.2–19.2] years; $p < 0.000$), no difference in QALYs ($p = 0.939$), but with a worse perception of health status (EuroQoL thermometer: 70 [50–85] vs 80 [55–90]; $p = 0.016$) and a higher Severity index (30 [10–50] vs 10 [0–30]; $p < 0.001$). Higher pre-ICU frailty also influenced further YLLs ($p < 0.001$) and fewer QALYs ($p = 0.013$). Patients who required IMV had significantly more YLLs (14.8 [9.8–20.2] vs 8.2 [4.2–13.2]; $p = 0.004$) and fewer QALYs (17.8 [10.2–23.2] vs 28.2 [16.2–42.2]; $p < 0.001$); however time of IMV did not influence YLLs ($p = 0.893$) and QALYs ($p = 0.494$). ICU stay also did not impact YLLs ($p = 0.514$) neither in the QALYs ($p = 0.078$) (Table 1).
Conclusions: At one year follow-up, the burden of COVID-19 critical illness is important, with a high mortality that increases according to the life support received, age and frailty. Most of the mortality is attributed to the hospitalization period. Critical illness due to COVID-19 has had a high impact on years of life lost and quality of life, especially in women, frail and elderly patients, and in those in need of invasive ventilatory support.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001149

Introduction: Targeted temperature management (TTM) in comatose patients after cardiac arrest has been used for decades [1,2]. In 2013 the TTM trial [3] proved that there is no significant difference

between targeting 33 °C or 36 °C. In the last years more studies have been published, some suggesting a positive effect of hypothermia on neurological outcome [4], others (as the TTM2 trial [5]) reiterating the equality between hypothermia and normotermia. The latest ERC-ESICM guidelines [6] recommend monitoring the temperature of comatose patients and preventing fever in the first 72 h.
Objectives: To determine the incidence of fever (temperature > 37.7 °C) on a population of patients admitted to a cardiac ICU (Intensive Care Unit) after OHCA and to analyze its possible correlation to mortality and neurological outcome.
Methods: We performed a retrospective analysis on adult patients admitted to our cardiac ICU after a witnessed OHCA from Aug 2019 to Dec 2022, limiting the data set to those with known low flow and no flow times and measured Neuron Specific Enolase (NSE) value at 48 h.
Results: We found no significant difference between the two groups in age (p = 0.484), sex (p = 0.095), ICU (p = 0.828) and hospital (p = 0.879) length of stay, death in the ICU (p = 0.087), shockable rhythm presentation (p = 0.593), no flow (p = 0.808) and low flow (p = 0.246) times, Cerebral Performance Category (CPC) > 3 at ICU discharge (p = 0.864) and NSE value at 48 h (p = 0.693). We found that the patients in the fever group had a statistically significant higher probability of having a GCS (Glasgow Coma Scale) > 8 both at 24 (p = 0.021) and 48 (p = 0.019) hours (Table 1). We found a descending trend in the number of patients who developed fever over the years.

Table 1 (abstract 001149) OHCA times, NSE value and GCS according to the development of fever. Where not otherwise specified, all values are expressed as median and interquartile range

	Overall (38)	No fever (31)	Fever (9)	p-value
No flow (min)	0 (0–7)	0 (0–7)	0 (0–7)	.808
Low flow (min)	29 (17–59)	41 (20–59)	22 (17–40)	.246
NSE 48h (ng/ml)	49.6 (26–156.8)	59 (24.2–158.1)	34 (27.2–104.9)	.693
GCS > 8 24h	13.2%	4%	30.8%	.021
GCS > 8 48h	23.7%	12%	46.2%	.019

Conclusions: Of the 38 analyzed patients, 9 developed fever during the first 72 h of ICU stay. No statistically significant correlation was found between fever during the first 72 h after OHCA and most of the mortality and neurological outcome variables we analyzed. The correlation between better GCS during the first two days in the ICU and the development of fever is probably due to the reduction in the pressure to achieve a strict temperature control in patients who are not comatose when sedation is stopped or reduced.

A review of the efficacy of current Speech and Language Therapy practice for non-verbal communication support for those who are intubated and awake within the critical care setting: a service improvement study from a large London Teaching Hospital

K. Hook[1], Z. Garstang[1], J. Young[1], R. Sawyer[1]
[1]Speech & Language Therapy, King's College Hospital NHS Foundation Trust, London, United Kingdom

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001150

Introduction: The Faculty of Intensive Care Medicine (2022), stipulates patients with communication difficulties need prompt Speech & Language Therapy (SLT) intervention.
Wojnicki-Johansson (2001), identified a disparity between nursing and patient perception of communicative success, raising the question as to whether critical care patients receive effective communication support and whether referrals to SLT for this purpose are made.
There is currently no clear guidance or criteria for referring intubated patients for non-verbal communication assessment.
Objectives: Establish whether intubated patients with a GCS 10 + receive appropriate communication support via the current method of SLT referral/prioritisation.
Explore whether GCS impacts the ability to provide bespoke communication guidelines for intubated patients.
Explore whether the presence of a neurological diagnosis impacts the ability to provide bespoke communication guidelines for patients who are intubated.
Methods: A service improvement study was conducted by a SLT team within a Tertiary Hospital over one month. All patients within the six adult ICUs were screened and referral to SLT triggered for those who were intubated and ventilated with a minimum GCS of 10 sustained over a four-hour period.
An assessment of non-verbal communication was completed by a qualified SLT working in ICU and provision of communication guidelines were directed by clinical reasoning.
The following data was collected:
GCS score, intubation status, presence of a neurological diagnosis, provision of bespoke communication guidelines post SLT assessment, consistency of non-verbal yes/no response.
Results: A total of 31 patients were prioritised for communication assessment. Of these, seven were extubated prior to SLT assessment.
Of those patients who were assessed, 81% had a GCS of 11 and 19% had a GCS of 10.
83% of all patients assessed were provided with bespoke communication guidelines post assessment (Table 1).
71% of all patients assessed were found to have a reliable non-verbal yes/no response which had not been established prior to SLT assessment (Table 2).
Conclusions: A tenfold increase in intubated patients prioritised for non-verbal communication assessment occurred during this improvement study. The majority of the patients who underwent assessment were provided with bespoke communication guidelines indicating impact of SLT intervention.
A higher GCS score was observed to correlate with the provision of communication guidelines. A more detailed review of GCS & its impact on provision of communication guidelines is therefore necessary.
The presence of a confirmed neurological diagnosis correlated with a lower success rate in establishing a consistent, non-verbal yes/no &/or provision of communication guidelines, however the small sample size is acknowledged.
These results support the need for improved SLT referrals for this patient group to ensure optimal care is provided, with further exploration into this indicated.

Table 1 (abstract 0001150)

	GCS 10	GCS 11	Confirmed neurological diagnosis	No confirmed neurological diagnosis
Communication guidelines provided	40%	94%	67%	93%
Communication guidelines not provided	60%	6%	33%	7%

Table 2 (abstract 0001150)

	GCS 10	GCS 11	Confirmed neurological diagnosis	No confirmed neurological diagnosis
Reliable & consistent non-verbal yes/no	60%	74%	60%	79%
Unreliable & consistent non-verbal yes/no	40%	26%	40%	21%

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001151

Introduction: Hydrocephalus is one of the most common complications of aneurysmal subarachnoid hemorrhage (aSAH), contributes to poor neurological outcomes and seriously affects and shortens survival time1,2. People who survive aSAH carry an increased risk for various complications including epilepsy, depression, cognitive impairment, shunt requirement for hydrocephalus, and shunt complications3.

Methods: We retrospectively analyzed data from patients with aSAH admitted at a Neurocritical Care Unit (NCCU) from january-2018 until june-2022. Clinical files were reviewed for age, gender, location of aneurysms, Glasgow coma scale (GCS) score, severity of hemorrhage according to Fisher and Hunt and Hess grading scales, therapeutic options (neurosurgical clipping/endovascular coiling), placement of external ventricular drain (EVD) and its duration, clinical outcome and ICU and in-hospital lengths of stay. EVD-associated meningitis and requirement of life long ventriculoperitoneal shunt (VPS) in patients after using EVD were also assessed. Clinical outcome was evaluated according to Glasgow Outcome Scale (GOS).

Results: The study group consisted of 199 cases (**Table 1), 67 of which (33.7%) with hydrocephalus and EVD requirement.

Comparing patients with hydrocephalus with those without hydrocephalus, the mean age was similar as well as the ratio male/female (Table 1).

Regarding GCS at hospital admission, it was less than 6 in 18 patients (26.9%) in the hydrocephalus group (HG) and in 10 patients (9.1%) in the group without hydrocephalus (NHG).

Concerning Hunt and Hess severity scale, 52.3% of patients (n = 35) with hydrocephalus had grades IV or V. HG had higher Fisher and Hunt and Hess grades at admission.

There was no difference between the two groups regarding therapeutic strategy and location of the aneurysm.

Twelve patients (17,9%) had infection of the central nervous system (CNS) during ICU stay.

More than 1/3 of patients (n = 25) needed a VPS after EVD.

At NCCU discharge, only 16,5% (n = 11) of patients with hydrocephalus had a good outcome (GOS 4–5), compared with 54,5% (n = 72) of the patients without hydrocephalus. Vegetative outcome in HG was 9% (n = 6) and mortality occurred in 17,9% (n = 12) of patients.

ICU and hospital lengths-of-stay were longer in hydrocephalus group (**Table 1).

Hydrocephalus was an independent predictor to worse functional outcome (GOS $\leq$ 3) at 28 days, three and six months ($p < 0.001$).

Mortality at 6 months in HG was 27%, compared to 9,8% in NHG. However, it should be noted that nearly half of the patients in the HG improved clinically (n = 44 with GOS $\leq$ 3 at the time of discharge vs n = 21 at 6 months) (Table 2).

Conclusions: We conclude that the outcome is worst in patients who developed hydrocephalus, with higher rates of mortality and higher degree of functional dependence at NCCU discharge and throughout the follow-up up to 6 months.

Further research is needed to better understand the impact of other variables in outcomes in patients with aSAH who develop hydrocephalus, like the presence of vasospasm and infectious complications.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001153

Introduction: The usage of a high-flow nasal cannula (HFNC) has been widely applied to patients with mild-to-moderate Coronavirus disease 2019-associated acute respiratory distress syndrome (CARDS). The use of the ROX index, as calculated by the ratio of oxygen saturation (SpO2)/fraction inspired oxygen (FiO2)-to-respiratory rate, in the first few hours after the initiation of HFNC can assist identify the patients who will fail HFNC therapy. However, few studies documented the use of the ROX index during the period of HFNC therapy in patients with CARDS.

Objectives: We aimed to illustrate the diagnostic performance of the ROX index in predicting the failure of HFNC treatment when applied throughout the period of HFNC therapy. Additionally, we would like to determine the best cut-off point of the ROX index in determining the occurrence of HFNC failure and to compare it with the established ROX index cut-off point at ≤ 4.88 [1].

Methods: We retrospectively conducted the study from the patients with CARDS who received HFNC at the Faculty of Medicine Vajira Hospital, Navamindradhiraj University, Thailand, between April 1 and August 30, 2021. We calculated the ROX index every 4 h throughout HFNC treatment and defined HFNC failure as a subsequent need for mechanical ventilation. We analyzed the diagnostic performance of the ROX index using the area under the receiver operating characteristic (AUC) curve for the ROX index ≤ 4.88 in predicting HFNC failure and acquired a new ROX cut-off point using Youden's index.

Results: This study enrolled 212 patients with CARDS who commenced HFNC therapy. Of these, 81 patients (38.2%) suffered HFNC failure. An acceptable diagnostic performance was determined when using the ROX index ≤ 4.88 in predicting HFNC failure, with the AUC of 0.77; 95%CI, 0.72–0.83; $p < 0.001$. However, a new cut-off point of the ROX index of ≤ 5.84 delivered more optimal performance, with the AUC of 0.84; 95% CI, 0.79–0.88; $p < 0.001$). A significant enhancement in the discriminative ability in the ROX index of ≤ 5.84 was found when compared with the ROX index cut-off point ≤ 4.88, with a p-value of 0.007 (Figure 1).

Conclusions: A ROX index ≤ 5.84 provided optimal performance in predicting HFNC failure in patients with CARDS.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001154

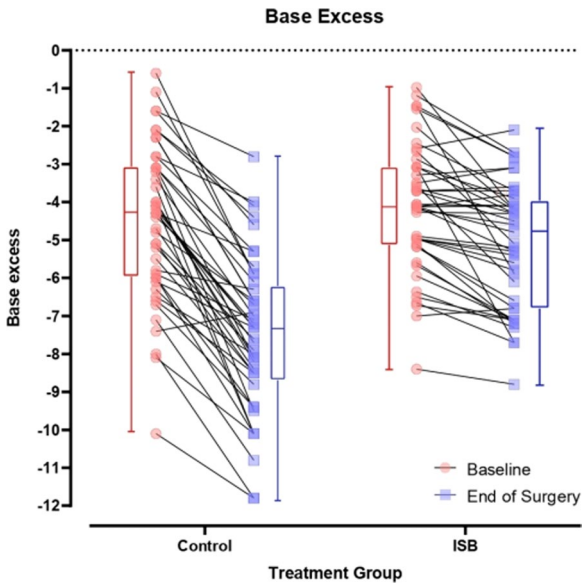
Introduction: Acid–Base disorders are common among surgical patients undergoing emergency laparotomy. Normal anion gapmetabolic acidosis develops due to direct loss of sodium bicarbonate from GIT or administration of chloride richsolutions during resuscitation in these patients. In order to treat this, administering sodium bicarbonate makesphysiological sense.

Methods: After ethical approval and written informed consent, 90 patients (ages 18 to 60 year) diagnosed with perforated.

peritonitis and required emergency laparatomy surgery were randomaly allocated in two groups 45 each. Group -

ISB (Isotonic Sodium Bicarbonate Group) received 2 ml/kg/hr 1.3% Isotonic bicarbonate and group -BSS (Balanced Salt Solution Group) received 2 ml/kg/hr Ringer Lactate (RL) as maintenance fluid during the intraoperative period. Primary outcome was to compare the difference in base excess (BE) between the two groups at the end of surgery. Secondary outcomes (pH, pCO2, HCO3, lactate levels, postoperative duration of mechanical ventilation, ionotrope requirement, ICU/HDU stay and incidence of Acute Kidney Injury) were observed and compared at different time intervals between the groups.

Results: The BE, median (Q1, Q3) was − 7.30 (− 8.50, − 6.30) in the ISS and − 4.80 (− 6.80, − 4.10) in the BSS group (p = 0.017). Themedian (Q1, Q3) pH, HCO3 and lactate values [7.3 (7.27,7.32) vs 7.33 (7.31,7.35); 18.1 (17.3, 19.3) vs 19.0 (18.1,20.2); 1.6 (1.3,2.1) vs 1.3 (1.1, 1.89)] were found significantly different at the end of surgery between group ISSand BSS respectively. The difference in duration of mechanical ventilation, ionotrope requirement and ICU/HDUstay were also found significant between the groups.
Conclusions: Intraoperative administration of isotonic sodium bicarbonate infusion improves perioperative acis-base statusamong patients undergoing emergency laparotomy.



The BE values at the end of the surgery among the Study and the Control group.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001155

Introduction: It has been documented that citrate anticoagulation during continuous renal replacement therapies (CRRT), mediated through reducing ioniic calcium, attenuates inflammation and limits oxidative stress. Wether this is biologically relevant or not in terms of survival or recuperation of renal function, it seems that citrate anticoagulation would be more biocompatible by decreasing complement activation and neutrophil degranulation in the filter.
Objectives: To analyze oxidative stress in patients with acute renal failure treated with two anticoagulation modalities of the extracorporeal clearance system (heparin and citrate) and determine if there are differences between them.
Methods: Multicentric, prospective study, with random assignment of patients to system anticoagulation groups (heparin or citrate) during treatment with CRRT in the ICU. Twenty patients with acute renal failure were included. In each patient the plasma concentrations of oxidized (GSSG), reduced (GSH) glutathione and myeloperosixadase (MPO) were determined before the start of therapy, at 60 min and at 24 h in samples taken prefilter and postfilter.
The determination of GSSG and GSH in whole blood is performed by high performance liquid chromatography coupled with a mass spectrometry tandem. Quantification of peroxidase activity is based on the ability of these enzymes to oxidize tetramethylbenzidine (TMB) in the presence of hydrogen peroxide, and quantification of the reaction by spectrophotometry.
Quantitative variables are expressed as mean ± standard deviation or as median and interquartile range (25% and 75%), as appropriate. To quantify the relationship between variables, the Student's T test or the Mann–Whitney U test was used. Categorical variables are expressed as counts and percentages and were compared using the Fischer test and odds ratio calculation to quantify the relationship between variables. A significance level of 5% bilateral was considered.
Results: There were no significant differences between the two groups regarding gender (85% male) and age (global mean age of 64.6 ± 9.2). Significant differences were detected for GSH concentrations at the beginning of the treatment and at 60 min pre-filter (111.2 ± 40.53 vs 130.13 ± 27.73 µmol/ml; p 0.004) for the overall sample and for the post-filter concentrations at 60 min according to the anticoagulation modality (102.6 ± 42.83 µmol/ml for the heparin group vs 148.6 ± 50.52 µmol/ml for the citrate group; p 0.04). No significant differences were detected for GSSG concentrations. GSSG/GSH ratios were significantly higher for patients in the heparin group at 24 h: prefilter 3.40 (IQR 2.34–6.21) pmol/ml for heparin vs 1.36 (IQR 1.17–1.98) pmol/ml for citrate (p 0.006) and postfilter 3.92 (IQR 2.17–6.41) pmol/ml for heparin vs 1.67 ± 8.39 pmol/ml for citrate (p 0.015).
Significant differences were found for the pre-filter and postfilter MPO values 60 min after the start of the technique. In the heparin group, significant differences were detected between the pre-treatment MPO concentration and the pre-filter concentration at 60 min (pre-filter MPO < pre-treatment MPO) and between the pre-filter and post-filter MPO values 60 min after the start of the technique (MPO postfilter > MPO prefilter), so that the differences found between MPO prefilter and postfilter at 60 min are attributable to the increase in MPO for the heparin group.
Mortality was 35% (4 patients in the heparin group and 3 in the citrate group, with no significant differences). No differences were found in oxidative stress values between survivors and deceased.
Conclusions: CRRT treatment of patients with ARF results in increased oxidative stress. Patients in the citrate anticoagulation group had higher GSH values, lower GSSG values, a more favorable GSSG/GSH ratio, and lower MPO values. These differences are detectable early, and suggest that support with CRRT and anticoagulation with citrate would be a less inflammatory stimulus.

Introduction: CMV infection is common in immunocompetent critical patients. Among other risk factors, dysfunction of the immune response seems to be important. Therefore, in patients with SARS CoV-2 pneumonia, immunosuppressed by therapies and with immunoparalysis due to the infection itself, could be at risk of CMV viral co-infection.
Objectives: To describe characteristics of critically ill patients with SARS CoV-2 pneumonia and CMV co-infection (CMV-COVID), its incidence, clinical features, and outcomes.
Methods: A retrospective single Center observational cohort study was performed. All consecutive patients admitted in our Department with SARS-CoV-2 pneumonia from 17/3/2020 to 28/12/2021 were included. SARS CoV-2 infection was confirmed by PCR of in nasopharyngeal swab. We define CMV infection/disease as detection of the CMV by PCR in plasma, and clinical manifestations, according to the definitions of the CMV Drug Development Forum. Weekly CMV DNA quantification (IU/ml) was performed.
Epidemiological data were collected (mechanical ventilation, severity scores, mortality, average length of stay, intra-ICU infections). Data are expressed as means ± standard deviation and results are compared using $\chi 2$ tests.
Results: A total of 437 patients were screened, and among them, 30 patients (6.9%) were diagnosedwith CMV infection/disease.
26 of the CMV-COVID patients developed at least one associated intra-ICU bacterial or fungal infection and 14 (46%) of the patients had *Aspergillus* confection.
In our cohort, ICU mortality in CMV-COVID patients was 45% (n = 13/30) versus 16.2% (71/437) in COVID patients ($p = 0.00$). In-hospital mortality was 48.4% (15/30) in CMV-COVID vs 17.1% (75/437) in COVID patients (p = 0.00).
Mean ICU LOS among CMV-COVID was 59 days and 22 days in COVID patients.
Conclusions: In our cohort, CMV-COVID co-infection was associated with more severe clinical feature, which was reflected with longer ICU length-of-stay and higher mortality. We should further study this association to get in deep about the pathophysiology, natural evolution, and related factors, to develop diagnostic and therapeutic bundles to improve the outcome of these patients.

	Pacientes CMV (n=30)	Total pacientes (n=437)
Sexo (hombre)	27 pacientes (90%)	306 pacientes (70%)
Edad media	64.7 +/-8 años	58.7 +/- 13 años
Ventilación mecánica en 1ª 24 horas de ingreso en UCI	29 pacientes (96.6%)	306 pacientes (70%)
APACHE II	18.2 +/- 8.5	16 +/- 8.2

Hemolysis in short-term mechanical cardiac support and extracorporeal membrane oxygenation

A. Krüger[1], P. Ostadal[1], M. Janotka[1], J. Naar[1], D. Vondrakova[1], P. Neužil[1]
[1]Cardiovascular Center, Na Homolce Hospital, Prague, Czech Republic
Correspondence: A. Krüger
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001158

Introduction: Developments in the treatment with using of extracorporeal membrane oxygenation (ECMO) and percutaneus short-term ventricular assist devices (pVAD) have substantially improved the chances of survival of critically ill patients. However, alongside with the benefit of increase of the number of these procedures, also an increase of the occurrence of complications can be seen. One of the most frequent complication of using these devices in treatment is a hemolysis.
Objectives: The main aim of our study was to evaluate the relation between free hemoglobin levels and mortality or acute renal failure in patients supported with a pVAD or ECMO.
Methods: We analyzed data from 34 patients who received percutaneus short-term mechanical cardiac support of left ventricle—Impella (Abiomed Inc., Massachusetts, USA) or ECMO—CardioHelp (Maquet, Wayne, NJ) in a peripheral V-A or V-V configuration or a combination of supports (Impella + V-A ECMO). The free hemoglobin levels from patients were collected and assessed the severity of hemolysis depending on the type of support or combination of supports. At the same time, we assessed the risk of developing acute renal failure and the mortality of these critically ill patients.
Results: The average age in our group was 58 years (35–82). V-V ECMO has been used in 16 patients (47%) due to respiratory failure (COVID infection), in 18 patients (53%) we used peripheral V-A ECMO, Impella or their combination due to cardiogenic shock.
The value of free hemoglobin levels in the Impella group was comparable to the ECMO group (468 ± 73 vs 470 ± 61mg/L), the free hemoglobin levels was significantly higher in the case of the combination of supports (V-A ECMO + Impella) (2213 ± 1163 mg/L, $P < 0.05$) than the both previous groups. Overall mortality in our group was 24% and correlated with higher values of free hemoglobin levels (1367 ± 383 vs 492 ± 66mg/L; $P < 0.05$). Patients with a higher degree of hemolysis had significantly higher risk of acute renal failure and use the hemodialysis (3428 ± 1892 vs 503 ± 54mg/L; $P < 0.05$).
Conclusions: The presence and degree of hemolysis represents one of the serious complications use extracorporeal circulation and mechanical cardiac supports. Our results indicate that free hemoglobin levels are a strong predictor of acute renal failure and higher levels are associated with mortality.

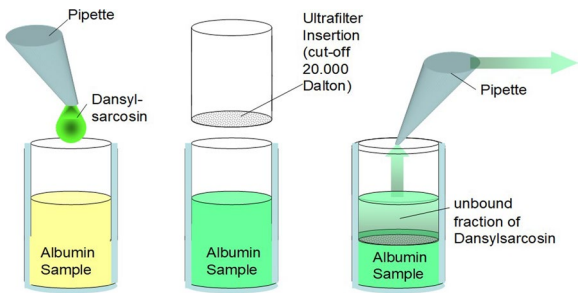
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001164

Introduction: Albumin is the central transport protein for endogenous and exogenous toxins in the kidney, and its function determines the excretion of various substances. Recent studies on chronic liver and kidney insufficiency have shown that the binding capacity of albumin depends on the excretion capacity of the target organ and can be partially correlated with it. Acute kidney injury (AKI) is a complex syndrome that affects a significant proportion of critically ill patients. The impact of AKI on each patient's clinical condition has come to the fore in recent years, and growing awareness has driven research. Nevertheless, there is an urgent need to improve diagnostics.
Objectives: The aim of this study was to investigate a possible correlation between albumin binding capacity (ABiC), as a measure of albumin function, and severity, as measured by the stage of the disease, in acute renal failure.
Methods: In a prospective, uncontrolled and non-interventional clinical observational study, blood samples from 104 patients were collected sequentially over one week and evaluated. Albumin binding capacity was measured to investigate albumin function. By determining the unbound portion of the fluorescent marker dansylsarcosine, statements about the binding site-specific loading state of the albumin molecule could be made.
Results: The mean ABiC of the patients was significantly negatively correlated ($p = 0.001$) with the KDIGO stages of AKI. Patients with sepsis had a significantly lower ABiC than non-septic patients ($p < 0.001$), and even patients who developed sepsis during the course had a significantly lower ABiC on the day inclusion ($p = 0.042$). Patients who died during hospitalization had a significantly lower ABiC ($p = 0.038$) than survivors. Follow-up measurements over one week showed that ABiC also correlated with changes in ANV stage over time. ABiC change was significant from day one to day four ($p = 0.001$) and from day one to day seven ($p = 0.002$).
Conclusions: In AKI patients, the impairment of albumin function can be quantified, is related to the severity and to the course of the disease. In the future, ABiC could complement the portfolio of clinically practical biomarkers and may improve the prediction of the progression of acute kidney injury.



Albumin Binding Capacity (ABiC): a binding site II-specific test.

"We are here to learn"—an interpretative phenomenology research (IPA) study to explore the lived experiences of clinical nurse educators facilitating interprofessional simulation-based education

K. Hill[1]
[1]Critical Care, Queen Elizabeth University Hospital, Glasgow, United Kingdom
Correspondence: K. Hill
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001165

Introduction: There is a plethora of research on the benefit of a collaborative learning amongst participants in interprofessional education and simulation-based education. It would be insightful to explore how this concept of shared learning extends to the faculty members facilitating these educational sessions. From the perspective of the clinical nurse educator, this research study offers a unique insight into the nature of the collaborative teaching experience, processes of knowledge acquisition and transferability of learning and their influence on both clinical and teaching practice. This is of relevant to clinical nurse educators working in professional practice in critical care.
Objectives: To illuminate the lived experiences of clinical nurse educators facilitating interprofessional simulation-based education (IPSBE) to gain deeper insight on how this approach can influence their future practice.
Methods: An Interpretative phenomenology analysis (IPA) was chosen as the qualitative research approach for this study as it sought to illuminate the experiences of clinical nurse educators through the interpretation and validation of their unique 'first hand' experiences. A small purposive sample of clinical nurse educators that facilitated IPSBE was recruited to take part in semi-structured interviews. Data was inductively analysed using a systematic, step-by-step approach, generating meaningful themes and concepts that can be applied to the context of practice. Ethics approval sought from Glasgow Caledonian University.
Results: Four master concepts were derived from the interpretative analysis of the interviews: 'looking at things through a different lens'; the centrality of the debrief; 'we are actually learning all the time' and personal and professional growth. It was evident from the interviews that the clinical nurse educators learned from the participants and fellow faculty members when facilitating interprofessional simulation-based education. There was a recognition of the significance and importance of working, learning and teaching together. Interprofessional simulation-based education creates a safe space for learning that promotes an opportunity for shared learning to occur which can positively influence interprofessional relationships and practices, which can influence patient care and safety.
Conclusions: IPSBE creates a safe space for learning that promotes an opportunity for shared learning amongst faculty to occur which can positively influence interprofessional relationships and practices. These positive team based behaviours are transferable to which can impact patient care and safety. The detailed analysis and interpretation of the research findings led to recommendations for practice, education, policy and research.

Introduction: Acute respiratory distress syndrome (ARDS) complex biological behavior and clinical heterogeneity require identifying distinct subgroups of patients to target specific therapy, improving the efficacy of interventions. ARDS sub-phenotypes with distinct clinical and biological features and differential treatment responses have been identified using latent class analysis (LCA). (1) Computerized tomography (CT) is a powerful lung imaging method that may contribute to better disease stratification. (2,3).
Objectives: We hypothesized that a deep-learning analysis of lung CT in patients with SARS-CoV-2-induced respiratory failure could describe specific morphological and quantitative alterations of the lung parenchyma, reflecting the severity of gas exchange impairments. We hypothesize that these findings will correlate with patient outcomes.
Methods: This is a clinical study of lung CT images in patients confirmed SARS-CoV-2 positive by PCR analysis. Lung-CT data from 853 patients were collected during the first wave of the COVID-19 pandemic in Italy within a multicenter observational study titled (NCT04395482). CT images were segmented using an established convolutional neural network previously validated in COVID-19 patients. (4) After segmentation lung masks were inspected by a trained investigator and manually adjusted using ITK-snap software. (5) For each CT, six parameters were analyzed: average CT intensity in Hounsfield Units (HU), lung gas volume and tissue mass by density analysis, percentage of consolidated tissue (CT intensity > -200 HU), percentage of ground glass opacity (CT intensity -750 to -200 HU), and percentage of total injury (CT intensity > -750 HU). (6) We applied a latent class model by using 18 relevant CT variables to the lung CT data (7) to stratify patients into three cohorts of 183, 421, and 249 for class I,II, and III, respectively.
Results: Among the 3 CT phenotypes, the 6 CT explored parameters significantly differed between classes. Lung injury severity was the lowest in class 3, intermediate in class 2, and highest in class 1 (Table1).

Survival at 90 days significantly differed across the three different CT clusters, as highlighted in Figure 1.
Conclusions: LCA on CT data in COVID-19 patients allowed us to identify three different CT clusters associatedwith survival at 90-day follow-up.

Table 1 (abstract 001168) Lung CT parameters are divided by CT classes. Values are expressed as mean (Standard Deviation)

	1 (A)	2 (B)	3 (C)	p-value
n	183 (21.4)	421 (49.4)	249 (29.2)	/
Lung density (HU)	-539 (107)	-699 (61)	-813 (34)	< 0.001
Lung gas volume (L)	1.84 (0.81)	2.68 (0.92)	4.15 (1.10)	< 0.001
Lung weight (kg)	1.51 (0.52)	1.12 (0.32)	0.92 (0.18)	< 0.001
Total injury, fraction	0.66 (0.14)	0.45 (0.13)	0.21 (0.07)	< 0.001
GGO, fraction	0.48 (0.12)	0.4 (0.12)	0.18 (0.06)	< 0.001
Consolidation, fraction	0.18 (0.11)	0.06 (0.03)	0.03 (0.01)	< 0.001

Differences between the 3 clusters of lung CT images were assessed by one-way ANOVA (p-value column). HU = Hounsfield Units; GGO: Ground Glass Opacities.

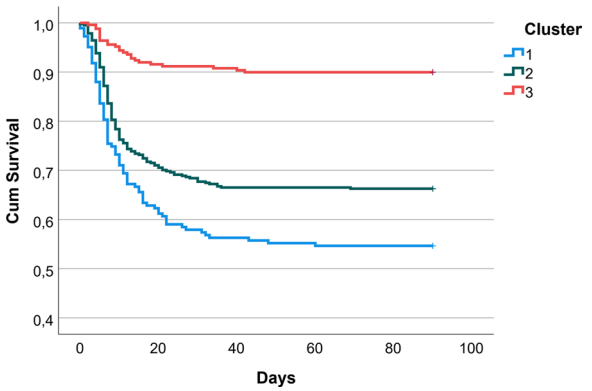

Figure 1 (abstract 001168) Survival analysis stratified across 3 clusters of lung CT injury at 90-day follow-up

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001169

Introduction: Despite the clear progress, prognosis in cardiogenic shock (CS) remains poor. Even though the metabolism of lactate is complex and elevated levels may have numerous causes, lactate is a frequently used prognostic marker. However, it is not well known, which measurement of lactate is the most meaningful in terms of predicting ICU-mortality (intensive care unit).
Objectives: This study sought to compare various values of lactate of the first 24 h after ICU-admission (intensive care unit) for mortality prediction in patients with cardiogenic shock: concentration at admission (FL) and after 24 h (LL), peak concentration (PL) as well as the 24 h lactate clearance (LC) were analyzed. The SAPS3-score (simplified acute physiology score) was also described. The findings of this study might support the early decision-making regarding treatment of CS.
Methods: For this retrospective analysis 600 consecutive patients were screened for cardiogenic shock. Exclusion criteria were intoxication, pregnancy, missing measurements of lactate and age < 18 years. 64 patients were analyzed. Baseline characteristics as well as FL, PL, LL and LC were analyzed in univariant and multivariant logistic regression to determine prognostic performance. The AUROCs (area under receiver operating characteristics curve) of FL, PL, LL and LC were calculated and tested for significant differences. Cut-off-values were described. The primary outcome was ICU-mortality.
Results: The ICU-mortality of the study population was 34,4%. The mean age was 62 years, 72% were male and the average SAPS3-score was 72 points. The age was a univariate predictor of ICU-mortality, the SAPS3-score also a multivariant predictor. FL did not show significant results. FL was not a significant predictor in the multivariant analysis, but showed a significant AUC in the ROC-Analysis (p = 0,028). The results of LL and LC were significant in the multivariant analysis (both p < 0,01) as well as in the ROC-analysis (both p ≤ 0,001). LL had the greatest AUROC (0,809), but did not show significant difference to the AUROC of SAPS3 (0,799; p = 0,5304) and LC (0,762; p = 0,5047) in the De-Long-Test. However, the AUROC of LL did differ significantly from AUROC of PL (0,659; p = 0,0142) and FL (0,573; p = 0,0029).
Conclusions: In terms of predicting ICU-mortality in cardiogenic shock the lactate concentration after 24 h (LL) was superior to the concentration on admission (FL), the peak concentration (PL) and the 24 h clearance (LC).

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001170

Introduction: Hypercoagulopathy caused by COVID-19 may be responsible for mortality, so it is important to identify markers for an effective anticoagulant strategy for physicians (1). D-dimer and fibrinogen levels have been found to have prognostic values in COVID-19 patients but, data on the impact of antithrombin (AT) levels associated with the outcome are scarce (2).
Objectives: We primarily aimed to analyze the relationship between AT levels on intensive care unit (ICU) admission and mortality in critically ill COVID-19 patients. The secondary aim was to reveal the impact of other markers on the prognosis of COVID-19.
Methods: We retrospectively enrolled consecutive critically ill patients (≥ 18 years old) with COVID-19, who were admitted to the ICU of Istanbul University from March 2020 to June 2021. The Ethics committee of the University Hospital approved the study (2020/64179). We collected demographic, clinical, and laboratory data of the patients on the ICU admission. Descriptive analyses were applied and normality has been checked with the Kolmogorov–Smirnov test. Mean standard deviation values of continuous data were reported accordingly. Categorical data were given with counts and percentages. Group comparisons were calculated with Student's T-test due to the large sample size (sample size > 200) for continuous variables. A receiver operating characteristic (ROC) curve analysis was used to determine the cutoff values. Statistical analysis was performed with the SPSS 25.0 statistical package and $p < 0.05$ was set as statistically significant.
Results: Four hundred ten critically ill patients with COVID-19 were included in the study. The demographic, clinical characteristics of the patients are summarized in Table 1. The laboratory parameters are depicted in Table 2. Significantly lower AT levels were recorded in non-survivors than survivors (77,9% vs. 82,5). ROC curves were designed according to AT and D-dimer levels (Figure 1). The cutoff levels for AT and D-dimer were 70,5% and 1585 µg/L, respectively. Cumulative survival was lower in patients with AT ≤ 70,5% and D-dimer ≥ 1585 µg/L than AT > 70,5% and D-dimer < 1585 µg/L (p = 0,001) (Fig. 2).
Conclusions: The main finding of this study is low AT levels on the ICU admission in COVID-19 patients are associated with mortality. Previous studies showed that there was no significant difference between non-survivors and survivors in terms of AT, although AT levels were lower in non-survivors than survivors (84% vs. 91%) (3). In our study, significantly lower AT levels were found in non-survivors than survivors. Our statistical difference most probably is because of the large sample size. Recent studies reported that elevated D-dimer levels may identify patients at higher risk for mortality (2, 3, 4). In our study, non-survivors had significantly higher D-dimer levels. When AT and D-dimer were analyzed together, the mortality prediction was better than D-dimer or AT.

Table 2 (abstract 001170) Laboratory parameters of patients on the ICU admission

Variables	Survivors	Non- Survivors	*P* value
Antithrombin activity (%)	82,5±19	77,9±21,1	**0,027**
CRP (mg/L)	122±100	147±186	0,116

Changes in respiratory support therapies after oxygen saturation alarms: a retrospective study

S. A. I. Klopfenstein[1], A. R. Flint[1], E. Salgado[1], M. Prendke[1], J. Chromik[2], F. Balzer[1], A. S. Poncette[1]

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001171

Introduction: Working on safer clinical alarm systems based on data-driven decisions is one of the National Patient Safety Goals® defined in 2023 by the Joint Commission [1]. Oxygen saturation (SpO2) alarms are critical as they might indicate deterioration in ventilation.
Objectives: We aimed to retrospectively analyze respiratory support therapies (RST) interventions performed timely after SpO2 alarms in two intensive care units (ICUs) of an university hospital and determine the associated actionable to non-actionable alarms ratio.
Methods: Following IRB approval (EA1/127/18), we transposed previously developed annotation guidelines and ventilation-related mappings into Python scripts: The mappings link ventilation devices, modes and airway devices to seven gradually escalating RST [2] based on medical knowledge and ISO 19223:2019 norm [3]. We queried 656 days of data from two ICUs between 2019 and 2021. SpO2 alarms were actionable when a RST escalation presumably followed within 30 min of their start.
Results: We identified 1.963 unique patients with 251.314 SpO2 alarms. 12.729 SpO2 alarms (5%) from 821 unique patients were actionable. Most escalations were performed in patients with low dose oxygen therapy (OT, 52%) or high flow oxygen therapy (HFOT, 38%) pre-alarm. The RST pre-alarm was most often escalated to the next superior RST, except for patients with OT pre-alarm: Out of 6.604 escalations, 75% were associated with the RST "ventilation-mode group 4a" (assisted ventilation) post-alarm (Table 1 and Figure 1).

Table 1 (abstract 001171) Actionable alarms based on escalations with the associated RST pre- and post-alarm; OT: Low Dose Oxygen Therapy, HFOT: High Flow Oxygen Therapy, VMG: Ventilation-mode Group, HFJV: High Frequency Jet Ventilation

RST Pre-Alarm	RST Post-Alarm					
	OT	VMG 4b	HFOT	VMG 4a	VMG 1b,2b,3	VMG 1a,2a,HFJV
Spontaneous breathing (no oxygen supply)	306	-	10	37	19	9
OT	-	47	445	4952	917	243
VMG 4b	-	-	8	2	1	2
HFOT	-	-	-	3626	734	496
VMG 4a	-	-	-	-	692	101
VMG 1b,2b,3	-	-	-	-	-	82

Conclusions: Our study is the first to granularly examine changes in RST after an alarm. Results suggest that personnel should pay attention to patients on OT or HFOT and focus on alarm management strategies, e.g., by setting individual, meaningful alarm thresholds in these patients. However, the current classification is rule-based and documentation-dependent. To get a more comprehensive picture of SpO2 alarms' actionability and derive policies, we will include more interventions such as changes of airway devices or modifications of ventilation parameters, and contextual information about the cohort, as well as validate the alarm classification in follow-up studies. Findings of our studies could be incorporated in the development of future clinical decision support systems.

New Onset Refractory Status Epilepticus (NORSE): possibility of a good outcome despite prolonged and complicated ICU stay

F. Stretti[1], F. Casagrande[1], A. Eisele[2], SY. Bögli[2], E. Keller[1], G. Brandi[1]
[1]Intensive Care Medicine, University Hospital of Zürich, Zürich, Switzerland; [2]Neurology, University Hospital of Zürich, Zürich, Switzerland

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001172

Introduction: NORSE is a neurologic emergency without an immediately identifiable cause [1, 2]. The complicated and long ICU stay of the patients [3–5] can lead to perceive a prolongation of therapies as futile. However, a recovery is possible even in severe cases [6]. This retrospective study investigates NORSE patients, with focus on ICU treatment, outcome and ethical decisions.
Methods: 283 adults were admitted with status epilepticus (SE) to the Neurocritical Care Unit of the University Hospital Zurich, Switzerland, between 01.2010 and 12.2022. We identified 25 NORSE cases [2]. We collected demographic, clinical, therapeutic and outcome data.
Results: Most patients were female (68%), previously healthy (Charlson comorbidity index 1 [0–4]), and relatively young (53 [17–67] years). 96% presented with super refractory SE. Despite extensive workup, the majority (64%) of cases remains cryptogenic.Most patients had a long and complicated ICU-stay (Table 1). The in-hospital mortality was 40%. The cause of death for 75% of the patients was the withholding/withdrawing of therapies. The decision was triggered by medical staff except for one patient. The End-of-life (EOL) decision was taken 22 days after diagnosis. Death occurred 4 days after the decision. Most surviving patients (67%) were seizure-free after 1 year. The functional outcome improved with time (Figure 1).

Number of AEDs (median[IQR])	5 [4–7]
Duration of treatment with anaesthetic agents (days, median[IQR])	8 [6–18]
Duration of invasive mechanical ventilation (days, median[IQR])	17 [9–25]
ICU complications (n of patients)	22 (88%)
infections	18 (72%)
respiratory	16 (64%)
metabolic	14 (56%)
gastrointestinal	10 (40%)
cardiac	9 (36%)
Length of stay on ICU (days, median[IQR])	21 [18–31]
Length of stay in hospital (days, median[IQR])	39 [26–55]
Death	12 (46%)
Limitation of treatment (n = 12)	9 (75%)
mRS at discharge* (n = 16, median and range)	4 [4–5]
mRS at last available follow-up* (n = 13, median and range)	2 [1–3]

Conclusions: In this case series, a mortality comparable to that previously reported was observed in young and previously healthy patients with NORSE. A higher proportion of conscious EOL decisions was taken compared to available data [6, 7], where this issue was not specifically addressed and may have been underreported.
In comparison to other diseases, the EOL decision was taken relatively late. For NORSE patients, a longer period of observation and treatment is necessary: the turnover time of many investigations usually takes many days (e.g. autoimmune testing). Furthermore, no validated prognostic tools exist due to the rarity and the geographical spread of the cases, which makes the prognostication harder.
Medical staff mostly triggered the EOL decision, but the next of kin was always involved in the discussion, so it is assumable that the decisions were informed and based on presumed patient's wishes. Futility is highly dependent on an individual's values. Based on the few Advance Directives (3/12 patients), most individuals perceived disability as an undesirable outcome and life-sustaining therapies therefore as futile. In these cases, the therapy was redirected.
Until reliable prognostic scores are available, EOL decisions can only be made to the best of medical knowledge and considering the patients' presumed wishes. Because the long-term outcome can be favorable in NORSE survivors, clinicians should be careful in taking EOL decisions to avoid the risk of a self-fulfilling prophecy. Our results encourage clinicians to continue treatment even in initially refractory cases.

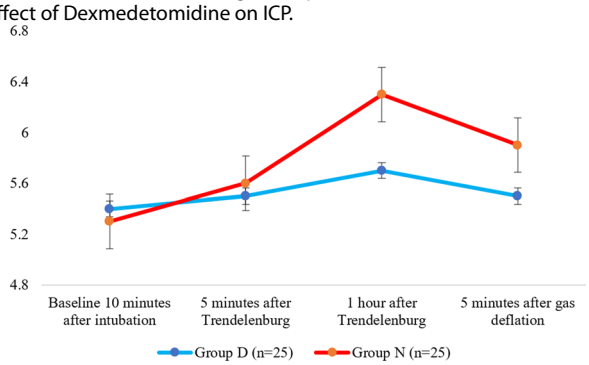
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001174

Introduction: Optic nerve sheath diameter (ONSD) has been extensively studied as a non-invasive substitute for ICP monitoring. The potential for increased intracranial pressure (ICP) in patients with increased intra-abdominal pressure (IAP), although poorly documented, has been demonstrated through higher ONSD values in laparoscopic procedures with steep Trendelenburg position1,2. This often leads to transient acute consfusional states in the postoperative period3. The effect of dexmedetomidine on ICP or ONSD has remained controversial over the years.

Methods: We conducted a randomized controlled trial on 50 adult patients of ASA I and II presenting for laparoscopic procedures with Trendelenburg position > 25 degrees, to assess the effect of intraoperative dexmedetomidine 1 µg/kg followed by 0.4 µg/kg/hr against a placebo-controlled group that received 0.9% saline (NS) infusion at the same rate. Both groups received general anaesthesia as per standard protocol. The ONSD and intra-ocular pressures were measured at T1—baseline (10 min after endotracheal intubation), T2—Five minutes after Trendelenburg position, T3—one hour after T2 and T4—five minutes after releasing pneumoperitoneum.

Results: Both groups were well balanced in terms of demographics and baseline parameters. In our study, patients who received dexmedetomidine had statistically significant lower mean ONSD in group D at 1-h after Trendelenburg position in comparison to group NS (5.7 ± 0.8 mm vs. 6.3 ± 0.8 mm; P = 0.002). Also, the patients who received dexmedetomidine had statistically significant lower mean ONSD in group D in comparison to group NS at 5-min after gas deflation (5.5 ± 0.7 mm vs. 5.9 ± 0.9 mm; P = 0.041). There was no clinically or statistically significant difference in perioperative hemodynamics or sedations scores.

Conclusions: From our study we may conclude that Dexmedetomidine may potentially lower ICP as per changes in ONSD compared with placebo group in laparoscopic surgeries in steep Trendelenburg position. Further studies with larger sample size are needed to validate the effect of Dexmedetomidine on ICP.



Trends of ONSD between groups.

Validation of the accuracy of the ICH Score in Japanese patients with cerebral hemorrhage and identification of predictive factors

Y. Fujimoto[1], S. Egawa[2]
[1]Department of Emergency and Critical Care Medicine, St. Marianna University School of Medicine, Kawasaki, Japan; [2]Department of Neurointensive Care, TMG Asaka Medical Center, Asaka, Japan
Correspondence: Y. Fujimoto
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001175

Introduction: An accurate neurological prognosis in the acute phase of a cerebral hemorrhage would be very effective in clinical practice to ensure a shared understanding of severity among medical staff, provide explanations to the patient's family, and predict the result of the acute phase of the hemorrhage. The intracerebral hemorrhage score (ICH score) is suggested in guidelines as a prognostic score and is utilized in clinical practice. However, the ICH score is based on data from > 20 years ago and includes cases of withdrawal from life-sustaining therapies. In Japan, we frequently experience that the ICH score does not predict the prognosis following a clinical practice.
Objectives: The study aimed to clarify the accuracy of the ICH score at our hospital and to assess prognostic factors appropriate for cerebral hemorrhage cases.
Methods: The study design was a single-center retrospective medical record survey. We retrospectively analyzed the medical records of all patients admitted with intracerebral hemorrhage between January 2018 and December 2021 at the Toda Medical Group Asaka Medical Center in Saitama, a 446-bed hospital in Saitama, Japan. Patient age, gender, history, medical history, GCS at presentation, the site of hemorrhage, hematoma volume, ventricular perforation, midline shift, acute symptomatic seizures, 30-day mortality, neurologic outcome at discharge, and transfer destination were examined. At the Japanese Society of Intensive Care Medicine's annual meeting, this study was presented halfway through the 2018–2020 data; however, as there were so few instances, multivariate analysis was not feasible. As a result, one more year of data was added, and the study was reevaluated. Statistical processing was conducted using SPSS (ver. 25), and the accuracy of the ICH score was first examined using the receiver operator characteristic curve. Univariate analysis was employed to narrow down the items with a relatively high association with 30-day mortality, and multivariate analysis was used to find predictive factors.
Results: The precision of the ICH score in predicting 30-day mortality at our institution remained low (AUC of 0.66 [95%CI: 0.49–0.84]). In univariate analysis, GCS $\leq$ 10 (OR11.0 95%CI; 1.2–100.6, p = 0.02), blood loss $\geq$ 100 ml (OR15.3 95%CI; 2.2–104.5, p = 0.02), midline shift (OR5.8 95%CI; 0.9–36.0, p = 0.07), and maintenance dialysis (OR24.8 95%CI; 3.37–182.8, p = 0.01). Multivariate analysis found GCS at presentation and maintenance dialysis to be significant.
Conclusions: The accuracy of the ICH score at our institution remained low compared to previous reports. Although some items were proposed as predictors of 30-day mortality, we believe it is suiTable to take into account GCS and maintenance dialysis as the basis for a comprehensive study. We hope that more accurate prognostic factors will be identified for cerebral hemorrhage patients in Japan in the future.

Real-time remote audio-visual system versus standard buddy system to monitor the doffing of personal protective equipment during Covid 19 pandemic: An observational study

N. Naik B[1], M. S. Lazar[1], V. Ganesh[2], A. Singh[1], P. G D[1]
[1]Anaesthesia and Intensive care, Post Graduate Institute of Medical Education & Research, Chandigarh, Chandigarh, India; [2]Anesthesiology, All India Institute Of Medical Sciences New Delhi, New Delhi, India
Correspondence: N. Naik B
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001176

Introduction: Literature states a higher self-contamination rate among healthcare workers (HCWs) while doffing personal protective equipment (PPE). During the Covid-19 pandemic, onsite trained observers were not always available to monitor PPE compliance. The remote audio-visual doffing surveillance (RADS) system has the potential to overcome this limitation (Figure 1). [1,2] We aimed to compare the efficacy of this real-time RADS system against the onsite buddy system for monitoring the doffing of PPE.
Objectives: To compare the efficiency and safety of the RADS system versus the standard onsite buddy system. The incidence of breach/error in biosafety and the satisfaction levels among HCWs doffing PPE with both systems were determined.
Methods: This prospective, observational study was carried out at our tertiary care centre in northern India. Study wasregistered in the clinical trial registry India (CTRI/2020/11/038172)0.200 HCWs who cared for Covid-19 patients in the intensive care units/operation theatres were included. Group A included HCWs who performed doffing with the help of an onsite trained observer and group B included HCWs who performed doffing with the RADS system. An independent observer noted the error at any step using the CDC doffing checklist, in both groups. An online questionnaire to analyze the level of satisfaction post-doffing was also surveyed.
Results: The proportion of errors committed during doffing was significantly lower in group B compared to group A with a low relative risk of 0.34 (95% CI 0.22 to 0.51) (p < 0.001) (Fig. 2 A & B). In both groups, there was no difference in HCWs feedback regarding the ease of the system and fear of committing an error. Though the perceived quality of monitoring was felt better with onsite buddy, the overall confidence rating of being safe after doffing was better with the RADS system.
Conclusions: Real-time RADS system may be more effective than the onsite buddy system for ensuring the safety of HCWs during doffing PPE. HCWs level of satisfaction related to the ease and anxiety with the monitoring systems were comparable. RADS system can reduce reliance on HCW resources and can integrate well into existing healthcare systems.

Figure 1 (abstract 001176) A trained observer assisting doffing from remote location using real time RADS system

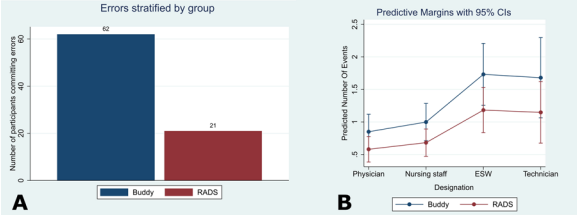

Figure 2 (abstract 001176) (A) Barplot showing the number of participants committing errors in each group; (B) Point plot showing the predictedmargins (incidence rate ratios, with 95% CIs) of committing a greater number of errors/events across occupationdesignation classes during doffing stratified by experimental groups. (ESW = Environmental Sanitation Workers, RADS = Remote Audio-visual Doffing Surveillance System)

Exploring service equity in the Speech and Language Therapy management of patients with delirium in a Critical Care setting

J. Young[1], R. Sawyer[1], K. Potter[1], Z. Garstang[1]
[1]Speech & Language Therapy, King's College Hospital NHS Foundation Trust, London, United Kingdom
Correspondence: J. Young
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001177

Introduction: Guidelines exist which provide overarching recommendations for the prevention, assessment and management of delirium in acute hospital settings. NICE CG103 (2010) reference the need to adequately address dehydration by ensuring sufficient fluid intake for patients and highlight the importance of observing for non-verbal signs of pain, particularly for those patients who are unable to communicate using their voice, for example those with a tracheostomy in situ. The NICE guidance also recommends orientation and communication is optimised for patients with delirium, with involvement from family and friends. Speech and Language Therapists (SLTs) play a pivotal role in facilitating return to oral intake (aiding management of dehydration and normalising mealtime routines) and managing barriers to effective communication.
Whilst the RCSLT position statement (2019) highlights the role of SLT in the management of delirium within critical care, there remains a scarcity of clinical guidelines in this area. As a result it was hypothesised that there was likely to be variation in how patients with delirium were being managed across SLT, leading to inequity within the service.
Objectives: To explore current Speech and Language Therapy clinical practice for patients with delirium who present with communication and swallowing disorders within Critical Care in order to establish equity of service.
Methods: Two questionnaires were created and distributed to the Critical Care SLT team in a tertiary London hospital (completed by 5 SLTs).

- **Clinical scenarios (questionnaire 1):** 6 × referral-based clinical scenarios provided with multiple choice answers pertaining to management options
- **Confidence rating and knowledge-based (questionnaire 2):** 6 × open-ended questions to establish current practice and 1 × Likert scale for confidence rating

Results: Questionnaire 1:

- There was no consensus regarding SLT management of patients with delirium
- Referrals more likely to be accepted: (a) for patients with a confirmed neurological diagnosis and delirium, (b) when there is an identified negative impact on patient wellbeing

Questionnaire 2:

- Variable perception of SLT impact
- Lack of consistency in management approaches utilised
- Good knowledge of Multidicilinary Team (MDT) roles in delirium management
- 20% of the team felt 'very confident' in managing patients with delirium

Conclusions: Currently there is a lack of consistency in how patients with delirium are managed by SLTs within Critical Care. Whilst knowledge of MDT roles in the management of delirium was identified as a relative strength, there is room for improved SLT confidence in the management of this patient cohort. Due to these factors, there is scope for ongoing service improvement initiatives to optimise equity of service for patients with delirum.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001179

Introduction: The spleen in its anatomy is an intra-abdominal organ, due to embryological origin,is located in the left lateral flank, posterior to the stomach, and lose to the kidneys.; habitually should be in that anatomical position and normally there should be only one spleen, although in occasions there are accessory spleens.

Analysis of the splenic vasculature, it is assessed by the splenic resistance index (SRI), is closely related to cardiovascular function and can be used to evalued preload reserve; a reduction > 9% is a parameter of rvolume response with specificity of 100%, and a reduction > 4% is associated with an improvement in splanchnic circulation and a decrease in systemic vascular resistance. This has been confirmed by its correlation with changes in serum lactate and central venous saturation. Therefore, the splenic resistive index in context of shock state can be modified in a similar way to other markers of hypoperfusion.

Objectives: To compare the splenic resistive index with clinical sings, biochemical and ultrasonographic hypoperfusion markers in a patient in state of shock at admission to Intensive Care Unit.

Methods: This analysis was disign as a descriptive, prospective an transversal study. In the intensive care unit of the Juarez Hospital in Mexico from March 1, 2022 to March 1, 2023. Evaluating the patient upon at admission to the intensive care unit, in a state of shock regardless the cause, The SRI was evaluating and messure by two ultrasonographers with experience in this technique, through the speed of diastolic and systolic blood flow. Taking as reference an elevation of the splenic resistive index more than 0.6. Using difference CO2 and serum lactate as a hypoperfusion sistemic state.

Results: When comparing the splenic resistive index in shock patients with respect to other markers of sistemic hypoperfusion. We found The splenic resistive index and serum lactate have a similar elevation directly proportional in a shock patients (Confluence value 0.025). We found a close correlationshio between the elevation of the renal resistance index and the leng od stay in the intensive care unit, of 29 patients, the 16% o (4.6 p) has a leng of stay of more than 5 days in the ICU. In this case 3 patients was death,.

The prevalence of death was the 2% of all population.

Conclusions: The splenic resistive index is an ultrasonographic marker, it is directly related to the elevation of clinical and biochemical markers of sistemic hypoperfusion. Therefore, it can be used as an initial evaluation at bedside of patient admission to the intensive care unit As well as lpredictor of engthof stay in the intensive care unit.

Improving patient safety with unfamiliar medications on ITU

L. Moore[1], D. Lloyd[1], S. Dibble[1]

[1]Critical care unit, Royal Cornwall Hospital, Truro, United Kingdom

Correspondence: L. Moore

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001180

Introduction: Hospital electronic prescribing (EP) is an important item on the UK government health policy agenda: Hospitals in England were expected to be paperless by 2020 but are behind schedule. It is argued the greatest benefits are associated with integrated EP systems because they offer improved communication between prescribers, pharmacists and other stakeholders; by aiding decision or administration support; and providing a robust audit trail for the entire medicines use process. Medication incidents are often multifaceted. Human and electronic factors must be considered when investigating medication incidents.

Methods: Following a patient safety incident on critical care, where a patient received three times the required dose of rituximab on critical care, an appreciative inquiry approach was used to identify root causes for potential errors when administering rarely used medicines. Medical, nursing & pharmacy professions consulted. Electronic and human factors were investigated with the aim for preventing future occurrences.

Results: Twenty-four contributory factors were identified during the investigation. The main themes were (1) lack of knowledge by doctors, nurses and pharmacists on where to look for information (2) Lack of Trust protocol relating to medication administration. (3) Incorrect prescribing on the EP record and (4) Inappropriate pharmacy supply.

Multi-pluralistic approaches to the investigation were used to avoid conflict. It was further minimised by ensuring positive and negative processes were identified in all groups rather than one member within the multi-professional team being singled out to avoid blame culture.

A Trust protocol for safe and standardised rituximab use in vasculitis has been written and published on the Trust e-library.

A new pharmacy specific single point of entry for notes was created in electronic record which has subjected to two to plan-do-study-act cycles to maximise effectiveness. This is accessible to all members of the multi-professional team.

The pharmacy on-call training for critical care needed revision.

The results of the investigation were shared with all critical care and pharmacy staff via email and presented within the forum of departmental governance meetings to ensure shared understanding and learning.

The number of medication incident reports for critical care has reduced since the above interventions have been introduced.

Conclusions: Good communication is essential to multi-professional working.

Ensuring a consistent, easy access, single point of access for all pharmacy information was important to the multi-professional team.

An improved critical care induction for on-call pharmacists, with familiarisation with the specific critical care integrated EP system has been necessary.

Integrated EP systems have the potential to minimise medication errors but the importance of good clinical understanding of medication must not be underestimated.

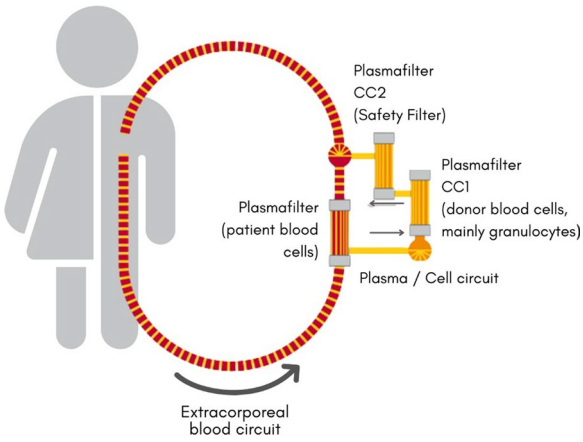
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001181

Introduction: Sepsis and septic shock induce immune dysfunction characterized by immune cell depletion, T cell exhaustion, reduced production of pro-inflammatory cytokines, and reduced expression of cell-surface molecules such as human leukocyte antigen DR (HLA-DR). This so-called sepsis-associated immunoparalysis may impair the elimination of pathogens, increase susceptibility to secondary infections and reactivate dormant viruses. Granulocyte concentrate (GC) transfusions, as the only available immune cell concentrates, potentially induce tissue damage via local effects of neutrophils. Therefore, using donor immune cells purely extracorporeally is an attractive option. A clinical trial is ongoing to investigate the effects of purified GC with extended shelf-life in a simplified extracorporeal plasma treatment, following prior successful trials utilizing standard GC in the treatment of 20 patients.
Methods: We describe data from a prospective, phase II, multicenter, randomized controlled parallel-group clinical trial in patients with septic shock. Subjects suffering from septic shock according to Sepsis-3-Definition who additionally require norepinephrine at a dose of $\geq$ 0.15 mcg/kg/min (and/or vasopressin at any dose) are randomized to receive either standard of care therapy or extracorporeal immune cell therapy on top of standard of care, in a 1:1 ratio. A total of 120 evaluable patients will be enrolled at multiple sites within Germany. Primary endpoint is safety and tolerability consisting of new onset of serious adverse events. A key secondary endpoint is the evaluation of the course of recovery from immune dysfunction in both groups. The comparison between the two groups will be evaluated at the interim analysis after 50 patients and at the final analysis. Additionally, the study also includes an evaluation of the normal course of immune paralysis in the control group, which will measure various cytokine levels and functional immune cell parameters of specific lymphocyte subsets, monocytes, and granulocytes on selected days.
Results: This study has been started in 2022. First results of the ongoing study will be presented focusing on the course of immune paralysis based on multiple cellular and humoral immune parameters.
Conclusions: The extracorporeal immune cell plasma perfusion therapy may on one hand provide immune support and may avoid unwanted local side effects on the other hand. Recovery from immune dysfunction is a prerequisite for avoiding secondary infections and ultimately also for recovery from sepsis.



Scheme of the extracorporeal immune cell plasma perfusion therapy. Plasma is continuously filtered from the patient´s extracorporeal blood circuit and transferred into a closed-loop 'cell circuit', where the patient's plasma is brought into direct contact with therapeutically effective, human-donor immune cells (i.e. granulocyte concentrate).

Correspondence: A. Akcan-Arikan
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001182

Introduction: Acute kidney injury (AKI) is associated with increased morbidity and mortality in pediatric patients and can be hard to detect in healthy children who do not have pre-illness serum creatinine measurements. Community-acquired AKI (CA-AKI) is not infrequent, less well-known, and poorly recognized. Best practice alerts (BPA) in electronic medical records (EMRs) can improve detection and management of AKI when linked to actionable care pathways.
Objectives: We created and implemented a BPA to improve our detection and management of CA-AKI to: increase CA-AKI diagnosis

to > 75% with a false positive rate of < 10%, to trigger nephrology consult for stage 3 AKI all patients, to reduce the length of stay (LOS) by 10%.
Methods: We created an active electronic BPA using age- and gender-based creatinine reference ranges that would fire and alert our emergency department nurses and physicians using the KDIGO creatinine definition. The alert notified the clinician of the stage of AKI and was coupled with a care bundle in the form of an order set stratified to the stage of AKI. This order set allowed the emergency department team to manage the AKI and investigate the etiology. Through a series of Plan-Do-Study-Act cycles, we evaluated and modified the BPA to maximize detection while minimizing alert fatigue.
Results: In the first year our EMR alert went live, we had over 12,000 alerts fired (firing multiple times until a clinician acts on the alert). There were 377 unique encounters with CA-AKI (55% stage 1, 19% stage 2, 26% stage 3) with multiple patients who sustained multiple kidney injuries with a 5.6% false positive rate. Our recognition and diagnosis of CA-AKI improved from 19% (pre-alert) to 76% (with BPA). Our LOS decreased by 22%. Nephrology consultation frequency did not change; however, this data is based on a consult order being placed in EMR and we cannot tell if emergency physicians simply called nephrology for advice but did not place an order.
Conclusions: An actionable EMR embedded BPA improved CA-AKI detection in the pediatric ED and decreased resource use. Future steps will include analysis of BPA associated reduction in nephrotoxic medication exposure and impact on mid and long-term follow-up of CA-AKI.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001184

Introduction: The literature identifies that critical illness and associated care in the intensive care unit (ICU) presents several psychological challenges for patients and families. However, this evidence has generated little discussion for practice and policy implications.
Objectives: We used a meta-ethnography synthesis to examine the psychological responses of patients receiving ICU care and draw their implications for practice.
Methods: Literature searches in CINAHL, MEDLINE, EMBASE, PsycINFO, Scopus, Dissertations and Theses Global databases was conducted using predefined eligibility criteria. We employed the CASP tool to assess the quality of included articles. Data synthesis was based on Noblit and Hare's approach, and reporting on the eMERGe framework.
Results: A corpus of twenty-one studies from thirteen countries were synthesized. Three main themes, *tormenting emotional experiences*, *disruptions in identity and social connections*, and the *disempowered warrior*, formed the fundamental experience of ICU patients. About 80% of patients in this review responded to ICU hospitalization with negative emotions, including depressive feelings, fear, anxiety, panic, agony, pessimism, emotional pain, perceived torment, acute existential distress, powerlessness, and dehumanization. Professional support, continued tailored education on what to expect, development of hope and optimism are perceived to reduce the emotional toll of ICU experience.
Conclusions: Negative emotions in care may cause poor psychological adjustment and delayed recovery. Patients are likely to acquiesce in care situations when control is vested in powerful others. Our study revealed the need for patient-centric insights into the ethical relationships between patient autonomy and medical paternalism in modern critical care medicine. Our research refocuses attention on the practicalities of empowering patients. It highlights challenges in negotiating care elements and pathways in ways that foster patients' autonomy in care.

Safety of restrictive resuscitation after major burn trauma
R. Gigengack[1], A. Dijkstra[2], B. Cleffken[3], S. Koopman[4], C. Van Der Vlies[5]
[1]Intensive Care and Anesthesiology, Amsterdam UMC, locatie VUmc, Amsterdam, Netherlands; [2]Burn Center, Maasstad Hospital, Rotterdam, Netherlands; [3]Department of intensive care, burn and trauma surgery, Maasstad Hospital, Rotterdam, Netherlands; [4]Department of Anesthesiology, Maasstad Hospital, Rotterdam, Netherlands; [5]Department of Burn and Trauma surgery, Maasstad Hospital, Rotterdam, Netherlands

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001185

Introduction: Burn trauma is accompanied by an immune response resulting in pathophysiological processes and induces a reduction in cardiac function, vasoplegia and endovascular leakage. This reaction has been known for several decades. Through the years the Parkland formula has been the mainstay in guiding fluid resuscitation. More recent literature shows possible fluid overload and the fluid creep. These findings resulted in more awareness for the risks of high-volume fluid resuscitation in patients after burn trauma. Because of these findings, the fluid resuscitation protocol in the Netherlands changed from the liberal 4 ml/kg/%TBSA to a restrictive 3 ml/kg/%TBSA. The aim of this study was to investigate whether restrictive resuscitation is non-inferior to liberal resuscitation.
Methods: This retrospective, before-and-after study, was performed in the Maasstad Hospital in the Netherlands and included adult patients admitted to the burn intensive care for resuscitation therapy according to the parkland formula ($\geq$ 15% total body surface area (TBSA)). The study was reviewed by the institutional review board. The resuscitation protocol changed mid-2018, and all patients 2.5 years before and after this change were included. A database was constructed containing all baseline burn and patient characteristic, and included all parameters recorded during intensive care treatment. Primary outcome parameter was renal function measured in maximum change of creatinine in the first 7 days and was analyzed using a non-inferiority analysis based on the development of stage 1 KDIGO AKI. Other outcome parameters were tested using a logistic model and corrected for differences in gender, full-thickness burns, and SOFA-score.
Results: In total 44 patients were resuscitated according to restrictive protocol and 56 according to the liberal protocol. The patients were indeed resuscitated in accordance with the restrictive or liberal protocol at 24 h: 2.96 ± 1.63 ml/kg/%TBSA vs. 3.95 ± 1.91 ml/kg/%TBSA. No significant differences were present in the hemodynamic or respiratory parameters, or mortality (8.9% vs. 9.6%, respectively). Hospital length of stay was significantly shorter in the restrictive group: 24 (19–35) vs 38 (24–62) days. No inferiority was proven in the restrictive group comparing to the liberal group in maximum change in creatinine (8 ± 26 vs. 8 ± 31, CI [-11, 8].
Conclusions: This study shows that a more restrictive resuscitation strategy (3 ml/kg/%TBSA) in patients with large burn trauma is non-inferior compared to a liberal strategy (4 ml/kg/%TBSA) in the development of acute kidney injury after resuscitation. Furthermore, a restrictive strategy could decrease the hospital length of stay significantly and showed no differences in hemodynamic or respiratory

parameters. These findings indicate that a restrictive strategy is promising for future burn patients.

Effects of positive end-expiratory pressure delivered by helmet on ventilatory parameters: a crossover physiological study

L. Moretto[1], D. Raimondi Cominesi[1], B. Fumagalli[1], K. Ferrari[2], L. Fumagalli[2], F. Cipulli,[2], M. Pozzi[1], G. Foti[1], E. Rezoagli[1], M. Giani[1]

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001186

Introduction: Non-intubated patients with acute respiratory failure may have an excessive respiratory drive and breathe with large tidal volumes (Vt). This may lead to self-inflicted lung injury (P-SILI) [1,2]. Positive end-expiratory pressure (PEEP) is a key strategy to improve alveolar recruitment in invasive, non-invasive (NIV) and continuous positive airway pressure (C-PAP) ventilation [3,4]. Currently, ventilation monitoring during NIV is not usually available. ExSpiron®Xi (TVExSpiron) is a non-invasive monitoring device for continuous tidal ventilation in spontaneously breathing patients, based on bioelectrical impedance technology [5].
Objectives: To describe how ventilatory parameters (Vt, minute ventilation [VE], and respiratory rate [RR]) vary during spontaneous breathing, before and after administering PEEP with helmet C-PAP.
Methods: This is a single-centre cross-over physiological study performed in intensive care unit in patients with clinical indication to helmet CPAP. Exclusion criteria were age < 18 y/o, pregnancy, and contraindications to PEEP. We performed a zero end-expiratory pressure (ZEEP)-PEEP trial with a helmet C-PAP, consisting of three steps: 1) before helmet implementation (PRE-H) with an inspiratory oxygen fraction (FiO2) that was kept constant across all steps; 2) ten minutes after helmet implementation without PEEP (ZEEP), and 3) one hour after PEEP application. Ten minutes of tracings were analysed for each step. Ventilation monitoring was performed through the bioelectrical impedance-based monitor ExSpiron®Xi (TVExSpiron). At the end of each step, arterial blood gas analysis was recorded. Mean Vt, VE, RR and P/F ratio among all steps were compared through repeated-measures one-way ANOVA.
Results: We enrolled eight consecutive critically-ill patients, including one woman and seven men. Demographic and baseline characteristics are shown in Table 1. Seven out of ten patients started the trial with a Venturi mask, two with high-flow nasal cannula and one with nasal prongs. Table 2 shows the means and standard deviations of each ventilatory parameter during the trial; no statistical difference was observed in Vt ($p = 0.24$), VE ($p = 0.16$), and RR ($p = 0.9$) among the three steps. Figure 1a, b, and c show how Vt, VE, and RR vary during the ZEEP-PEEP trial, respectively. Although not significantly, VE rises at ZEEP step and decreases to baseline after PEEP setting. Vt trended to decrease with PEEP setting. PaO2/FiO2 increased significantly after each step ($p < 0.01$), while PaCO2 remained stable.

Age, years	60.5 (58–71)
BMI, Kg/cm2	26.7 (23–27.8)
Comorbidities	
Hypertension, n° (%)	6 (60)
Diabetes, n° (%)	3 (30)
Cardiopathy, n° (%)	3 (30)
Chronic kidney disease, n° (%)	3 (30)
Smoke, n° (%)	2 (20)
COPD, n° (%)	1 (10)
Other, n°(%)	6(60)
ICU admission diagnosis	
ARDS/AHRF, n° (%)	5 (50)
Septic shock, n° (%)	2 (20)
Trauma, n° (%)	1 (10)
Baseline	
SOFA score on study day	3 (2–6)
FiO2	0.5 (0.4–0.5)
PEEP (PEEP step)	8 (8–8)

Conclusions: Helmet C-PAP with PEEP maintained a similar VE and RR as compared to no helmet or helmet at ZEEP. However, despite the lack of statistical significance and the limited sample size due to the preliminary data analysis, PEEP trended to a lower Vt as compared to pre-H and ZEEP.

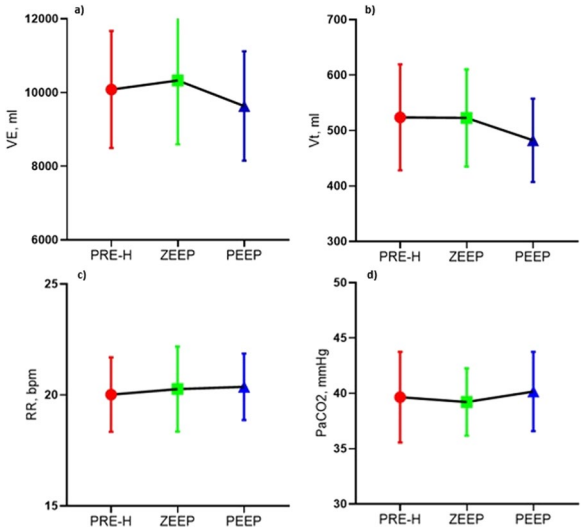

Figure 1. a), b), c) and **d)** respectively show VE, Vt, RR and $PaCO_2$ trends across the ZEEP-PEEP three-step trial; standard errors are presented. VE: minute ventilation; Vt: tidal volume; RR: respiratory rate; PRE-H: trial first step; ZEEP: zero end-expiratory pressure; PEEP: positive end-expiratory pressure.

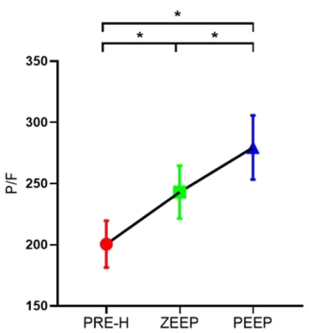

Figure 2. PaO_2/FiO_2 trends across the ZEEP-PEEP three-step trial; standard errors are presented, asterisks indicate significance. P/F: PaO_2/FiO_2; PRE-H: trial first step; ZEEP: zero end-expiratory pressure; PEEP: positive end-expiratory pressure.

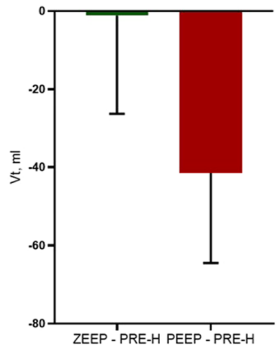

Figure 3. Mean difference in Vt between ZEEP and PRE-H steps, compared to mean difference in Vt between PEEP and PRE-H. Standard errors are presented. Vt: tidal volume; PRE-H: trial first step; ZEEP: zero end-expiratory pressure; PEEP: positive end-expiratory pressure.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001187

Introduction: The predictors negative outcome of AKI among Afro-Caribbean patients with COVID-19 disease is unknown. Majority of COVID-19 patients in Jamaica were admitted to University Hospital of the West Indies (UHWI).
Objectives: to evaluate negative predictors of outcome in Afro-Caribbean patients with COVID-19 infection and Acute Kidney Injury.
Methods: A retrospectively conducted study reviewing 138 AKI patients with confirmed COVID-19 infection in at a single institution between March 10, 2020–March 10, 2021. Parameters including, presenting symptoms, laboratory values, requirement for aggressive management associated and need for renal replacement therapy were evaluated. The likelihood of a fatal event was evaluated by univariate and multivariate analysis among the study participants.
Results: Forty-nine percent of patients attained a peak AKI Stage 1, 17% with AKI Stage 2 and 34% AKI Stage 3. The mean age was (62 ± 14) years with 59% being male. The presenting symptoms of dyspnoea and fever were the most likely to be associated with adverse outcomes. Mean serum creatinine difference between baseline and peak creatinine levels achieved were a greater indicator of AKI severity than the baseline serum creatinine levels. Patients who peaked at AKI stage 3 were more likely ($p < 0.05$) to be oliguric/anuric ($r2 = 0.264$), receive remdesivir ($r2 = 0.303$) and require dialysis ($r2 = 0.201$). Increased mortality was associated with increased number of symptoms at presentation ($r2 = 338$) and oliguria/anuria ($r2 = 0.580$). Low serum albumin levels (aOR: 0.734; 95%CI: 0.654–0.825) and oliguria (aOR: 8.631; 95% CI: 2.835–26.278) were the most significant predictors of mortality.
Conclusions: Low serum albumin levels and increased number of symptoms at presentation are key predictors of adverse outcomes in AKI patients with COVID-19 infection.

Feasibility and safety of percutaneous closure system (MANTA TM) for the arterial access in V-A ECMO: retrospective case series and comparison with traditional technique

M. Laiolo[1], M. Pozzi[2], G. Redaelli[1], G. Deleo[3], E. Maggioni[1], C. Benatti[3], M. Normanno[1], V. Segramora[3], L. Avalli[2], G. Foti[2]

Correspondence: M. Laiolo
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001188

Introduction: Compression method has traditionally been applied for the removal of the arterial cannula required for VA ECMO support. Numerous vascular and hemorrhagic complications associated with this procedure have been reported over the years.
Recently, endovascular devices for the closure of large-caliber arterial vascular accesses became available. MANTA is a femoral artery closure device for large-caliber accesses, structured with a resorbable collagen pad, a radio-opaque stainless steel locking component. Initially used for smaller calibers than ECMO cannulas with satisfactory results in terms of reduction in complications and rapid learning curve, it has been recently applied in management of ECMO arterial access.
Objectives: To investigate feasibility and safety of MANTA for managing arterial access site in VA ECMO, in terms of bleeding and vascular

complication compared with an historical cohort of patients managed with traditional methods.
Methods: In this observational study we collected data of all consecutive patients who underwent deconnection from VA ECMO, between 01/2018 and 09/2022. Starting from 04/2021 MANTA was implemented in collaboration with Vascular Surgery Department.
Inclusion Criteria were age > 18 years and femoro-femoral VA ECMO support. Collected data included demographic and clinical characteristic, vascular complications, bleeding complications, coagulation status in 4 different time-points.
Results: 52 patients met the inclusion criteria (9 management with MANTA e 42 with compressive technique). One patient underwent surgical removal. Patients managed with MANTA were more frequently anticoagulated ($p = 0.01$) and had higher Charlson Comorbility Index ($p = 0.029$). In both groups, the main indication for ECMO was represented by Cardiac Arrest (MANTA 44.4% vs compressive 56.1%).
In both groups it was possible to resume anticoagulation a few hours after the procedure, without significant differences between the two groups ($p = 0.113$) and dosages ($p = 0.070$). There was no difference for transfusion requirements ($p = 0.854$).
Among the patients treated with compression we observed early (1 thrombosis, 2 hematomas) and late (1 aneurysm, 2 dissections) vascular complications. In patients with MANTA, we observed early vascular complication (one arteriovenous fistula and one acute limb ischemia which required urgent surgery). Acute complications observed in MANTA group were associated with inadvertent cannulation of superficial femoral artery.
Conclusions: Comparing the two techniques, there were no significant differences interms of bleeding complications or transfusion; the frequency relative of early vascular complications was higher in the MANTA group. In emergency setting, inadvertent cannulation of superficial femoral artery could worsen clinical outcome.

Revolutionizing ICU Prognosis: Developing a Site-Specific Predictive Score for Enhanced Prediction of Outcomes in all Age Ranges Including the Very Elderly Patient

R. Fumis[1], B. Tomazini[2], N. Matos[1], E. Colonnezi[1], L. C. P. D. Azevedo[3], L. Pastore Junior[4], E. L. V. Costa[5]
[1]Intensive Care Unit, Hospital Sirio Libanes, São Paulo, Brazil; [2]Critical Care, Hospital Sirio Libanes, São Paulo, Brazil; [3]Academic Research Organization, Albert Einstein Israelite Hospital, São Paulo, Brazil; [4]Icu, Hospital Sirio Libanes, São Paulo, Brazil; [5]Research and education institute, Hospital Sirio Libanes, São Paulo, Brazil

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001189

Introduction: Octogenarians are often perceived as unsuitable candidates for ICU admission based on the expectation of reduced survival rates. On average, these patients indeed experience higher ICU mortality rates and longer post-ICU hospital stays compared to younger patients. However, many can resume daily activities at similar levels as younger patients one year after ICU discharge. Factors such as prior functional status, admission diagnosis, and comorbidities likely impact mortality and post-discharge functional status more than age. Traditional scores, like SAPS3 (1), can overestimate hospital mortality rates for this age group. Institutional factors and regional differences in local practices also affect the accuracy of current prognostic models.
Objectives: Our study aimed to develop and validate an institution-specific score incorporating baseline functional status, and site-specific data to improve prognostic accuracy for all age ranges, including very elderly patients.
Methods: This was a retrospective cohort study from a 30-bed ICU in Hospital Sírio-Libanês, São Paulo, Brazil. Data were retrieved from patients consecutively admitted to the ICU from January 2014 to April 2019. Patients were categorized as: less than 60 years old, 60–79 years old, and ≥ 80 years old (very elderly). The sample was divided in two halves, the first to develop and the other to validate a prognostic score (Fumis score). Mortality predictors included all SAPS3 variables, SOFA, baseline functional status, and Charlson Comorbidity Index. All variables were assessed using a multivariable logistic regression model, which was used to develop and validate the prognostic score of in-hospital mortality.
Results: A total of 9,631 patients were admitted to the ICU during the study period with 28.3% belonging to the very elderly group. Very elderly patients had higher ICU (7.0%) and in-hospital mortality (12.9%) than the other age groups ($p < 0.001$). The SAPS3 underestimated mortality in all age groups, but specially in the very elderly (Figure 1), in whom the standardized mortality ratio was 0.56 (95% CI 0.47, 0.67). Conversely, the Fumis score had good discrimination in the derivation and validation sets and was well calibrated for all age categories (Figure 1) with an SMR of 0.90 (95% CI 0.79, 1.04) in the very elderly.
Conclusions: This study successfully developed and validated the Fumis score, an institution-specific prognostic tool that used site-specific data for improved accuracy in predicting in-hospital mortality among all age groups, including very elderly patients. By utilizing site-specific data, this innovative approach overcomes the limitations of traditional scoring systems, such as SAPS3, which rely on multicenter data and often fail to account for the unique characteristics of individual hospitals. This idea of a site-specific prognostic tool paves the way for more accurate ICU admission decision-making.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001190

Introduction: Innate immunity is evolutionarily and functionally connected to haemostasis [1, 2]. PTX3 is a fluid-phase molecule of the innate immunity essential in resistance against bacterial and viral infections [3]. By interacting with defense fibrinogens, PTX3 amplifies effector functions of the innate immune system [4]. At wound sites and thrombus, PTX3 regulates the injury-induced thrombotic response. It promotes wound healing by favouring timely fibrinolysis by interacting with fibrin and plasminogen (Plg) through its N-terminal domain. PTX3-mediated enhancement of fibrinolysis involves interaction with Plg in acidic microenvironments and independence of increased plasmin formation. [5]. Human septic coagulopathy is characterized by an increase in naturally occurring anti-fibrinolytics, favouring the apposition of thrombi in the microvasculature and ultimately resulting in multiorgan failure [6].
Objectives: We aimed to study the potential effect of PTX3 and its N-domain in the blood of healthy donors and critically ill patients affected with *Staphylococcus aureus* (SA) bacteremia.
Methods: Citrated whole blood collected from healthy donors and critically ill patients (within 48 h of confirmed SA infection) was incubated (15 min) with purified recombinant PTX3 (222 nM), N-terminal domain (222 nM) or phosphate-buffered saline (PBS) and underwent viscoelastic analysis with the ROTEM using EXTEM assay. Six healthy donors and four patients (mean SOFA score 4 ± 2) were enrolled.
Results: Main ROTEM parameters are shown in Table 1. Viscoelastic tests of SA patients showed longer initiation of clotting compared to healthy donors, but clot firmness was significantly increased (73 ± 5 vs 57 ± 3 mm, $P < 0{,}01$) and lysis at 45 min reduced (3 ± 1 vs 5 ± 4%, p = 0.35) suggesting a hypercoagulable state with fibrinolytic shutdown. The addition of PTX3 or N-domain to normal blood did not exert any viscoelastic effect compared to blood treated with PBS. In SA patients, the addition of the N-domain decreased clot firmness compared to the control group (62 ± 9 vs 73 ± 5 mm, $P < 0{,}05$) and increased lysis at 45 min (19 ± 19 vs 3 ± 1%; $P = 0.15$) whereas a tendency towards increased fibrinolysis is observed using PTX3 (5 ± 5 vs 3 ± 1%, p = 0.26) (Figure 1).
Conclusions: Initial results indicate a potential pro-fibrinolytic effect of PTX3 and its N-terminal domain in the blood of patients with SA infection. The main causes associated with coagulopathy include inhibition of fibrinolysis due to the production of classical Plg activator inhibitors and acidosis.

Table 1 (abstract 001190) Mean ± standard deviation of the main ROTEM parameters of the study groups

Introduction: There is a lack of consensus as to drug and dose that should be administered to critically ill patients for the pharmacological treatment of acute delirium. Critically ill patients frequently have altered volume of distribution and impaired metabolism and clearance of many drugs. Unlike other drug classes, such as antimicrobials (1), there are no data for antipsychotic drugs in this patient population. Pharmacokinetic data will inform therapeutic strategies and the pharmacokinetic models generated will allow the investigators to propose optimized dosing regimens.
Objectives: To measure plasma concentration of olanzapine and quetiapine and their metabolites, and to describe population pharmacokinetic parameters of these drugs in critically ill patients.
Methods: This was a single centre prospective observational study. Patients who were ≥ 18 years of age and receiving immediate release enteral olanzapine or quetiapine for acute delirium were eligible. Blood samples were taken at regular time points for peak and trough concentrations for up to 4 days. The assay was designed, and batch analysis were conducted, to measure total and unbound olanzapine and quetiapine, as well as concentrations of the major metabolites, desmethylolanzapine and norquetiapine. Dose, frequency of administration, anthropometric measures, organ dysfunction, smoking history and concurrent medications were accounted for in the analysis.
Results: Thirty patients (sex: 25 [83%] male; age: mean (SD) 51 (15) years; and weight: 93 (19) kg) provided 109 samples. Nineteen patients were receiving quetiapine and 11 patients were receiving olanzapine. Based on the first sample obtained for each patient, there was wide variability for: total olanzapine (min. 2.68 ng/mL; max. 32.16 ng/mL) and associated unbound olanzapine (below limit of quantitation; 1.29 ng/mL respectively); and for total desmethylolanzapine (min. 0.00 ng/mL; max. 0.69 ng/mL). This variability was also observed for: total quetiapine (min. 72.87 ng/mL; max. 693.24 ng/mL) and associated unbound quetiapine (3.96 ng/mL; 34.58 ng/mL respectively); and for total norquetiapine (min. 0.98 ng/mL; max. 54.21 ng/mL). Detailed population pharmacokinetic modelling will be presented.
Conclusions: There is marked variability in plasma concentrations of olanzapine and quetiapine, both total and unbound, and their metabolite, when administered for acute delirium. Given the lack of existing data, population pharmacokinetic modelling will inform suitable dosing regimens.

Introduction: ICU patients lose muscle mass rapidly and maintenance of muscle mass may contribute to improved survival rates and quality of life. Protein provision may be beneficial for preservation of muscle mass and other clinical outcomes, including survival. Current protein recommendations are expert-based and range from 1.2 to 2.0 g/kg. Thus, we performed a systematic review and meta-analysis on protein provision and all clinically relevant outcomes recorded in the available literature.
Methods: We conducted a systematic review and meta-analyses, including studies of all designs except case control and case studies, with patients aged ≥ 18 years with an ICU stay of ≥ 2 days and a mean protein provision group of ≥ 1.2 g/kg as compared to < 1.2 g/kg with a difference of ≥ 0.2 g/kg between protein provision groups. All clinically relevant outcomes were studied. Meta-analyses were performed for all clinically relevant outcomes that were recorded in ≥ 3 included studies.
Results: A total of 30 studies published between 1983–2022 were included. Outcomes reported in the included studies were ICU, hospital, 28-day, 30-day, 42-day, 60-day, 90-day and 6-month mortality, ICU and hospital length of stay, duration of mechanical ventilation, vomiting, diarrhea, gastric residual volume, pneumonia, overall infections, nitrogen balance, changes in muscle mass, destination at hospital discharge, physical performance and psychological status. Meta-analyses showed differences between groups in favour of high protein provision for 60-day mortality (Figure 1), nitrogen balance (Fig. 2) and changes in muscle mass (Fig. 3).
Conclusions: High protein provision of more than 1.2 g/kg in critically ill patients seemed to improve nitrogen balance and changes in muscle mass on the short-term and 60-day mortality. Data on long-term effects on quality of life are urgently needed.

Introduction: COVID-19 pandemic overwhelmed critical care health services across the world, making an effect on selection of the patients, limitations of treatment and controversial choices of therapy. Now, in the aftermath of the pandemic the effect on health related quality of life (HR-QoL) can be evaluated.
Objectives: The aim of this study is to evaluate the HR-QoL in critical care survivors of severe COVID-19 pneumonia and to determine the risk factors that may be associated with it.
Methods: This was a retrospective analysis of patients treated for COVID-19 in ICU in the period from 2021 June to 2022 January in Vilnius, Lithuania. The study was conducted in a tertiary reference hospital. The patients who survived the stay in the ICU and agreed to participate in the follow up program were included in the study. Demographic, co-morbidity and general ICU course indicators were collected. The HR-QoL was measurement with 36-Item Short-Form Health Survey (SF-36). Mental and physical components were evaluated separately, regression analysis was conducted to determine the risk factors of worse HR-QoL.
Results: The data of 53 patients was collected. These patients were typical ICU patients for the 3rd wave of the COVID-19 pandemic in Lithuania. The cohort favors the moderate risk definition according to APACHE II (median = 7 [5–10]) and ISARIC 4C scores (median = 7 [5–10.5], a shift expected as only ICU survivors were included in the study. Mean follow up time of the patients was 7.64 ± 1.61 months. The mean physical health composite was 60.89 ± 25.33, and the mean mental health composite was 64.97 ± 22.78. For the physical health composite in the univariate regression model higher age (B = (-)0.575 CI95%: (-)1.14- (-)0.01 p = 0.048), presence of diabetes (B = (-)18.78 CI95%: (-)36.80– (-)0.74 p = 0.042) and higher ISARIC 4C mortality risk (B = (-)2.665 CI95%: (-)4.18– (-)0.59 p = 0.006) were shown to have an effect on worse scores. In the final regression model only ISARIC 4C mortality risk remained as sole independent predictor (B = (-)2.655 CI95%: (-)4.72– (-)0.59 p = 0.013). The univariate regression of SF-36 mental health composite determinants did not reveal any statistically significant predictors.
Conclusions: The patients after severe COVID-19 pneumonia and stay in critical care are affected and present with lowered HR-QoL after 6 months, mostly in the physical composite score. The main risk factors for worse physical condition are co-morbidities and age, a similar pattern observed in other respiratory infections.

Validation of 2021 ERC/ESICM guidelines in TTM2-trial data: a retrospective analysis of the prognostic accuracy in neurological prognostication after cardiac arrest

A. Lagebrant[1], Ttm2 Trial Investigators[2]
[1]Department of Clinical Sciences, Lund, Lund University, Lund, Sweden; [2]Department of Clinical Sciences, Lund University, Lund, Sweden
Correspondence: A. Lagebrant
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001196

Introduction: About two thirds of in-hospital deaths following successful resuscitation after cardiac arrest are due to hypoxic-ischaemic brain injury. (1,2) Most occur after a decision to withdraw from life sustaining therapy (WLST) in patients where meaningful neurological recovery is unlikely. (2) In 2021 the European Resuscitation Council (ERC) and the European Society of Intensive Care Medicine (ESICM) published a simplified guideline algorithm for prediction of neurological outcome after cardiac arrest, broadening the screening criteria to also include flexion posture. (3) External validations on its prognostic accuracy have previously reported 53–60% sensitivity with 100% specificity. (4,5).
Objectives: This study aims to validate the ERC/ESICM 2021 guidelines on neurological prognostication after cardiac arrest in a large international multicenter population. (3).
Methods: Retrospective descriptive analysis of the Targeted Hypothermia versus Targeted Normothermia after Out-of-Hospital Cardiac Arrest (TTM2) trial data. Patients with available motor score on day 4 and neurological outcome at 6 months were included. (6) The prognostic accuracy of ERC/ESICM 2021 algorithm, including clinical examinations (pupillary and corneal reflexes ≥ 72 h (h), early status myoclonus ≤ 72 h), neurophysiological tests (EEG > 24 h, SSEP ≥ 24 h), neuroimaging (CT ≤ 72 h, MRI 2–7 days) and biomarkers (serum neuron-specific enolase (NSE) at 48 and/or 72 h), was assessed.
Results: A total of 1324 patients met the inclusion criteria, of which 753 (57%) were eligible for neurological prognostication according to the screening criteria (Tab.1, Figure 1). Preliminary results indicate that the ERC/ESICM algorithm correctly identified 258 patients with poor neurological outcome and 213 of the total 491 patients not fulfilling the guideline criteria had a good outcome. The overall sensitivity for the algorithm was 48% (95% CI: 44–52%). Four cases of false positive predictions were identified, yielding a specificity of 98% (95% CI: 95–99%). Further results will be presented at the conference.
Conclusions: This validation study is the first to report a non-perfect specificity for the ERC/ESICM 2021 guidelines on neurological prognostication after cardiac arrest. The individual reports of false positive predictions and the potential interference with sedation must be further evaluated to assure validity in prognostication and avoid patients unrightfully being put at risk of WLST in clinical practice. Increasing the number of patients correctly identified with poor

neurological outcome while assuring a 100% specificity remains the goal for further development of guidelines. Limitations in this study include bias due to allowance of WLST during trial, possible residual effects of sedation and that the analysis was performed on reported examination results.

Table 1 (abstract 001196) Descriptive Table on included and excluded patients. Patients with missing neurological outcome, missing FOUR motor score at 72–96 h and who were deceased prior to 72 h were all excluded. Continuous variables are presented as median (inter quartile range) and categorical variables are described as count of numbers (percentages of all available data)

Table 1. Demographics of study population		
Baseline data	Included, N=1324	Excluded, N=537
Age (years)	65 (54-73)	67 (59-76)
Male	1070 (80.8)	407 (75.8)
Witnessed	1216 (91.8)	486 (90.5)
Bystander CPR	1089 (82.3)	398 (74.1)
Minutes to ROSC	25 (16-36)	30 (19-49)
Initial shockable rhythm on ECG	1036 (78.2)	335 (62.4)
TTM 33°C	664 (50.2)	266 (49.5)
Neurological outcome at six months		
Poor outcome (mRS 0-3)	607 (45.8)	381 (75.4)
Missing data		32

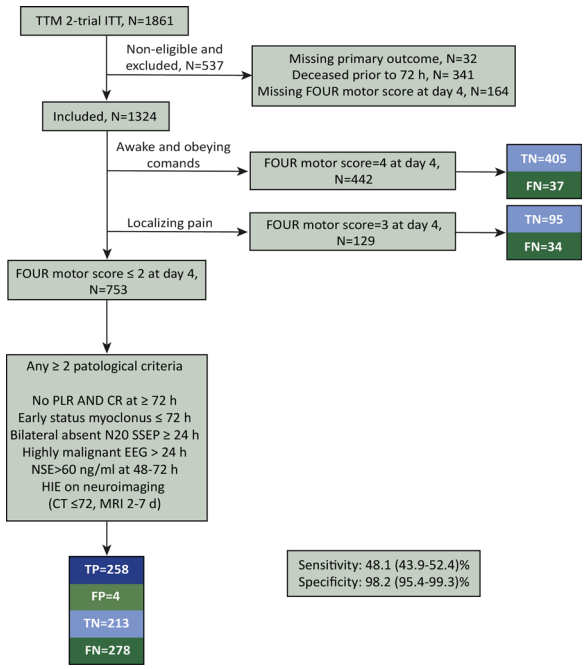

Figure 1 (abstract 001196) Flowchart of inclusion for validation of ERC/ESICM 2021 guideline algorithm on neurological prognostication after cardiac arrest. CR = corneal reflexes. FN = false negative, normal examination and poor outcome. FOUR = Full Outline Unresponsiveness (0 = no motor response, 1 = extension posture, 2 = flexion posture, 3 = locating pain, 4 = making signs). (7) FP = false positive, pathological examination and good outcome. HIE = hypoxic-ischaemic encephalopathy. PLR = pupillary light reflexes. TN = true negative, normal examination and good neurological outcome. TP = true positive, pathological examination and poor neurological outcome

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001197

Introduction: Infection with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) and the subsequent disease Covid-19 is mainly characterized by respiratory symptoms, with lung infiltrates being present in more than 50% of hospitalized cases. Pneumothorax is potential complication in pulmonary infections. Several studies have reported that pneumothorax occur frequently in patients with Covid-19 pneumonia ranging from 15 to 20% of those receiving invasive ventilation.

Objectives: This study aimed to (1) investigate the incidence of pneumothorax in adult patients with severe Covid-19 pneumonia, (2) compare the incidence of pneumothorax with patients with influenza pneumonia, and (3) identify the risk factors for pneumothorax in patients with severe Covid-19 pneumonia.

Methods: Nationwide population-based study conducted using the Korean National Health Insurance Service data-base. Adult (aged ≥ 19 years) patients with severe Covid-19 pneumonia hospitalized from December 2019 to December 2020 and patients with severe influenza pneumonia hospitalized from 2020 January 2018 to December 2021 were evaluated. Severe pneumonia was defined as patients receiving ICU-level respiratory organ support (high-flow nasal cannula, noninvasive or invasive mechanical ventilation, extracorporeal life support). Development of pneumothorax was defined as having a diagnosis of pneumothorax or having received a closed thoracotomy.

Inverse probability of treatment weighting (IPTW) was used to adjust for differences in patients between Covid-19 and influenza pneumonia.
Results: A total of 46,508 patients with severe Covid-19 pneumonia were identified (median age 62 years; 52.9% male). Among them, 344 (0.74%) were diagnosed with pneumothorax. In the IPTW matched cohort, development of pneumothorax was significantly more frequent in Covid-19 compared to influenza pneumonia (0.74% vs 0.49%, P < 0.001; OR 1.52; 95% CI, 1.05–2.21).
In the multivariable logistic regression, old age (OR, 1.03; 95% CI, 1.02–1.04; P < 0.001), male sex (OR, 1.34; 95% CI, 1.06–1.70; P < 0.001), and patients treated with ventilator (OR, 36.70; 95% CI, 29.80–52.90; P < 0.001) or extracorporeal life support (OR, 2.97; 95% CI, 2.16–4.09; P < 0.001) were associated with development of pneumothorax in severe Covid-19 pneumonia.
Conclusions: This nationwide cohort study found that the incidence of pneumothorax in severe Covid-19 pneumonia was 0.74% and more frequent compared to influenza pneumonia. Old age, male sex, and patients treated with ventilator or extracorporeal life support were risk factors for pneumothorax in severe Covid-19 pneumonia.

Hemodynamic determinants of urine output during continuous renal replacement therapy

L. Bitker[1], C. Biscarrat[1], M. Chivot[1], G. Chazot[1], G. Deniel[1], JC. Richard[1]
[1]Medical Intensive Care Unit, Hôpital de la Croix-Rousse-HCL, Lyon, France
Correspondence: L. Bitker
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001198

Introduction: Low cardiac output and hypovolemia are candidate macrocirculatory mechanisms of de novo oliguria and anuria in ICU patients undergoing continuous renal replacement therapy (CRRT), but therapeutical hits such as norepinephrine or excessive ultrafiltration may also be implicated [1, 2]. To date, the impact of systemic hemodynamics on urine output (UO) remains unknown in the context of CRRT.
Objectives: We aimed to determine the hemodynamic parameters associated with the longitudinal course of UO in ICU patients treated with CRRT.
Methods: This is an ancillary analysis of the PRELOAD CRRT observational, single-center study (NCT03139123), which evaluated the prevalence of preload-dependent hypotensions in patients undergoing CRRT [3]. Enrolled patients (≥ 18 years) had severe acute kidney injury treated with CRRT for less than 24 h, and were monitored with a calibrated continuous cardiac output monitoring device. Hemodynamics, norepinephrine dose, and preload-dependence (identified by continuous cardiac index variation during passive leg raising) were reported 4-hourly, over a maximum duration of 7 days [4]. Cardiac output was calibrated every 4 h by transpulmonary thermodilution to compute the systolic volume index (SVI). Net ultrafiltration (UFNET) and 4-hourly UO were collected from ICU charts and expressed in ml.h-1.kg-1. Two study groups were defined at inclusion: non-anuric participants if the cumulative 24 h UO at inclusion was ≥ 0.05 ml.h-1.kg-1, and anuric otherwise. Quantitative data was reported by its median [interquartile range]. Mixed-effects regression models evaluated longitudinally the association of UO with hemodynamics and CRRT settings, with a random intercept (patient study identification number) and a random slope (time since inclusion) to account for the repetition of measurements in a given patient.
Results: Between May 2017 and September 2020, 42 patients (age 68 [58–76] years) were enrolled 6 [1–15] hours after CRRT start and were followed for 119 [57–143] hours. At inclusion, 40 patients (95%) received norepinephrine, 39 (93%) were treated with CVVH, and 32 (76%) were not anuric. Hemodynamics did not differ significantly between study groups at inclusion. During follow-up, UO decreased significantly in non-anuric patients, with 23/32 (72%) progressing to anuria within 19 [10–50] hours. Mean arterial pressure, norepinephrine dose and UFNET did not significantly differ between study groups during follow-up, while SVI and preload-dependence showed a significant association with the interaction of study group and time since inclusion. In multivariate analysis, UO was significantly associated with SVI, mean arterial pressure, preload-dependence and time since inclusion (**Figure 1 for the description of model results and interpretation), but not with UFNET or norepinephrine dose. Fluid balance between inclusion and H72 of inclusion was significantly higher in the anuric group, compared to non-anuric participants (-3 [-10–1]% vs. + 6 [1–11]%, $P = 0.02$). CRRT free-days at day 90 were similar between study groups (0 [0–52] vs. 0 [0–76], $P = 0.56$).
Conclusions: In ICU patients treated with CRRT, those without anuria at treatment start showed a rapid loss of diuresis after CRRT initiation and a positive fluid balance. Hemodynamic indicators of renal perfusion and volemia were the principal determinants of UO during follow-up, while other suspected confounders (such as norepinephrine or UFNET) were not. Finally, presence of anuria at CRRT commencement was not associated with worse clinical outcome.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001199

Introduction: Plant poisoning are rarely described in the literature and their effects can be fatal.
Objectives: The aim of the study was to describe the circumstances, routes of exposure, type of plant, associated toxidrome, treatment and outcome of patients admitted for plant poisoning in intensive care unit.
Methods: It was a retrospective descriptive monocentric study of clinical cases with plant poisoning admitted to intensive care unit of CMYAMU from January 2006 to June 2021.
Results: We included 55 patients with a female predominance and a mean age of 45 ± 20.8 years [9–93]. The most frequent comorbidities were diabetes and hypertension (18%, n = 10). Circumstances of poisoning were accidental (58%), therapeutic (20%), addictive (16%) and for suicidal purpose (6%). Datura (31%) and Ricin (26%) were the most poisonous plants, followed by Black Henbane (11%), common oleander (11%), Belladonna (9%), Harmal (4%), Mandrake (4%) and isolated intoxications with Camphor, Lupin and Cherry seeds. Anticholinergic toxidrome was observed during Datura, black henbane, belladonna, mandrake and lupine seeds poisoning. Digestive signs were predominant during ricin and Harmal poisoning but they were more pronounced during ricin intoxication with a longer duration of hospitalization [1–8]. The cardiac signs were predominant during common oleander poisoning. Cherry seeds mimicked cyanide poisoning with digestive signs associated with hyperlactatemia. Treatment was symptomatic, and four patients required mechanical ventilation: Datura intoxication (n = 2), black henbane (n = 1), camphor intoxication (n = 1).The evolution was favorable for the majority of cases with an average hospitalization time of 2.3 ± 1.7 days [1–12], except for fatal camphor poisoning.
Conclusions: The present study identified Tunisian plants with toxicological risks and provides a date base for a more rational approach to prevention,diagnosis,and treatment of plant poisoning cases.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001201

Introduction: MSCT pulmonary angiography (MSCT PA) is a golden standard diagnostic test for pulmonary embolism (PE). Significant irradiation, contrast induced nephropathy and costs are the main drawbacks of this imaging modality. The majority of PEs have a source in the lower extremity proximal deep veins. Ultrasound examination of proximal leg veins is a simple, highly specific, bedside available test for diagnosing deep venous thrombosis (DVT). Better sensitivity can be reached if the calf veins are also examined, as is required by the BLUE protocol (1), but such an approach is more time consuming. DVT is an indication for anticoagulation treatment, so the finding of concomitant PE will not influence the treatment in hemodynamically stable patients. Criteria for fibrinolytic treatment are clinical and supported by ultrasound studies, while MSCT PA usually does not influence the decision.
Objectives: To determine the proportion of patients with positive femoral and/or popliteal ultrasound for DVT among those with MSCT PA proven PE. Also, to assess if the avoidance of MSCT PA in patients with ultrasound proven DVT would be safe.
Methods: In this retrospective study, medical records of patients admitted to the medical intensive care unit due to MSCT PA proven PE were reviewed. Patients who required fibrinolytic treatment were excluded.
Results: During a five-year period (2014–2019) 117 patients were admitted due to MSCT PA proven PE. Three of them required fibrinolytic treatment and were excluded from the study. Of 114 included patients with median age of 67.5 years (22–92 years), 58 were females (50.9%). One patient died during the hospitalization, due to reasons unrelated to the PE (hospital mortality 0.87%). MSCT PA study categorized 78 (68.4%) patients as those with massive and 36 (31.6%) with sub massive PE, while signs of right ventricle overload were seen on 60 (52.6%) MSCT PAs.
All patients were examined for femoral and popliteal DVT by ultrasound within the first 72 h from admission. DVT in the femoral and/or popliteal region was found in 66 patients (57.9%); femoral in 19, popliteal in 28, and both femoral and popliteal in 19 patients. No additional important information was observed by MSCT PA. The calculated average dosage of irradiation was 241 mGycm with an approximate risk of one malignancy for 5000 MSCT PA studies.
Conclusions: In patients with the clinical suspicion of PE, an ultrasound finding of femoral and/or popliteal DVT could be enough for the initiation of the anticoagulation treatment with no need for MSCT PA (2, 3). In the observed population no additional important information was provided by MSCT PA.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001202

Introduction: There is growing evidence to support early mobilization of mechanically ventilated adult patients. However there is no consensus about what type of practices are most beneficial for patients and how, when and where to start it.
Objectives: To describe current early mobilization practices in critical patients who received invasive mechanical ventilation (IMV) for longer than 48 h in Catalonian ICUs.
Methods: 1-day, multicentric, observational, prevalence study in 17 Catalonian ICUs in February 2022. Included patients were over 18 years

old and received IMV for longer than 48 h. The data retrieved was: ICU characteristics (resources and organizational) demografics, mobilization technique based on airway, reason for no mobilization, adverse events and ICU acquired muscle weakness (ICUAMW) diagnosis.

Results: 188 patients were included. The average age was 63 (standard deviation 12.13), average SOFA of 6 (0–17) on the day of the study. Patient source of admission was the emergency room (29%), followed by the general ward (27%). The most frequent reason for admission was respiratory failure (42%) and the main reason for intubation was SARS CoV-2 pneumonia (42.6%).

The great majority of ICUs (88.2%) had a physiotherapist available, and in the 70.6% the physiotherapist was available 5 days per week. The time the physiotherapist was available for is 0–4 h in 41.2% of the ICUs, followed by 4-8h in 35.3%. 70.6% of the ICUs count with an early mobilization protocol.

Regarding the decision to mobilize the patients: the ICU specialist participated in 73% of the cases, followed by the physiotherapist (61%) and nurses (59%). The professionals who most frequently mobilized patients were physiotherapists (82%) and nurses (79%).

ICUAMW was evaluated in 93 (49.5%) patients; 85% of which were diagnosed with ICUAMW because of MRC < 48. In relation to the 50.2% non-evaluated patients, 61% had RASS < -2.

In regard to mobilization; 87.2% of the patients were mobilized, resulting in 301 mobilizations; 249 of which were in bed and 52 out-of-bed (83% vs 17%, p = 0.03).

Concerning mobilizations based on the airway, active mobilization (20% vs 12%, p = 0.002), spine control (7% vs 1%, p = 0.001) and sitting on chair (10% vs 3%, p = 0.001) were the most frequent in patients with tracheostomy, as opposed to intubated patients. In the remainder of the mobilizations there were no significant differences between both groups. No patient with an endotracheal tube walked.

From the 12.8% non-mobilized patients, the main reason was respiratory followed by hemodynamic instability.

There were no significant side effects of mobilization and the incidence was low < 1%.

Conclusions: Out-of-bed mobilization of patients with invasive ventilation is low, the group with endotracheal tube being the least mobilized. Patients with no mobilization whatsoever have a contraindication in a majority of the cases. The adverse effect incidence was low, < 1%.

Introduction: During assisted mechanical ventilation a good matching between patient assigned ins and expiratory times, so called neural times, with the actual resulting mechanical times delivered by the ventilator is of the essence. Pressure support ventilation (PSV) relies exclusively on a pneumatic signal (the flow signal) for triggering and cycling-off. In some circumstances this limitation can cause a mismatch between the neural and mechanical times resulting in patient-ventilator asynchrony. Neural Pressure support (N-PSV) is a new hybrid mode combining assistance in PSV but substituting the pneumatic trigger by a neural trigger based on the electrical activity of the diaphragm (EAdi).
Objectives: To investigate whether a neural triggered PSV, N-PSV results in better time synchrony and better inspiratory times (neural and mechanical) matching in patients under assisted ventilatory support.
Methods: Prospective, physiological, comparative study in an unselected population of patients on assisted ventilation. PSV and N-PSV were compared during 2 consecutive periods of 30 min. Ventilator settings and level of support during PSV were those programmed by the attending clinician. During N-PSV these settings were maintained but trigger and cycle-off was based on the EAdi signal (obtained by a conventional NAVA catheter) instead of the flow signal. The following variables were compared: trigger time mismatch (TTm) the anticipation or delay between the start of patient's neural inspiratory cycle and the start of the assisted inspiratory cycle, expiratory cycling time mismatch (ECTm) anticipation or delay between the end of patient's neural inspiratory cycle and the end of the assisted inspiratory cycle, mechanical inspiratory time (TIm), neural inspiratory time (TIn) and the difference between them (TIdif). Comparisons were made with the t-student test for related samples or the Wilcoxon test for variables following a normal or non-normal distribution respectively.
Results: Preliminary analysis the first 13 included patients of an ongoing clinical study. Results are presented in Table 1 and Figure 1. N-PSV resulted in a reduced TTm (35 ms) and ECTm (105 ms) $p < 0.001$. The time mismatch was due to both anticipation and delay in triggering and cycling-off. There were no differences in absolute TIm and TIn values but a trend toward a better correspondence between both (less TIdif) during N-PSV.
Conclusions: In this unselected population N-PSV resulted in better time synchrony than PSV supporting the superiority of a neural signal over the pneumatic signal for triggering and especially for expiratory cycling. This could be an advantage in restrictive and obstructive patients with common early and late triggering and cycle-off problems in which patient-ventilator synchrony could be improved in N-PSV.

The Hypotension Prediction Index (HPI) is reliably available for finger cuff-derived arterial waveforms; a comparison of its clinical performance between invasively and non-invasively obtained measurements

SR. Rellum[1], E. Kho[2], J. Schenk[2], BJP. Van Der Ster[2], APJ. Vlaar[1], DP. Veelo[2]

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001205

Introduction: Continuous blood pressure monitoring can be essential for identifying hypotensive events (1). This detection can be improved using the Hypotension Prediction Index (HPI), as shown in recent clinical trials (2–6). Using invasive blood pressure, these trials accomplished significant hypotension reduction through timely alerting. Recently, HPI has been made available on continuous non-invasive blood pressure data. Four studies have evaluated the performance of non-invasive HPI, with promising results (7–10). However, a comparison of simultaneously obtained invasive and non-invasive data has not yet been published.
Objectives: The primary objective was to determine whether the clinical performance of HPI based on non-invasive data is significantly different from its invasive counterpart. The statistical difference between the area under their receiver operating characteristics curves (AUC) was assessed for this. Secondary outcomes assessed additional characteristics obtained from performance classification. Finally, the time to event for each dataset was evaluated.

Methods: This retrospective observational study performed at the Amsterdam UMC, location AMC, the Netherlands, included adult patients scheduled for elective non-cardiac surgery. Invasive data were collected on an EV1000TM system, and non-invasive data were simultaneously collected on a ClearSightTM system (Edwards Lifesciences, Irvine, CA, USA). HPI performance classification involved assigning predictive binary classifiers over the full range of HPI thresholds. Classes were assigned using 20-min timeframes. Herein, hypotension was defined as a mean arterial pressure (MAP) < 65 mm Hg lasting at least a full minute. Consequently, an HPI alarm with subsequent hypotension within that timeframe was classified as true-positive. Then, all four false and positive classes were assigned using the same logic. As an exception, false-negative classes were discarded if, within that timeframe, an HPI alarm emerged before hypotension.
Results: The study included 91 patients containing 21,109 and 20,565 min of data in the invasive and non-invasive datasets, respectively. The number of hypotensive events was similar. Performance classification of invasive HPI attributed to an AUC of 91.6%, while the non-invasive dataset yielded an AUC of 94.4%. A two-tailed t-test showcased a non-significant difference with a p-value of 0.36. All other classifiers, including the sensitivity, specificity, and positive and negative predictive values, were also not significantly different. Finally, the median time-to-event values ranged from 5.00 to 7.33 min in both datasets.
Conclusions: The results show that HPI performs well regardless of how blood pressure is obtained. This means that non-invasively obtained HPI is reliably available to clinicians during non-cardiac surgery when there is no sign of impaired pressure transfer through the finger or additional need for an arterial line.

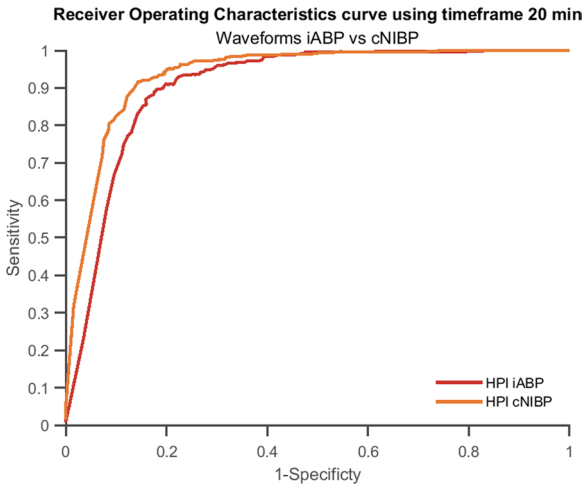

Figure 1 (abstract 001205) Receiver Operating Characteristics curve comparing the invasive and non-invasive datasets using a 20 min timeframe
HPI: Hypotension Prediction Index; iABP: invasive (radial) arterial blood pressure; cNIBP: continuous non-invasive (radial arterial reconstructed) blood pressure; min: minute (s).

Automated infrared pupillometry as a tool for prognostication in patients with intracerebral haemorrhage

F. Magarotto[1], A. Marudi[1], E. Marinangeli[1], G. Bettelli[1], G. Melegari[1], S. Giordana[1], E. Bertellini[1], I. Corrado[2]
[1]Anestesia e rianimazione, Ospedale Civile di Baggiovara, Baggiovara, Italy; [2]Neurochirurgia, Ospedale Civile di Baggiovara, Baggiovara, Italy

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**0001206

Introduction: The assessment of pupillary light reflex (PLR) is essential in critical care. The interest in automated infrared pupillometry in the intensive care unit practice for the evaluation of neurocritical patients has been growing recently, due to the reliability of this method and its non-invasiveness. Nevertheless, a clear indication for the applications of this instrument has not been firmly established yet.
Objectives: The objective of this study was to determine whether automated infrared pupillometry can provide useful information on the prognosis of neurocritical patients affected by intracerebral haemorrhage (ICH).
Methods: We conducted a single-center observational retrospective study. We included patients with intracerebral haemorrhage admitted to Neurointensive Care Unit in Modena Hospital from 2019 to 2022. We collected serial automated infrared pupillometry measurements using the NeurOptics® NPi®-200 pupillometer, which provides a scalar value called Neurological Pupil index® (NPi®), that is calculated with pupillary parameters such as maximum and minimum pupillary size, constriction and dilation velocity and others. We calculated the average NPi® value (avgNPi®) for each patient to assign a single value to their clinical course. We considered an avgNPi® value < 3 as an indicator of poor outcome (ICU mortality). Two-tailed Fischer's test was used to study the correlation between ICU mortality and avgNPi® values.
Results: Of 81 patients (average age 68.8 years [21–92]) admitted to the ICU for ICH, 49 were discharged from the ICU (average avgNPi®: 4.24; SD ± 0.41) while 32 died in the ICU (average avgNPi®: 1.43; SD ± 0.81). We observed a significant correlation between avgNPi® and

mortality (sensitivity = 81.3%; specificity = 95.9%; positive predictive value = 92.9%; negative predictive value = 88.7%; p-value < 0.0001). ROC curve analysis provided an AUC of 0.893 (Figure 1).

Conclusions: Our data suggest that automated infrared pupillometry could be a useful tool in the evaluation of neurocritical patients affected by intracerebral haemorrhage. Further studies could take into consideration the role of intracranial pressure alongside the NPi® to provide more accurate evaluation of the patient.

Correspondence: E. Swingwood

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001207

Introduction: Implementation of Mechanical Insufflation-Exsufflation (MI-E) in UK intensive care units (ICU) is limited, despite emerging evidence of efficacy (1,2,3) and safety (3,4) with intubated patients. A UK survey of respiratory physiotherapists working in ICU highlighted barriers to device use including the need for training and experience; resource availability and culture of the physiotherapy and wider ICU team (5).

Objectives: To further explore barriers and enablers for MI-E use in the acutely intubated, critically ill patient group, as perceived by ICU clinicians.

Methods: Semi structured online interviews were conducted with doctors, nurses and physiotherapists working in ICU, recruited using purposive sampling.

An interview guide was developed based on the Theoretical Domains Framework (TDF) (6,7) and piloted by clinicians with MI-E expertise. Interviews were recorded and transcribed verbatim.

Descriptive statistics described demographic data. Interview transcripts were analysed using content analysis, assigning quotes to TDF domains. Links across domains were considered.

Results: There were 29 interviews completed (18 physiotherapists, six doctors, five nurses). Clinicians had been qualified for 12 (2–32) years (median (range)) with 7 (1–21) years in a static ICU position. Thirteen clinicians held post-graduate qualifications (MSc or equivalent). Interviews were 31 (16–52) minutes duration. In total, 1137codes were generated covering all TDF domains.

Knowledge and skills were important determinants of MI-E initiation. Differences across professions regarding current and perceived knowledge and skills were present, impacting profession specific roles for MI-E use. Profession specific roles were important in the decision-making process and the practical application of MI-E.

Culture of single professions and the wider multidisciplinary team was influential in the initiation and ongoing use of MI-E, having positive and negative outcomes. The impact of hierarchy within professions had negative consequences on device implementation, device exposure and subsequent development of skills and knowledge of others.

A positive opinion of MI-E was demonstrated regarding current and future use of MI-E in the acutely intubated population. A collaborative approach was seen as important to enable clinical progression and change regarding the use of MI-E in ICU.

Conclusions: This study highlights barriers to device use consistent with previous literature. Knowledge and skills are important determinants of MI-E use in the intubated population. Education strategies should consider learning needs and profession specific roles prior to initiation. Despite a positive opinion of MI-E, multidisciplinary team culture and hierarchy have negative consequences. A collaborative multidisciplinary team approach was viewed as important to optimise future MI-E implementation outcomes.

The diastolic blood pressure is related to peripheral tissue microcirculatory dysfunction in COVID-ARDS patients

B. Ergin[1], C. Ince[1], HE. Endeman[1]
[1]The Department of intensive Care, Erasmus University Medical Center, Rotterdam, Netherlands
Correspondence: B. Ergin
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001208

Introduction: Covid-19-related acute respiratory distress syndrome (C-ARDS) causes severe hypoxia, hyperinflammation, and microcirculatory dysfunction that is associated with multiple organ failure and mortality (1). Despite many studies being conducted for investigating the effects of mean arterial pressure (MAP) or systolic blood pressure (SBP) on microcirculation, the relationship between diastolic blood pressure (DBP) and peripheral microcirculation is completely unclear. Herein, we hypothesized that the alteration of DBP may contribute to peripheral tissue hypoxia and microcirculatory dysfunction.
Objectives: The relation between DBP and systemic-peripheral microcirculation in C-ARDS patients admitted to Intensive Care Unit, Erasmus MC, Rotterdam in 2021 was investigated.
Methods: 17 patients with COVID-19 (13:4 m/f) were divided into two groups with low DBP (lower than 65 mmHg, n = 8) and high DBP (n = 9). For this purpose, systemic hemodynamics, arterial blood gas, and electrolytes were assessed. While peripheral microcirculation was measured by thenar tissue spectrophotometry, a Hand-Held Vital Microscopy (HVM) was used for determining systemic (sublingual) microcirculatory alteration.
Results: The patients with L-DBP had significantly lower p-stO2 ($p < 0.05$) and p-Flow ($p = 0.055$) than the patients with H-DBP despite having a similar P/F ratio and lactate (Figure 1 and Table 1). The arterial oxygen content (art-O2 content) of patients with L-DBP was also lower than that of patients with H-DBP ($p < 0.05$) (Table 1). Logistic regression analysis showed a significant correlation between the DBP and p-stO2 ($p < 0.05$) (Fig. 2). There were no differences in sublingual microcirculatory parameters (Fig. 3).

Table 1 (abstract 001208) Systemic (sublingual) microcirculatory and oxygenation parameters

	H-DBP	L-DBP
TVD (mm/mm2)	22 ± 1,8	22,4 ± 3,8
FCD (mm/mm2)	20,9 ± 2,2	21,3 ± 3,9
RBCv (mm.sec-1)	324,6 ± 79	317,5 ± 33,7
tRBCp (AU)	47,1 ± 14	45,9 ± 10
Arterial O2 content (ml.O2.min-1)	9,97 ± 1,29	8,6 ± 1,1*
Lactate (mmol/L)	1,3 ± 0,4	1,5 ± 0,5
stO2 (pulse oximetry)	95,5 ± 1,7	95,2 ± 2,9
P/F ratio	158 ± 67	166 ± 48

The sublingual microcirculatory parameters, arterial oxygen content, lactate and oxygen saturation values. TDV; Total vessel density, FCD; Functional capillary density, RBCv; Red blood cell velocity and tRBCp; Tissue red blood cell perfusion. $p < 0.05$ vs H-DBP group. Values are represented as mean ± SD.

Conclusions: DBP can be used for estimating the alteration of peripheral tissue perfusion and oxygenation, therefore, guiding future therapies in C-ARDS patients. Further research is needed to determine the underlying mechanism of relation DBP to peripheral microcirculation in hyperinflammatory states of C-ARDS.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001210

Introduction: Numerous grading scales have been suggested for subarachnoid hemorrhage (SAH) in order to categorize the likelihood of unfavourable neurological outcomes and the risk of delayed cerebral ischemia (DCI), but their performance is variable.
Objectives: To evaluate and compare the performance of SAH grading scores, including the WFNS, Modified Fisher (mFS), VASOGRADE, HATCH, Sequential Organ Failure Assessment (SOFA) and Acute Physiology and Chronic Health Evaluation (APACHE II) scores in predicting DCI, mortality and functional outcome in non-traumatic SAH patients.
Methods: Retrospective analysis of adults patients with non-traumatic SAH admitted to the intensive care unit (ICU) between January 2016 and December 2021. Demographic, radiological and clinical data were collected, and the performance of the grading scores in predicting DCI, mortality and unfavourable neurological outcome (UO, GOS 1–3) at 3 months was assessed using the area under the receiver operating characteristic (AUROC) curves and logistic regression analysis.
Results: A total of 262 patients were included in the final analysis; DCI was observed in 82 (31.3%) patients, while 75 (28.6%) died and 133 (50.8%) had UO. APACHE II showed the highest performance in predicting UO, with an AUROC of 0.84 (95% CI 0.79–0.89), followed by the HATCH (AUROC 0.83, 0.77–0.87) and the SOFA score (AUROC 0.82, 0.77–0.87), Figure 1. They all performed significantly better than the other scores, but none of them was statistically superior. APACHE II, HATCH and SOFA also had the highest performance to predict in-hospital mortality, with AUROC of 0.82 (0.77–0.87), 0.79 (0.73–0.84), and 0.78 (0.72–0.84), respectively, Fig. 2. Again, the difference between them was not statistically significant. None of the scores performed significantly better than the others in predicting DCI, all showing low performance (AUROC < 0.65), Fig. 3.
Conclusions: In this study, APACHE II, HATCH and SOFA score, with comparable performance, were the best predictors of UO and in-hospital mortality among the different SAH scores. The performance of such scores to predict DCI remained limited.

Introduction: The requirements of nutrition therapy in the obese are different due to their anthropometric and metabolic characteristics from other ICU patiens.
Objectives: The aim of this pilot study is to evaluate the adequacy of the caloric and protein intake in obese, as well as the number of associated complications with nutrition therapy in these patients.
Methods: Multicenter prospective observational study (n = 38) (NCT: 03634943) that included patients who needed nutrition therapy. Patients were classified according to body mass index (BMI) as: normal (18.5–24.9 $kg \cdot m^{-2}$), overweight (25–29.9 $kg \cdot m^{-2}$) and obese (≥ 30 $kg \cdot m^{-2}$). Demographic data, comorbidities, nutritional status, nutrition therapy first 14 days and its complications, together with supportive therapy, were recorded in a database (RedCAP®). Univariate and multivariate analysis were performed by SPSS 25.0.
Results: A total of 525 patients were included, of whom 165 (31.4%) had a normal BMI, 210 (40%) were overweight, and 150 (28.6%) were obese. The majority were medical patients (63.8%), received early nutrition therapy (74.9%) and a large proportion were at nutritional risk (mNUTRIC > 4 = 44.4%). The obese had a higher incidence of hypertension (normal:33.9%, overweight:41.9%, obese:56.7%; p < 0.001) and diabetes (normal:21.2%, overweight:20%, obese:36%; p = 0.001).
The mean caloric and protein intake was 19 ± 5.6 kcal/Kg/d and 1 ± 0.4 g/Kg/d respectively in the entire sample. A lower caloric (normal:20.7 ± 4.8, overweight:18.1 ± 3.6, obese;14.2 ± 4.3 kcal/Kg/d;p < 0.001) and protein intake (normal:1.1 ± 0.3, overweight:1 ± 0.3, obese) was observed (normal:1.1 ± 0.3, overweigth:1 ± 0.3, obese:0.7 ± 0.2 g/Kg/d;p < 0.001) with the increase in BMI. However, obese patients were those who received a better adequacy (> 70% administered requirements) of caloric intake (normal:80%, overweight:61.4%, obese:86%) in relation to the overweight patient (p = 0.001), while protein intake was clearly lower (normal:81.8%, overweight:60%, obese:43.3%;p < 0.001). There were no differences regarding complications related to nutritional therapy, although the incidence of complications was low (11.6%), as well as the needs for life support and ICU mortality. The multivariate analysis found that obese patients showed worse protein intake compared to patients with normal (HR:0.72; 95% CI:0.65–0.85;p = 0.007) and overweight (HR:0.86; 95% CI:0.72–0.96;p = 0.01).
Conclusions: In our study, an insufficient protein intake was observed in the critically ill obese patient. Strategies should be developed to optimize protein intake in these patients.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001212

Introduction: As life expectancy increases, the geriatric population is also rising, accounting for the fastest growing subset of the total population. In the US, segments older than 85 years are growing by almost 232%. Therefore, the number of elderly patients older than 80 years admitted to an ICU is also increasing—VIPs, estimated to be up to 25% of the total ICU admissions.
Objectives: Due to their age and the presence of common geriatric syndromes such as frailty, cognitive decline, reduced activity of daily life, and several comorbid conditions, this group is particularly challenging.3 Hence, the aim of this study is to identify the benefit of ICU admission, in terms of survival rate, for the very old (≥ 80 years).
Methods: A retrospective study was conducted, including patients admitted to the ICU between January of 2017 and June 2022. In addition to mortality (divided into within ICU stay, within hospitalization after ICU discharge, up to 1 year after hospital discharge, after 1 year after hospital discharge); age, sex, Clinical Frailty Score (CFS), age-adjusted Charlson Comorbidity Index (CCI), SAPS II, length of stay, if organ support was given (ventilation, vasoactive drugs or renal replacement therapy) and whether limitations of treatment were established during the ICU stay were also registered.
Results: A total of 245 patients with a median age of 83 years (P25-P75 81-85 years) were included in the final analysis, 141 (57,6%) were male and an average length of ICU stay of 4.45 days (SD 4.3 days). On admission, 196 patients (80%) had a CFS 4, 108 patients (44%) had an age-adjusted CCI 6 and SAPS II average of 45.7. During ICU stay 43.4% of the patients did not receive organ support. Overall, we observed a 49.4% survival rate; ICU mortality of 26.1%, hospitalization mortality after ICU discharge of 6.5%, mortality up to 1 year after discharge of 9% and mortality after 1 year of discharge accounting for 7.8%. A multiple linear regression was conducted between mortality up to 1 year after hospital discharge and other variables registered: ventilation

support and SAPS II demonstrating predictive value of mortality up to 1 year (adjusted R square 0.129, ANOVA significance < 0.001 with ventilation support significance < 0.001 and SAPS II significance 0.033).
Conclusions: Among the very old admitted to the ICU, half survived the ICU stay and almost two-thirds had a survival rate of up to 1 year after hospital discharge. We found that ventilation support, likely due to being a marker of disease severity but also related to complications, correlated with higher mortality up to 1 year after discharge. In addition, the data suggests a relationship between SAPS II and mortality up to 1 year after hospital discharge, as seen in other studies. However, this severity score, based on physiological data and age, may be limited in this portion of the population and the decision should always be individualized, weighing the risks and benefits associated with admission to the ICU for each patient.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001214

Introduction: The Ventilator-Associated Events (VAE) paradigm broadens the surveillance of preventable complications associated with mechanical ventilation (MV) beyond infections, with greater prediction accuracy for outcomes than ventilator-associated pneumonia. However, many ventilator-associated respiratory infections are dismissed as well as other common complications in ventilated patients such as atelectasis and pulmonary fluid overload. A recent study by our group using slighter thresholds to detect VAE in pediatric patients detected more than the double of events while maintaining its impact in outcomes.
Objectives: To assess whether using less restrictive criteria to detect VAE could improve the algorithm's sensitivity keeping its capability to predict outcomes.
Methods: Secondary analysis of a prospective, international, multicentre cohort study in 11 Intensive Care Units (ICU) from 4 European countries. Adult patients ventilated ≥ 48 h were eligible. **VAE** was defined as a sustained increase by ≥ 0.2 in the fraction of inspired oxygen (FiO2) or ≥ 3 cmH2O in the positive end-expiratory pressure (PEEP) for ≥ 2 days, with a previous baseline period of ≥ 2 days of stability or improvement. Three less restrictive definitions for VAE were proposed: 1)**Light-VAE**: sustained increase for ≥ 1 days in FiO2 ≥ 2 or PEEP ≥ 2 cmH2O or FiO2 ≥ 0.15 plus PEEP ≥ 1 cmH2O; 2) **VAE24:** VAE respiratory settings criteria sustained for ≥ 1 day; 3) **Light-VAE48**: Light-VAE respiratory settings criteria sustained for ≥ 2 days. Patients not following those criteria served as each type of VAE comparison group. Mortality, duration of MV and ICU length of stay (LOS) were the main outcomes end-points.
Results: A total of 2,706 ventilator-days among 261 adults ventilated > 48 h were analysed. Overall mortality was 35%. The duration of MV and ICU and LOS in the entire cohort (median, IQR) were 10 (5–21) and 14 (8–26) days, respectively. Incidence (per 1,000 ventilator-days) increased from 24 episodes for standard VAE, to 35 (145%), 41 (170%) and 55 (229%) for Light-VAE48, VAE24 and LightVAE, respectively. No significant mortality differences were identified. In contrast with standard VAE, extra (median) MV days increased from 10 to 25, 23, 22 days and extra ICU LOS from 14 to 25, 26, 28 days, respectively.
Conclusions: The use of less restrictive criteria to detect VAE among ventilated adults improved the sensibility of the algorithm while maintaining a significant impact on outcomes. Our findings support to update the tier using less restrictive VAE criteria over 48 h.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001216

Introduction: Major chest trauma is a leading cause of trauma-related death. (O'Connor and Adamski, 2010) A particularly life-threatening injury is traumatic hemopneumothorax (HPTX), but its diagnosis in the prehospital settings is challenging. (DeMasi et al., Netherton et al., 2019, Wilkerson and Stone, 2010) Microwave technology (MWT) has demonstrated the potential to detect free blood and air in the body by detecting changes in the microwave electromagnetic field caused by distinct dielectric properties of biological tissues. (Ahdi Rezaeieh et al., 2017, Christopoulou and Koulouridis, 2015, Candefjord et al., 2021, Fhager et al., 2018) MWT shows promise as a complementary diagnostic approach to existing methods.
Objectives: This study evaluated the effectiveness of MWT in assessing traumatic chest injuries in a porcine model of HPTX.
Methods: As part of a larger experiment evaluating MWT for assessing thoracic and abdominal injuries, this study was conducted in accordance with national legislation and with ethical approval from the Norwegian Food Safety Authority (Approval no. 11933). Ten female, prepubertal hybrid Duroc x Landrace/ Yorkshire (DDYL) pigs (63.7 ± 5.0 kg) were sedated and mechanically ventilated. To induce increasing levels of HPTX, blood (750 mL) was drawn from an arterial line placed in the femoral artery and consecutive volumes of air (50-1500 mL) were injected into the left thorax via a three-way stopcock

placed through a mini-thoracotomy. A wearable MWT device with eight antennas (A–H) was placed around the thorax (Figure 1), and all combinations of antenna pairs were measured in an automated fashion in a frequency range of 0.1–2 GHz. The resulting 36 coefficients were analysed for variation in magnitude (MAGN). A support vector machine (SVM) was used as a machine learning method to discriminate HPTX from baseline. Finally, the animals were euthanised under deep anaesthesia.

Results: The observed reduction in MAGN in the 0.6–2 GHz frequency range was significant for all stages of HPTX, with a correlation between HPTX volume and damping of the microwave signal. The most severe HPTX showed the greatest reduction in MAGN, up to 5 dB. The variance of the measurements depended on the MAGN of the signal, with higher variance in signals with lower MAGN and more severe HPTX. While the average variance for signals with high MAGN was 1%, some signals showed variations up to 10%. Classification analysis showed the highest accuracy when using all coefficients as input data, resulting in a sensitivity and specificity of 90% to correctly detect HPTX.

Conclusions: This is the first study evaluating a wearable MWT device for detecting traumatic chest injuries in a porcine model. Our results show that HPTX significantly alters microwave signals. The degree of alteration depends on the severity of the HPTX. Using an SVM, we achieved a high degree of accuracy in discriminating between healthy and HPTX conditions. However, our results are limited by high signal variance, which tends to increase in severe cases of HPTX, probably due to extensive physiological and anatomical changes and crosstalk phenomena between nearby antennas. (Candefjord, 2017, Candefjord et al., 2021) To improve and validate the classifier algorithm, further hardware improvements and larger subject numbers are needed before clinical trials can begin.

Acute stroke in aged brain: shoud we reperfuse?

J. Martins[1], A. Silva[1], T. Guimarães,[1], M. Monteiro,[1], A. Pereira,[1], P. Matos,[1], MG. Campello[1]
[1]Intensive Care Medicine, Centro Hospitalar Tâmega e Sousa, Penafiel, Portugal

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001217

Introduction: International guidelines specify no upper age limit for reperfusion therapies in acute ischemic stroke. Albeit, there are uncertainties about the clinical benefit of this therapies in very old population, as older age is a strong independent predictor of poor outcome.

Objectives: This study aims to identify the impact of reperfusion therapies (RT) on the funcional outcome and mortality of very old patients.

Methods: Observational retrospective study analysing the group of very old patients (aged 80 years or older) with acute ischemic stroke admitted in the emergency room of a tertiary hospital, between January 1st and December 31st 2022. We collected demographic data, degree of disability/dependence pre-stroke (modified Rankin Scale—mRS), admission stroke severity (National Institutes of Health Stroke Score—NIHSS), RT (intravenous thrombolysis and/or mechanical thrombectomy), mortality and funcional outcome (worsening ≥ 2 of mRS) at hospital discharge and at 3th month. Statistical analysis was performed with SPSS, version 27. We performed Chi-square and Fisher's exact tests; Mann–Whitney and Kruskall-Wallis tests. We also performed multivariate logistic regressions. Significance was set at $p < 0.05$.

Results: During the referral period, 251 patients were admitted in the emergency room with acute ischemic stroke and 91 (36.3%) of them were very old patients, of which 36 (39.6%) were males with a median age of 86.0 years (IQR: 84.0–89.0). The median mRS was 1.0 (IQR: 0.0–2.0) and the median NIHSS was 13.0 (IQR: 5.0–20.0). Reperfusion therapy was performed on 34.1% (n = 31).

We did not find significant association between RT and death ($p = 0.944$) or worse funcional outcome ($p = 0.777$) at hospital discharge. After 3 months we also did not find statistical relation between RT and death ($p = 0.978$) or worse funcional outcome ($p = 0.966$). Considering each type of RT, it maintains de lack of statistical relation with poststroke outcome (death at discharge $p = 0.898$ and at 3 months $p = 0.373$).

In multivariate logistic regressions, even when adjusted for age, mRS and NIHSS, RT was not statistically significant for mortality increase or worse funcional outcome. When considering mortality at hospital discharge, only NIHSS was statistically significant (p = 0.002, OR 1.12, IC [1.04; 1.21]). Analysing the decline in functional outcome at hospital discharge and at 3th month, only the mRS (p = 0.003, OR 0.51, IC [0.33; 0.80]; p = 0.011, OR 0.52, IC [0.31; 0.86], respectively) and NIHSS (p = 0.001, OR 1.14, IC [1.05; 1.23]; p = 0.020, OR 1.12, IC [1.02; 1.24], respectively) were statistical significant.
Conclusions: In our hospital there is no upper age limit for RT in acute ischemic stroke, according to international guidelines1,2. In the cohort of our study, RT was not associated with higher mortality or worse funcional outcome. Stroke severity (NIHSS) was an essential predictor of poststroke outcomes, in agreement with the literature3. Hence, our study indicates there may be no reason to withhold RT based merely on age.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001222

Introduction: The decision to extubate patients on mechanical ventilation is associated with a risk of failure, with up to 20–30% of patients requiring re-intubation (1–4). During the COVID-19 pandemic, this decision became even more challenging due to concerns about contamination risks and limitations in non-invasive ventilation. Thoracic ultrasound (TU), including lung ultrasound score (LUS) and diaphragm quantitative evaluation, is a safe and non-invasive technique (5) that has shown promise in previous studies for aiding decision-making in weaning. The hypothesis of this study was that thoracic ultrasound would have good diagnostic accuracy in predicting extubation failure within 72 h, and would evaluate the relationship between LUS and diaphragm function, both of which are associated with weaning.
Methods: A preliminary analysis was conducted in a prospective study that included ventilated patients admitted to a medical ICU at Hospital Moinhos de Vento in Porto Alegre, Brazil. Inclusion criteria were acute respiratory failure due to COVID-19 infection with mechanical ventilation for over 48 h. After a successful spontaneous breathing test (SBT), LUS, diaphragm excursion (DE), and diaphragm thickening fraction (DTF) were measured. The primary outcome was to determine whether TU could predict extubation failure.
Results: Twenty-seven patients were included in the study from March 2020 to March 2022. Eight (29.6%) patients experienced extubation failure, 18 (66.7%) were male, median age was 53 (IQR 25%-75%: 46–74), and median ICU length of stay was 36 (IQR 25%-75%: 23–60) days. Seven (87.5%) patients who failed extubation had LUS scores of 24 or higher, with a p-value of 0.03. There were no statistically significant differences observed in the comparison of mean values for DE (failure 2.28 cm and success 2.09 cm—p 0.54; CI − 0.4677 to 0.8704), DTF (failure 0.29 cm and success 0.27 cm—p 0.75; CI − 0.0960 to 0.1305), and mechanical ventilation time (p 0.42; CI -3.083 to 7.162). LUS and DE did not show a linear association (R2 = 0.04), nor did LUS with DTF (R2 = 0.07) or DE with DTF (R2 = 0.01). In the multivariate analysis with covariate correction, age and length of hospital stay were the variables that contributed the most to extubation failure, and LUS was not significant. However, with a larger sample size, this scenario may change. The data are a partial analysis of an ongoing study.
Conclusions: A Lung Ultrasound Score (LUS) of 24 or higher was found to be a good cutoff point for predicting extubation failure in COVID-19 patients, based on preliminary data analysis.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001223

Introduction: Optimal fluid balance is an essential part of organ perfusion management, namely in pancreas-kidney graft transplantation. Traditionally, a high positive fluid balance is implemented in order

to ameliorate renal graft function. PICCO® (Pulse index Continuous Cardiac Output) is an advanced haemodynamic monitoring device capable of evaluating cardiac output and preload. We established a protocol based on global end-diastolic index (GEDI), extravascular lung water index (ELWI) and diuresis in order to guide the immediate post-operative period in this type of patients.
Objectives: Evaluate the effect of PiCCO®-guided fluid balance in reno-pancreatic graft survival and delayed graft function.
Methods: A total of 64 simultaneous pancreas-kidney transplants were performed in our transplant center between 2017 and 2022. The patients were divided in two retrospective cohorts regarding fluid balance protocol. Group 1 received liberal continuous fluid infusion based on urine output > 200 mL/h (n = 28) whereas in Group 2 fluid balance was guided by PICCO® monitoring (n = 36) targeting normovolemia. All patients received induction with methylprednisolone and thymoglobulin and maintenance of immunosuppression with glucocorticoid, mycophenolic acid and tacrolimus.
Results: Mean fluid balance in the first 24 and 48 h was higher in Group 1 (4172 mL vs 3441 mL, p = 0,169; 2945 mL vs 2839 mL, p = 0,853). At day 3, there was a different trend, fluid balance was greater in Group 2 (691 mL vs 1295 mL, p = 0,236). Mean cumulative fluid balance in the first 72 h was significantly higher in Group 2 (7436 mL vs 9704 mL, p = 0,027). Mean P/F ratio was similar between the two groups in the first 24 and 48 h (447 vs 376, p = 0,766; 336 vs 343, p = 0,810), whereas on day 3 it was significantly higher in Group 2 (296 vs 304, p = 0,033). We documented a similar renal graft survival (88,2% vs 91,7%, p = 0,369) but a relevant increase in pancreas graft survival in Group 2 (73,9% vs 87,5%, p = 0,641). Renal delayed graft function had a meaningful decrease in Group 2 (22,7% vs 9%, p = 0,253); multivariate analysis revealed that renal cold ischemia time did not predict delayed graft function. No significant differences were found in biochemical values such as glomerular filtration rate and C-peptide. Hospital mortality was similar between the two groups.
Conclusions: Fluid management is an important factor known to affect delayed graft function and long-term transplant outcomes. The difficulty lies in achieving the best preload and graft perfusion without the deleterious effect of hypervolemia. Our six year cohort reports an increase in graft survival and decrease in delayed renal graft function, with higher P/F ratios, suggesting that PiCCO® monitoring might be beneficial to attain the optimal fluid balance tailored for each patient.

Introduction: Simultaneous pancreas-kidney transplantation is an accepted procedure for the treatment of Type I diabetic patients with end-stage renal disease. Pancreatic graft thrombosis remains one of the most frequent causes for transplant loss. In order to prevent this complication, we implemented an anticoagulation protocol using unfractionated heparin (UFH) infusion guided by the activated partial thromboplastin time (aPTT) ratio.
Objectives: Evaluate the effect of UFH infusion on thrombotic and hemorrhagic complications, one year graft survival and overall survival in simultaneous pancreas-kidney transplantation.
Methods: A total of 64 simultaneous pancreas-kidney transplants were performed in our center between 2017 and 2022. The patients were divided in two retrospective cohorts regarding heparin infusion protocol. Group 1 was submitted to aspirin from day one and prophylactic low molecular weight heparin (LMWH) while Group 2 was under aspirin and UFH infusion targeting an aPTT ratio of 1.5. All patients received induction with methylprednisolone and thymoglobulin and maintenance of immunosuppression with glucocorticoid, mycophenolic acid and tacrolimus. Hemorrhagic complications were defined as having at least three blood transfusions in one day, the need for emergent surgical intervention and hemorrhagic shock, which led to temporary suspension of anticoagulation therapy.
Results: An important decrease in pancreas graft thrombosis was found in Group 2 (17,9% vs 5,6%, p = 0,167); as well as a reduction in renal thrombosis (7,1% vs 5,6%, p = 0,817). We report higher hemorrhagic complications in Group 2 (28,5% vs 38,9%, p = 0,262): one gastrointestinal hemorrhage, one hemorrhage from the surgical incision and twelve hemoperitoneum; of these 64.3% (n = 9) required exploratory laparotomy. The median day of hemorrhage was similar in both groups (2 vs 4, p = 0,111). Median number of overall packed red blood cells transfusion was comparable (3,5 vs 2,0, p = 0,334), however, blood transfusions were significantly higher in the first 24 h in Group 1 (1,63 vs 0,57, p = 0,044) and in day four in Group 2 (0,00 vs 0,41, p = 0,001). We documented a relevant increase in pancreas graft survival (73,9% vs 87,5%, p = 0,641), and similar renal graft survival (88,2% vs 91,7%, p = 0,369). Hospital mortality was similar between the two groups.
Conclusions: Given the intrinsically low parenchymal microvasculature flow of the pancreas and the hypercoagulable state of the diabetic recipient, these patients are at a higher risk of graft thrombosis than other abdominal organ transplants. Currently there is no standardized protocol for the prevention of graft thrombosis, but it is believed most transplant centers use some form of anticoagulation. In spite of the increased number of hemorrhagic complications, our results demonstrate the effect of UFH on improving graft survival which is in line with published literature.

Hepatorenal syndrome in patients with acute-on-chronic liver failure: are we identifying it correctly?

J. Henriques[1], M. Batista[1], M. Barbosa[1], T. Isidoro Duarte[1], T. Sequeira[1], N. Germano[1]
[1]Intensive Care Medicine Department, Hospital Curry Cabral, Lisboa, Portugal
Correspondence: J. Henriques

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**0001228

Introduction: Acute-on-chronic liver failure (ACLF) is a serious condition defined as acute hepatic decompensation, which develops in patients with cirrhosis, leading to multiorgan failure, and high risk of short-term mortality. (1) Among these patients, there is a high prevalence of acute kidney injury (AKI), and it is important to classify it by cause, as it has prognostic implications. (2) Hepatorenal syndrome (HRS) is one of the phenotypes of AKI in these patients and its prognosis remains poor without liver transplantation. (3) In recent years, classification, nomenclature, diagnostic criteria and pathogenic theories regarding HRS have evolved. (4) However, stablishing the diagnosis of HRS in clinical practice is not always easy and it seems to be hard to distinguish it from other forms of AKI.
Objectives: To determine the prevalence of HRS in patients with ACLF by revaluating the diagnostic criteria.
Methods: We retrospectively studied patients with ACLF admitted in intensive care unit (ICU) at a reference centre on liver transplantation. Clinical files from the past four years were reviewed, and patients who had had the diagnosis of HRS as main cause for ACLF were characterized according to its severity, necessity of renal replacement therapy and survival, and distinguished from other causes of AKI by applying the new International Ascites Club criteria for HRS. (4) Demographic, confounding and outcome variables were collected.
Results: A total of 63 patients with ACLF were enrolled, 72,5% males, with a mean age of 55,3 years old. Eleven patients (17,6%) were initially reported to present with HRS as decompensation for ACLF; however, after revising the data, only 5 (7,8%) patients fit the criteria for diagnosis of HRS. Among these, 4 patients were classified as HRS-AKI (KDIGO criteria AKI-1 25%; AKI-2 50%; AKI-3 25%), and 1 as HRS-CKD. Two patients received albumin and terlipressin; 3 had renal replacement therapy; and 3 underwent liver transplant.
Although there were no differences in terms of severity of ACLF between patients with HRS and patients with other phenotypes of AKI (mean CLIF-SOFA 56,7 VS 56,8), the mortality was inferior in patients with HRS (20% VS 40%).
Conclusions: In this series of patients with ACLF, HRS was overdiagnosed. The severity of ACLF did not differ between other phenotypes of AKI and HRS, and the mortality rate was higher in patients who could not fit the criteria for HRS. These data differ from the literature, which could be explained by the low number of patients with HRS and the high proportion receiving liver transplant.

Exploring the experiential perspectives of nurses to understand the complexity of early recognition of sepsis

M. Nemeckova[1], T. Conner[2], A. Steven[3]

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001229

Introduction: Sepsis is a common but often unrecognised life-threatening condition associated with high mortality (Rudd et al., 2020). Early detection is associated with improved outcomes, but this is hindered by a lack of universally accepted diagnostic criteria and heterogeneous and difficult-to-recognise presentations of sepsis (Gauer, 2013, Vincent, 2016). The approach to early recognition of sepsis, while shaped in some part by protocols, is often in the hands of nurses caring for ill patients (Harley et al., 2019, Kleinpell et al., 2019).
Objectives: This study examined the experiential perspectives of nurses to understand the complexity of early recognition of sepsis.
Methods: Semi-structured interviews were performed with 26 nurses from various hospital settings, including intensive care, medical, surgical, research, oncology, neurosurgery, sepsis and practice development departments. The phenomenographic method was utilised to analyse the interviews (Åkerlind, 2005). Findings were arranged into categories based on the Cynefin Framework (Snowden and Boone, 2007).
Results: The findings revealed that recognising sepsis happened in various clinical contexts. The variability provided a direction for clinical decision-making, enabling the nurses to adapt the approach according to the specific context. When dealing with a clear disease pattern, nurses followed rules from a protocol to draw conclusions and determine actions. However, protocol-based care assumes single pathways, and in more complicated contexts, there was much more diversity than implied by protocols. Therefore, here nurses adopted an analytical approach. However, the approach implies knowable cause-and-effect relationships and the possibility of assigning probabilities to outcomes, but in complex contexts, there was much more unpredictability than the approach allowed for. Here, nurses adopted a more individualised approach, allowing nurses to adapt recommended care according to the individualised patient needs. This approach appeared more complex and labour-intensive, requiring an understanding of the clinical implications of the disease and contextual aspects, yet it provided a basic foundation for clinical reasoning in the most severely ill patients in intensive care.
Conclusions: Our findings suggest that sepsis recognition, as we know it, in which one set of criteria is applied to a huge spectrum of clinical situations without consideration for heterogeneous populations of patients with sepsis, may be of limited value. We recommend that sepsis criteria remain an important point of departure but are no longer the only one. Rather, progressing toward a context-specific approach to sepsis recognition that takes advantage of a series of strategies may be more relevant. This approach demands flexibility, adaptability and educational support; however, unless we support nurses in learning to adapt strategies in a more context-specific manner, a significant development in sepsis recognition might not be seen.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001230

Introduction: COVID-19 is a highly inflammatory disease which can lead to acute respiratory distress syndrome (ARDS). Angiotensin converting enzyme 2 (ACE-2) enables cellular entry of SARS-CoV2 and converts angiotensin (Ang) II into Ang (1–7). Ang (1–7) antagonizes the inflammatory effects of the ANG-II-AT1R axis with protective downstream effects via the Mas-receptor (MasR).

Objectives: To analyse the Ang (1–7) levels in BAL fluid of ARDS patients and to analyse the potential of ACE2 overexpression and Ang (1–7) in HEK293T cells and air–liquid-interface (ALI) cultures to inhibit inflammasome activiation.

Methods: HEK-293 T-Cells and air–liquid-interface (ALI) cultures together with U937 monocytes were cultured and stimulated with 10^-5 M Ang-II, 10^-5 M Ang (1–7) and 10^5 M A779 (a MasR inhibitor) over night. Inflammasome activation was done via 10^-6 M LPS and 10^-5 M nigericin. ACE2 overexpression in HEK293T cells and ALI-cultures was achieved via lentiviral vector transduction. IL-1ß and Ang (1–7) concentrations were measured via ELISA in the supernatants and bronchoalveolar lavage-fluid from ARDS patients with different underlying diseases.

Results: Ang (1–7) was markedly reduced in BAL fluid in ARDS patients due to COVID-19 and other viral and bacterial pathogens and indirect ARDS compared to healthy volunteers. Lower Ang (1–7) BAL fluid levels were also associated with 28-day mortality ($p = 0.018$). In cell-cultures, HEK293T and ALI co-cultures (with U937-cells) inflammasome induction could be induced. ACE2 overexpression lead to a reduction in IL-1ß levels in both HEK293T ($p < 0.001$) and ALI co-cultures ($p = 0.0165$). Treatment with Ang (1–7) lead to a marked reduction of IL-1ß levels in HEK293T ($p < 0.001$) and ALI co-cultures ($p = 0.01$) regardless of ACE-2 overexpression. ACE2 overexpression however increased the endogeneous production of Ang (1–7) following inflammasome activation. These effects were reversed by inhibition of the MasR (Ang-1–7-receptor) with increased levels of IL-1ß in both HEK293T and ALI co-cultures.

Conclusions: We show that IL-1ß due to inflammasome activation can be down-regulated via Ang (1–7). Endogeneous production of Ang (1–7) was increased with ACE-2 overexpression. Blockage of the MasR (Ang[1–7]-receptor) completely reversed the protective effect of Ang (1–7). Lower Ang (1–7) levels in ARDS patients were associated with mortality in COVID-19 patients. Thus, MasR agonists might be a potential treatment in a subgroup of ARDS patients.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001231

Introduction: Obesity as become an epidemic issue with associated healthcare burden and this particular form of malnutrition is now frequently observed in the intensive care setting. Adequate nutritional support is challenging in critically ill patients, especially those with obesity, since energy needs have normally been calculated through predictive formulas based on body weight underestimating patient´s needs.

Indirect calorimetry (IC) is regarded as the preferable means to determine resting energy expenditure (REE) by the European Society for Parenteral and Enteral Nutrition but it´s still not universally available, predisposing to inadequate nutritional support (underfeeding < 70% of REE and overfeeding > 110% of REE). In obese patients REE measurements have the best potential to accurately characterize the metabolic situation.

Objectives: The aim of our study was to assess how IC could improve nutritional evaluation and support in obese critical care patients, with a body mass index (BMI) > 30 kg/m2, from a mixed intensive care unit.

Methods: Comparative analysis of 41 critically ill obese patients REE, calculated through the simplified formula of 25 kcal/kg/day with the measured by IC, from a total sample of 127 intensive care patients. Adequate energetic support was considered when < 70% of REE measured by calorimetry in the acute phase—first three days of intensive care unit (ICU) and 70–110% from fourth day on.

Results: Obese patients presented a mean BMI of $35{,}8 \pm 5{,}7$ kg/m2, with mean APACHE score $23{,}32 \pm 7{,}7$ and SAPS score $52{,}98 \pm 16{,}6$. The majority, 22 patients (53,7%), had a medical cause for admission, 13 surgical and 6 had trauma. There were 21 male patients (51,2%) and a mean age of $67{,}5 \pm 13{,}1$ years old.

The mean REE calculated by the formula was $1493{,}29 \pm 318{,}76$ kcal/day and the one measured by IC was $1609{,}37 \pm 388{,}62$ kcal/day, with poor statistical correlation between both. Previously to IC introduction the administered caloric intake was $1098{,}24 \pm 439{,}51$ kcal/day. Of the 7 patients evaluated by IC in the acute phase, 2 (28,5%) were in overfeeding. After the fourth day in ICU: 16 patients (47%) were in underfeeding and 5 (14,7%) in overfeeding. From the total 127 patients, in the acute phase 38,9% were overfeeding and after day 4 of ICU stay 36,3% were underfeeding and 12,1% overfeeding.

Conclusions: Energy expenditure measured by gold standard—IC was different from the predictive formula of 25 kcal/kg/day in the obese patients, where the adjusted body weight tends to either over or underestimate energetic needs. The low accuracy of predictive equations led to overfeeding in almost a third (28,5%) of obese patients in the acute phase, comparing with the greater proportion in the total sample and underfeeding of almost half (47%) in the subsequent phase, comparing with the smaller proportion of underfed patients in the total sample. Predictive formula of 25 kcal/kg/day should not be used to estimate REE of obese critically ill patients for its hazard of over or underfeeding.

Diagnosis and risk factors of nosocomial Fungal infections in COVID 19 critically ill patients

H. Yahyaoui[1], H. D. Hamdi[1], B. F. Nebiha[1]
[1]Intensive care departement, Hôpital Habib Thameur, Tunis, Tunisia
Correspondence: H. Yahyaoui
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001234

Introduction: The new coronavirus, SARS COV 2, is causing, in the most severe cases, an acute respiratory distress syndrome which requires prolonged hospitalization in intensive care units. In these critical patients, the incidence of nosocomial infections and particularly fungal infections (FNI) has been reported as important factor of morbidity and mortality.
Objectives: To describe the epidemiological, biological and microbiological features of FNI and to search for risk factors to their occurrence.
Methods: The study was descriptive, retrospective and monocentric, including patients admitted for at least 48 h to the medical intensive care unit for SARS COV 2 infection during the period from 01/09/2020 to 30/06/2022. Demographic, clinical, microbiological, therapeutic data and outcomes were collected.
Results: We enrolled 450 patients. The mean age was 64.2 years ± 15 and the sex ratio was 1.14. One hundred and ninety-two (42.7%) patients were diabetic and 211 (46.9%) had hypertension. Weight was measured in 139 cases and the mean body mass index was 28.8 ± 5.7 kg/m2. The median IGSII, APACHE II and SOFA scores at admission were respectively 28 [22–33], 7 [6–10] and 3 [2–4]. NFI occurred in 71 patients with a total number of 75 episodes and a median time to occur of 10 days [7–13].
The NFI was diagnosed with a positive colonization index (CI) and a high candida score in 49 cases (with a median of candida score of 3 [3–4]), a positive urinary culture in 13 cases,, a positive mannan antigenemia in 10 cases,, a positive blood cultures in 2 cases and a positive protected tracheal sample in one case. The most frequently isolated candida was C.albicans (79%), C.Krusei (16%) and C.glabrata (5%).
According to the antifungigram, sixty-nine patients were treated with voriconazole and two with fluconazol. Length of stay had a median of 10 days [6–14]. Mortality in INF group was 94.4% ($p < 10–3$).
In multivariate analysis, the occurrence of NFI was significantly associated with previous antibiotic therapy (< 6 mois) (OR:2.8; 95% CI: 1.1–6.8; $p < 10–3$), severe ARDS (OR:7; 95% CI: 1.9–25.8; $p < 10–3$), venous central catheterization (OR:9.7; 95% CI: 3.2–29.5; $p < 10–3$), urinary catheterization (OR:41; 95% CI: 5.2–324.1; $p < 10–3$) and parenteral nutrition (OR:7.7; 95% CI: 1.6–35.9; $p = 0.009$).
Conclusions: **F**ungal infection in patients admitted for ARDS at Covid-19 is frequent. It affects the most critical patients and should be investigated early. However, larger studies are needed to confirm this finding.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**0001235

Introduction: Status epilepticus (SE) has a higher rate of morbidity and mortality. Factors influencing patients' outcomes are weakly understood.
Objectives: Our study aimed to describe initial patterns and to identify morbidity and mortality risk factors in patients with SE.
Methods: We conducted a monocentric retrospective study including patients admitted with SE from January 2018 to December 2022 in ICU. We made the diagnosis according to the formalised expert recommendations of 2018. We evaluated initial data and analysed morbidity and mortality predictors.
Results: Eighty patients with SE were enrolled with a median age = 53 years. 82.5% of patients were male. 37.5% of cases had a past history of epilepsy. The mean APACHE II and SAPS II scores were respectively 18 ± 2 and 37 ± 4. Seizures were generalized tonic–clonic in 87.2%. Main etiologies were: cerebrovascular accidents (hemorrhagic stroke in 21.7% and ischemic stroke in 10.9%); switching off the epileptic drug (19.6%), encephalitis (10.9%); cerebral venous thrombosis (6.5%); acute poisoning (6.8%) and metabolic abnormalities (2.2%). Invasive mechanical ventilation and neurosedation were needed in 76.2% of patients. ICU length of stay was 13 ± 22 days [1–132]. ICU mortality was 23.7%. In univariate analysis, mortality risk factors were age (50.6 vs 64 years, $p = 0.039$), intubation (0% vs 30%; $p = 0.03$), hemodynamic instability (6.8% vs 50%; $p = 0.001$) and nosocomial infection (12.9% vs 43.7%; $p = 0.024$). Independent mortality risk factors were age > 50 years (OR = 10.2 IC 95% [3.5–66.3], $p = 0.03$) and invasive mechanical ventilation (OR = 4.54 IC 95% [3.24–10], $p = 0.03$).
Conclusions: Patients with status epilepticus have a median age of 53 years and a male sex. Cerebrovascular disease was the most etiology of status epilepticus. ICU length of stay and mortality are high. Age and mechanical ventilation requirement are the mortality risk factors.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001236

Introduction: In the last decades, there has been a progressive increase in average life expectancy. Indeed, recent studies estimate an increase of habitants in Europe older than 80 years from 6% in 2018 to 12% in 20,501, expecting an increase in older patients needing intensive care unit (ICU)2. These patients present decreased physiologic reserves and more frailty, a challenge in recovering from critical illness 2,3, altering the Quality of Life (QoL) of those discharged from the ICU3. Therefore, progressive concern has been raised on management of very old intensive care patients (VIPs), regarding not only their mortality but their level of fitness or frailty and QoL after discharge from the ICU.
Objectives: To evaluate if ICU admission of VIPs had a significant impact on their level of fitness or frailty and QoL.
Methods: A retrospective study was conducted, collecting data from very old (≥ 80 years) patients admitted between January 2017 and June 2022. Data was collected between October and November 2022. Gender, length of stay, CFS before ICU admission, age-adjusted Charlson Comorbidity Index (CCI), SAPS II, need for ventilation, vasoactive drugs or renal replacement therapy and whether limitations of treatment were established during ICU stay were also collected. In addition, Clinical Frailty Score (CFS) after ICU discharge and EQ-5D-3L questionnaires after discharge were obtained for patients who had been admitted to the ICU between January and June of 2022.
Results: We included 245 VIPs, with a median age of 83 years old (P25-P75 81–85) and predominance of the male gender (57.6%). The mean length of stay was 4.4 ± 4.3 days. The mean SAPS II was 44.8 ± 13.7. ICU mortality was 26.1% and 49,4% of VIPs remained alive at the time of data collecting. Inregards to CFS and EQ-5D-3L questionnaires after ICU discharge, we included 19 VIPs from the establishedtime period. We observed that VIPs had higher CFS after ICU admission (mean CFS 3 vs 5, before vs after), however CFS remained unaltered in 42.1% of VIPs. Most VIPs reported at least a moderate impact on mobility and self-care (68.4% and 47.4% respectively). Anxiety & depression, usual activities and pain & discomfort were less affected (42.1%, 36.8% and

36.8% respectively). More than 90% of the patients reported a perceived health status higher than 50% of what they considered to be the best imaginable. When questioned about their QoL after admission in ICU, 21% of VIPs reported an improvement, 36.8% had the same health status and 42.1% reported a deterioration.
Conclusions: More than 40% of VIPs remain functionally unaltered after discharge from ICU, revealing a potential benefit from ICU admission. Mobility and self-care were the most affected domains on EQ-5D questionnaire. Although most VIPs had a functional decline after discharge, some patients reported an improvement in their QoL. Since quality of life is a subjective issue, admission to the ICU possibly changed their expectations and, as such, their perspective on quality of life, at least not worsening their health status in more than half of the patients.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001237

Introduction: Pupillary examination, in particular pupillary reactivity to light, is fundamental for the monitoring and daily follow-up in acute brain injury patients in intensive care units (ICU). As a matter of fact, intracranial pressure monitoring and pupillometry measurement are part of daily care of brain-injured patients in some ICUs.
Pupillometric indices combining different parameters of the pupillary light reflex has been described that has predictive value for intracranial hypertension and neurologic outcome, depending on the device, these two indices are known as NPi, proposed by Neuroptics, and QPi, proposed by IdMed, based on a statistical classification of the amplitude of the photomotor reflex.
Objectives: The objetive of this pilot study is to explore whether the QPi is equivalent to the NPi in patients with acute brain injury (TBI, SAH and ICH and post-cardiac arrest hypoxic-ischaemic encephalopathy).
To assess whether the parameters exploring the pupillary reactivity to light of both devices are equivalent.
Methods: A prospective, observational, pilot study was conducted in patients with acute brain injury (TBI, SAH and ICH and post-cardiac arrest hypoxic-ischaemic encephalopathy), consecutively admitted to our Intensive Care Department. All patients were in coma, with deep sedation. Isolated pupillometry measurements were performed sequentially by two investigators, blinded to the comparative examination, with two different pupillometers (NPi-200 and Neurolight). Demographic, clinical, and therapeutic variables were collected for all patients during ICU admission. A third researcher analyzed the results, using IBM SPSS Statistics, version 27.0. The percentage of observed agreement was calculated for all the categorical and dichotomous variables. The reproducibility of all measurements was evaluated by calculating the unweighted Cohen's kappa coefficient (κ) for measurements with dichotomous results and the weighted Cohen's kappa coefficient for measurements with multiple, ordinal answer options. All κ coefficients and ICC values were interpreted according to Landis and Koch; values between 0.01 and 0.20 were considered to indicate slight agreement, values between 0.21 and 0.40 to indicate fair agreement, values between 0.41 and 0.60 to indicate moderate agreement, values between 0.61 and 0.80 to indicate substantial agreement, and values between 0.81 and 1.00 to indicate almost perfect agreement.
Results: From December 2022 to March 2023, in our study, we included 53 patients (ICH 43%; SAH 32%; Post-cardiac arrest 15%; TBI 10%) and performed 86 measurements. Among them, 60% were male, with mean age 61 (±13), the mean GCS at admission was 7. We recorded 21 ICP measurements, with mean ICP of 10 mmHg.
Among pupillometry indices, we found a strong correlation between QPi and NPi (k 0.83; $p = < 0.001$), as well with pupillary light reflex variables (Var Neurolight and CH NPi-200, respectively) with substantial agreement (k 0.81; $p = < 0.001$).
Conclusions: In our pilot study, we found a strong (substantial) correlation between NPi and QPi, as well with pupillary light reflex variables (Var and CH), which nowadays are considered the most robust variables to assess neurologic outcome, based on NPi-200 studies.
Forward studies are needed to determine the equivalence among the two pupillometers to assess the neurologic outcome among acute brain injury patients with different ethiologies.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001238

Introduction: Infective endocarditis is a rare condition. Its incidence has increased due to the number of elderly patients with chronic diseases and intra-cardiac devices and the increase in intravenous drug abuse. Its diagnosis in the emergency department remains a challenge and its delayed diagnosis can lead to many serious complications.
Objectives: The aim of our study was to describe the clinical, microbiological, echographic, and evolutionary features of patients admitted to the emergency department for infective endocarditis.
Methods: This was a retrospective descriptive study including patients admitted to the emergency and medical intensive care unit between January 1, 2019 and December 1, 2022. We collected clinical, paraclinical, therapeutic and evolutionary data.
Results: We collected 10 patients admitted for infective endocarditis. The median age was 51 years [30–74]. The sex ratio was 9. Four patients had a history of intravenous drug use, one of whom had viral hepatitis C and three patients had renal failure at the hemodialysis stage. Blood cultures were positive in 8 patients. Four were staphylococcus, three were enterococcus and one was bacillus cereus. All patients had infective endocarditis on a native valve. Echocardiography was contributory in all cases and showed vegetation. Four patients had tricuspid valve involvement (three of whom were intravenous drug users), three had mitral valve involvement and three had aortic valve involvement. Six patients had at least one secondary infectious location. Only one patient had an indication for an urgent surgical treatment, it was a doubt about a perforation of the mitral valve pillar at the control echography performed at the 38th day of hospitalization and indicated by the non improvement under antibiotic therapy. The median length of stay in the emergency department was 5 days [3–19]. Three patients died, two of them during their hospitalization and one patient who consulted after a relapse. All three patients had endocarditis on the mitral valve.
Conclusions: Infective endocarditis on the native valve is a rare disease but it has a high mortality rate of 30%. Contributory investigations such as blood cultures and echocardiography remain the key

steps of the diagnosis and must be performed early. Management is multidisciplinary and surgical indications are still rare.

Early-onset versus late-onset ventilator associated pneumonia among severe COVID-19 related ARDS patients

M. Zghidi[1], R. Toumi[1], K. Meddeb[1], E. Ennouri[1], I. Ben Saida[1], M. Boussarsar[1]
[1]Farhat Hached Hospital, Medical Intensive Care Unit, Université de Sousse, Faculté de Médecine de Sousse, UR N° LR12SP09.Heart Failure, Sousse, Tunisia
Correspondence: M. Zghidi
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001239

Introduction: The pandemic of coronavirus disease 2019 (covid19) has resulted in high rates of hospitalization in intensive care units (ICU) with widespread use of invasive mechanical ventilation (IMV) which exposes patients to the risk of ventilator-associatedpneumonia (VAP). VAP is classified as early-onset (EVAP) or late-onset VAP (LVAP) (1).
Objectives: To compare patients with EVAP to those with LVAP and to identify its potential risk factors.
Methods: This was a retrospective study of patients hospitalized with severe COVID-19 from March 2020 to December 2021, in a medical intensive care unit who required mechanical ventilation for more than 48 h. VAP was identified by using a combination of imaging, clinical and laboratory criteria. The cut off point definition was $\leq$6 days for E-VAP and > six days for L-VAP (2). Univariate analysis and multivariable logistic regression were used to analyze the associated factors with EVAP and LVAP.
Results: 732 patients were admitted to the ICU, 465 (63.5%) had a confirmed COVID-19 infection, 247 (53.1%) required IMVand met the inclusion criteria. Patients' characteristics were: mean age, 65 $\pm$ 12 years; Median pre-ICU management delay, 4[3–7] days; Median SAPSII on admission, 31[26–38]; Median IMV duration, 10[7–16]; Median length-of-stay was at 12[7–17] days. The overall mortality rate was 84.6%.
Overall, 45 (18.2%) patients developed VAP with density incidence rate estimated at 18 VAP/1000 ventilator days. EVAP was observed in 15 patients (33.3%), whereas 30 patients (66.7%) developed LVAP. Patients with EVAP had longer pre-ICU management delay (5[2–6] vs 4[2–5], p = 0.030) and lower SAPSII on admission (26[22–31] vs 31[27–35], p = 0.020). The most frequently isolated organism in EVAP was *Pseudomonas aeruginosa,* 6 (40%) followed by *Acinetobacter baumannii* 5 (30%) and *Klebsiella Pneumonia*, 3 (20%).
Acinetobacter baumannii 19 (63.3%), *Pseudomonas aeruginosa,* 10 (30.3%), *Klebsiella Pneumonia*, 6 (20%) and *Staphylococcus aureus, 3 (7.5%)* were the most common pathogens associated with LVAP.
There were no significant differences between the two groups in the ICU length of stay (EVAP,13[9–22] vs LVAP, 13.5[10–18.5], p = 0.381), IMV duration (EVAP,10[7–13] vs LVAP,10.5[6.75–16.25], p = 0.073) and mortality rate (EVAP,12 (80%)vs LVAP,27 (90%), p = 0.364).
The only risk factor independently associated with EVAP was pre-ICU management delay (RR, 1.15; 95%CI, [1.04–2.27]; p = 0.026). Diabetes (RR, 1.7; 95%CI, [1.5–5.6]; p = 0.03) and high SAPSII on admission (RR, 1.09; 95%CI, [1.02–2.9]; p = 0.020) were risk factors independently associated with LVAP.
Conclusions: Both early-onset and late-onset VAP were associated with increased hospital mortality rate and prolonged length of stay. Pre-ICU management delay was risk factor independently associated with EVAP. Diabetes and high SAPSII on admission were risk factors independently associated with LVAP.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001241

Introduction: Pulse oximetry (PO) is a non invasive method measuring peripheral oxygen saturation in critically ill patients. Its outcomes depend on cardio-respiratory activity which can be evaluated using the pulse respiratory quotient (PRQ). The aim of our study was to evaluate the use of PRQ to predict PO fiability.
Methods: We conducted a prospective study of adults admitted to the intensive care unit from October 2022 to March 2023. Epidemiological, clinical, biological and therapeutic features were collected. PRQ was calculated by dividing the heart rate (HR) by the respiratory rate (RR). The measurement of pulse oxygen saturation (SpO2) will be made by a pulse oximeter and will be followed immediately by the realization of an arterial blood gas sample (by an arterial puncture or by a blood sample by the arterial catheter). DeltaSpo2 (Spo2-Sao2) will be calculated and analyzed according to PRQ.
Results: Two hundred and six measurements for 57 patients were enrolled. The sex-ratio was 1.19. At admission, 51 patients (89.4%) had acute respiratory failure, 24 (42.1%) had neurological distress and 10 (17.5%) had hemodynamic instability. The median IGSII, APACHEII and Sofa scores were respectively 29 [23–38], 13 [9–17] and 3 [2–5]. Median PRQ was 4.2 [3.4–5.3]. Our analysis concluded that delta SPO2 was negatively correlated with PRQ (spearman's rho = -0.141 and p = 0.044) (Figure 1).
Thirty six essays had delta SpO2 > -2 which was associated with a PRQ $\geq$ 5 (p = 0.003).
Conclusions: Delta SPo2 was correlated with PRQ and the fiability of SpO2 may be estimated by its analysis. For critical patient with a PRQ $\geq$ 5, an evaluation of oxygen saturation with SaO2 is more accurate.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001242

Introduction: Peripheral oxygen saturation (SpO2) is thought to be easier and less painful than direct measurement of arterial oxygen saturation. This arterial measurement can be realized by arterial catheterization or direct arterial puncture. However, SpO2 often underestimates arterial oxygen saturation (SaO2).
Objectives: We aimed to compare the difference between SpO2 and SaO2 (Delta SpO2) according to method of blood sampling (radial puncture and arterial catheterization).
Methods: We conducted a prospective study of adults admitted to the intensive care unit from October 2022 to March 2023. Epidemiological, clinical, biological and therapeutic features were collected. Patients were divided into two groups; group 1 (G1): arterial oxygen saturation measurement by arterial puncture and group 2 (G2): arterial oxygen saturation measurement by arterial catheterization. In all patients, the measurement of pulse oxygen saturation (SpO2) will be made by a pulse oximeter followed immediately by the realization of an arterial blood gas sample (by an arterial puncture (G1) or by a blood sample by the arterial catheter (G2)). DeltaSpo2 (Spo2-Sao2) was calculated and analyzed according to groups.
Results: Two hundred and six measurements for 57 patients were enrolled. The sex-ratio was 1.19. At admission, 51 patients (89.4%) had acute respiratory failure, 24 (42.1%) had neurological distress and 10 (17.5%) had hemodynamic instability. The mean IGSII, APACHEII and Sofa scores were respectively 29 [23–38], 13 [9–17] and 3 [2–5]. The comparison between the 2 groups objective that G2 was more critical (Table 1).
Forty (19.4%) assays were realised on patients under vaso-active drugs including 32 (80%) in G2. The total of 206 assays were divided into 172 (83.5%) measurements for G1 and 34 (16.5%) for G2. The gazometric features are detailed in Table 2.
Mean delta SpO2 was 1 [(-1.5)-1] for G1 and–2 [(-4)- (-2)] for G2. Sixty three assays had delta SpO2 > 4 or < -4. This assays were significantly more frequent in G2 (p = 0,043).
Conclusions: Mean delta SpO2 was 1 [(-1.5)-1] for G1 and–2 [(-4)- (-2)] for G2. Sixty three assays had delta SpO2 > 4 or < -4. This assays were significantly more frequent in G2 (p = 0,043).

Table 1: Comparaison of severity scores between the 2 groups.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001246

Introduction: Critically ill patients require close monitoring of blood oxygen saturation. Although the measurement of oxygen saturation in the arterial blood (SaO2) is the gold standard, pulse oximetry is a monitoring noninvasive tool used to clinically assess peripheral oxygen saturation (SpO2) and to guide therapeutic interventions. This technique is widely used, particularly in intensive care units.
Objectives: To evaluate the accuracy of pulse oximetry (SpO2) in critically ill patients.
Methods: This is a monocentric, evaluative, prospective and comparative study including patients admitted in an ICU department from December 12, 2022 to February 09, 2023. Demographic, clinical, biological and therapeutic data were collected. Pulse oxygen saturation measurement was performed in all patients at the level of the middle finger of the right hand. The measurement of pulse oxygen saturation was made by a pulse oximeter of the monitor. The measurement was followed immediately by the realization of an arterial blood gas sample (by an arterial puncture or by a blood sample by the arterial catheter). DeltaSpo2 (Spo2-Sao2) was calculated and analyzed to identify associated factor's variations.
Results: Two hundred and six measurements for 57 patients were enrolled. The sex-ratio was 1.19. Among this population, 30 (52.6%) had chronic respiratory failure which 16 (28%) were COPD, 23 (40.3%) had HTA, 22 (38.6%) had diabetes and 21 (36.8%) cardiac failure. At admission, 51 patients (89.4%) had acute respiratory failure, 24 (42.1%) had neurological distress and 10 (17.5%) had hemodynamic instability. The mean IGSII, APACHEII and Sofa scores were respectively 29 [23–38], 13 [9–17] and 3 [2–5].
Thirty-four ABG's (16,5%) were collected by arterial catheter and 172 (83,5%) by arterial punction.
An arrythmia was present during 66 measurements (32%) and forty (19.4%) assays were realised on patients under vaso-active drugs.
The median of temperature, respiratory rate and heart rate were respectively 37.2 [36.8–37.9], 24 [20–28] and 104 [90–116].
The median of vaso-active drug dose and oxygen inspiratory fraction were respectively 3mg/h [1–4] and 0,4 [0,35–0,6].
The analysis of ABG's showed that the median PH, PaO2, PACO2, bicarbonate, SaO2, SPO2 and PaO2/Fio2 ratio were respectively 7.39 [7.29–7.47], 83.5 [66–111], 41 [35–56], 26.4 [21.8–32], 96% [93–98], 96% [94–98] and 196 [140–280]Delta SPO2 (SpO2-Sa02) had a median of zero % [(-2)-3]. Thus, delta SpO2 > ±4% was found in 40 assays.
PaO2 < 68 mmHg was an independent risk factor for overestimating SpO2 (delta SpO2 > 4) with p = 10–3 (OR = 26 CI 95% [8.8–81.6]).
Shock was an independent risk factor for underestimating SPO2 (deltaSPO2 > -4%) P < 10–3,
(OR = 9.5, IC = 95%, [2.2–40]).
Conclusions: When estimated by pulse oximetry, oxygen saturation is overestimated in patients with hypoxemia and underestimated in patients with shock. SpO2 assessment must be realized according to other clinical and biological parameters.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001248

Introduction: SARS COV 2 infection is essentially manifested by a respiratory form that can, in severe forms, evolve to an Adult respiratory distress syndrome (ARDS). In parallel, there are other manifestations, such as pulmonary embolism, reported especially in critically ill patients.
Objectives: To describe clinical characteristics and outcomes of pulmonary embolism in COVID 19 critically ill patients.

Methods: Descriptive, retrospective and monocentric study including all patients admitted in ICU department for at least 48 h between 01/09/2020 and 30/06/2022. All patient's data including demographics, clinical, biological, radiological and outcomes were taken from patient's medical files.
Results: 450 patients infected by the SARS COV 2 were included. Sex ratio was 1.14 and mean age was 63 ± 15.
46.8% and 42.6% of patients had respectively arterial hypertension and diabetes mellitus and 51% had obesity. Mean SAPSII, APACHEII and SOFA score were respectively 30 ± 39, 30 ± 39 and $8{,}6 \pm 5$.
Mean DDimer at admission was: $3049 \pm 10{,}090$ ng/ul.
At admission or during their stay, 47 patients (10.4%) presented a pulmonary embolism (44 at admission).
All patients were initially taking venous thromboembolism (VTE) prophylaxis by low-molecular-weight heparin (LMWH) as recommended. All patients were treated by curative doses of LMWH and three patients, who presented a proximal bilateral PE, were treated by a successful thrombolysis with streptokinase.
D-dimers rate above 1200 µg/l and delay of admission > 12 days were reported as factors associated to thromboembolism events (respectively $P < 10–3$ and $p = 0.045$).
Pulmonary embolism was associated to sever ARDS (at admission) ($p = 0.046$) and to mortality ($p = 0.035$).
Conclusions: Pulmonary embolism is a frequent complication in COVID 19 critically ill patients who associate numerous risk factors. This complication worsens the prognosis. A clinical follow up and biological monitoring specifically of the D-dimers is primordial to an early diagnosis.

Role of serum ferritin level in predicting short term outcome after moderate to severe traumatic brain injury in correlation to glasgow coma scale

W. Kamshishy[1]
[1]Critical Care Department, Faculty of Medicine Kasr Al-Ainy, Cairo University, Cairo, Egypt
Correspondence: W. Kamshishy
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001249

Introduction: Traumatic brain injury is the most common cause of death and disability among young people. Severe TBI is associated with 30%–70% mortality rate.nevertheless, in clinical practice there are no effective biomarkers for the prediction of fatal outcome following TBI. Therefore, the aim was to determine whether serum ferritin level can be used as a prognostic marker and a predictor for management strategies in patients with traumatic brain injury.
Methods: This prospective cohort study enrolled 60 patients who suffered moderate (GCS 9–12) and severe (GCS 3–8) traumatic brain injury. The serum ferritin level was determined at ICU ad.
Results: High serum ferritin concentrations were significantly associated with low GCS scores, also there was a significant association between high serum ferritin levelsand fatal outcome with values (393 ± 7 ng/ml for non-survivors and 314 ± 35 ng/ml for survivors,respectively. furthermore, ferritin level had significant relation with specific interventions in management as mechanical ventilation, hemodynamic support and neurosurgical.
Conclusions: High serum ferritin level is associated with low GCS scores and fatal outcome in patients with TBI, ferritin level could predict management strategies such as mechanical ventilation, hemodynamic support and neurosurgical intervention in patients with.

2. Acknowledgment First and foremost, I feel always indebted to ALLAH, the Most Kind and Most Merciful. I'd like to express my respectful thanks and profound gratitude to Prof. Dr. Khaled Farouk Ibrahim, Assistant Professor of Critical Care Medicine, Critical care Medicine Department, Cairo University for his keen guidance, kind supervision, valuable advice and continuous encouragement, which made possible the completion of this

work. I am also delighted to express my deepest gratitude and thanks to Dr. Ahmed Kamal Abbas, Lecturer of Critical Care Medicine, Critical Care Department, Cairo University, for his kind care, continuous supervision, valuable instructions, constant help and great assistance throughout this work. I am deeply thankful to Dr. Waleed Farouk Mahmoud, Lecturer of Critical Care Medicine, Critical Care Department, Cairo University, for his great help, active participation and guidance. I would like to express my hearty thanks to all my family for their support till this work was completed. Last but not least my sincere thanks and appreciation to all patients participated in this study. Waleed ElKamshishy

Coagulopathy in onco-hematology patients presenting with septic shock and initial thrombocytopenia: a retrospective observational study

A. Hugerot[1], R. Clere-Jehl[2], V. Castelain[1]
[1]Service de Médecine Intensive Réanimation, Hôpital de Hautepierre-Hôpitaux Universitaires de Strasbourg, Strasbourg, France; [2]Service de réanimation, Nouvel Hôpital Civil-Hôpitaux Universitaires de Strasbourg, Strasbourg, France
Correspondence: A. Hugerot
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001250

Introduction: We studied the coagulation profile, based on routine hemostasis parameters, as well as clinical and biological outcomes of patients with hematologic malignancies hospitalized in the intensive care unit for septic shock with thrombocytopenia.
Methods: All patients admitted to the medical intensive care unit of Hautepierre hospital, Strasbourg, between 2015 and 2020 for septic shock, with thrombocytopenia < 100G/L and an evolving hematological disease were included in this retrospective cohort. For each patient, we collected hemostasis markers (platelets, INR, factor V, fibrinogen, D-dimer, antithrombin) within 24 h following admission, as well as mortality and occurrence of thrombotic or hemorrhagic events during the stay. Univariate and multivariate statistical analysis was performed.
Results: We included 149 patients, aged 58 ± 15 years, with mean SOFA score of 12.8 ± 2.9, respectively. Acute leukemia (45%; n = 67) and non-Hodgkin's lymphoma (38%; n = 57) were the most represented malignancies. Fifty-eight percent of patients required invasive mechanical ventilation (n = 86), and 28% required renal replacement therapy (n = 41). Neutropenia < 0.5 G/L was present in 59% of patients (n = 88). Eighty-six percent of patients (n = 116/135) had DIC according to the ISTH diagnostic score. Severe bleeding was encountered during the stay in 24% of patients (n = 35), and 7% of patients (n = 10) had venous or arterial thrombosis. Intensive care and in-hospital mortality were 46% (n = 68) and 52% (n = 77) respectively. Higher D-dimer, INR, ISTH and JAAM-DIC scores were associated with excess mortality in univariate analysis. High antithrombin activity was associated with the occurrence of severe bleeding events in multivariate analysis.
Conclusions: While confirming some previous data on sepsis-induced coagulopathy, established in patients without onco-haematological pathology, our study enlights a very high bleeding risk in this onco-haematological population, in particular when antithrombin activity is high. Nevertheless, we currently lack relevant diagnostic tools to reliably establish the diagnosis of DIC and to study it in this population, which justifies a prospective study to establish a dedicated diagnostic score, in view of specific therapeutic trials.

Introduction: Despite the lack of high-level evidence, aerosol drug therapy is being used in clinical practices while managing acute respiratory distress syndrome (ARDS) patients.
Objectives: The study aimed to find out the practice pattern of aerosol drug therapy in ARDS patients.
Methods: This study is a secondary analysis of a multicenter, prospective observational cohort study in critically ill patients to know the practice pattern of aerosol drug delivery (AERO-IN-ICU/ED Study), which was conducted after ethics committee approval and registration

with the Clinical Trial Registry of India (CTRI/2022/09/045679). For the primary study, nine participating ICUs screened all adult patients who had received aerosol drug therapy having artificial airways with or without requiring invasive mechanical ventilation (IMV) or non-invasive ventilation (NIV) admitted during the four-week study period. Patients with ARDS were followed-up for 14 days or till ICU discharge (whichever comes first) for details of aerosol therapy, drug type, aerosol-generating device, and its placement in the ventilatory circuit.

Results: During the study period, 1474 patient days were followed in 218 studied patients. Of 218 patients, 53 (24.3%) had ARDS (67.9% due to pulmonary causes) and were followed up for 330 patient days with 193 IMV days and 115 NIV days. Most of these ARDS patients (96.2%) were admitted for medical reasons, 64.1% of the male gender, older age group (60.2 ± 14.76 years) with comorbidities (DM, hypertension, COPD, CAD) in 83.0%, APACHE II, and SOFA score of 17.4 ± 7.08 and 7.7 ± 4.03 respectively. 26 (49.0%) of these ARDS patients had a chronic respiratory disease before ICU admission, and only 21 (39.6%) were on aerosol therapy.

Of 53 patients with ARDS (190 ARDS days), 51 (96.2%; 183 ARDS days) received 1285 aerosols over 6.30 ± 3.96 days of ICU stay. Most aerosols (86.2%) were administered in three centers (out of nine).

Out of 1285 aerosol sessions, 71.4% were given while patients were on IMV (5 aerosols per IMV days; 185 IMV days) and 25.7% on NIV (3 aerosols per NIV day; 115 NIV days). Bronchodilators (70.4%; 60.1% were shorter acting), corticosteroids (21.9%), mucolytics (10.9%), and antibiotics (3.3%) were the most frequently used drugs as aerosol therapy. Jet nebulizers (45.1%) were the most commonly used aerosol generators, followed by ultrasonic (23.1%), venturi-mask nebulizers (18.5%), and oxygen (13.2%). Only 29% (88 out of 304) of aerosol therapy during IMV with jet nebulizers had placed aerosol generators at the optimum position (15 cm from Y-piece).

Conclusions: Aerosol therapy is being used frequently in ARDS patients. Bronchodilators are the most common drug. The jet nebulizer is the most familiar aerosol-generating device, with only one-fourth at the optimum position.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001252

Introduction: The mortality rate of the patients suffered from severe pelvic bone fracture is reported to be 40 ~ 60%. Recently, PPP become The mortality rate of the patients suffered from severe pelvic bone fracture is reported to be 40 ~ 60%. Recently, Preperitoneal pelvic packing (PPP) has shown positive results as a new strategy to decrease exsanguinous mortality for the severely injured pelvic bone fracture. As the mortality of pelvic injury combines many factors, evaluation for the effect of PPP is difficult.

Objectives: This study was designed to evaluate PPP effect based on the 8 year-experience in a level-1 trauma center.

Methods: Between march. 2014 and December. 2021, 151 patients with hemodynamic instability caused by pelvic fracture were enrolled in this study. Using the electrical chart review, the data were collected retrospectively, and the effects of PPP were analyzed through propensity score matching.

Results: Mean age and mean ISS were 61 (49–73) years and 34 (25–38). Mean lactate and initial Hb level were 4,5 (2,8–8.4) and 10.8 (9.1–12.6) g/dL. 51 patients were managed by PPP and the other were not managed by PPP. (Only-resuscitation, angioembolization).

After matching by Propensity score, PPP-group (49 patients) and non-PPP group (49 patients) were compared each other. Other demographics were not significantly different each other. Overall mortality (PPP vs. non-PPP 24 (49%) vs. 19 (38.8%), $p = 0.25$), bleeding-mortality (13 (26.5%) vs. 15 (30.6%), $p = 0.64$), and 28 day-mortality (22 (44.9%) vs. 17 (34.7%), $p = 0.28$) were not different between two groups. PPP group showed a tendency of lower mortality due to bleeding and lower Odd-ratio (OR 0.82, $p = 0.65$) than non-PPP group, however these did not have statistically significance.

Conclusions: In unstable patients with pelvic fracture, PPP does not show the effect definitively to the mortalities yet. Prospective randomized control study is needed to evaluate the effect of PPP.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001255

Introduction: Anticoagulation therapy is necessary during VV ECMO to prevent thrombus formation in the circuit and oxygenator because the contact of blood with an extracorporeal surface and shear stress can trigger activation of the coagulation system. The modality of anticoagulation is still under debate and guidelines do not give clear cut suggestions. However hemorrhagic complications continue to pose serius challenges and the COVID-19 pandemic has further complicated the picture with its pathophysiological increase in the risk of thrombosis.

Objectives: To describe the type of anticoagulation and bleeding events in a cohort of patients undergoing VV ECMO for several causes of acute respiratory failure (ARF) and define the differences on this topic among patients affected with COVID-19 and other causes of ARF.

Methods: Multicenter prospective observational international cohort study of consecutive V-V ECMO patients enrolled by 41 centers in 19 countries from December, 2018, to December, 2020. Patients were divided in two groups according to the presence of COVID-19 infection as a cause of ARF or other causes of ARF. Bleeding episodes were described according to severity with adjusted categories of the Bleeding Academic Research Consortium score. Type 1: requiring heparin infusion rate reduction or packed red blood cells transfusion (PRBC) transfusion; 2: bleeding requiring heparin infusion rate reduction and PRBC transfusion or non-surgical procedure to stop bleeding; 3: life-threatening bleeding that required PRBC transfusion and surgical intervention for control of bleeding or ECMO discontinuation; Type 4: fatal bleeding.

Results: 652 adults under VV ECMO were enrolled, and data of 8471 days on ECMO were analyzed. Among them 218 were affected

with COVID-19 and 434 had other causes of ARF. COVID patients were older [53 (43–60) vs 51 (38–60)], were more frequently males [n 181 (83%) vs 282 (65%)], had higher BMI [29.4 kg/m2 (26.2–35.5) vs 27.8 (24.3–33)] and were on mechanical ventilation for longer prior ECMO [4 days (1.7–6.7) vs 1.5 (0.4–4.2)]; all p values < 0.01.
During the ECMO stay in both groups the most used anticoagulant drug was unfractionated heparin (UFH) [195 patients (89.5%) in the COVID group and 311 (71.7%) in the others] but in the COVID group an initial strategy without anticoagulation was less frequent [14 patients (11.5%) vs 108 (24.9%); p < 0.01. This was confirmed during the ECMO stay since COVID patients were less frequently without any anticoagulant: 560/3619 days (15.5%) vs 1032/4852 days (21.3%), p < 0.01. This was accompanied by higher anticoagulant dose and higher activated partial thromboplastin time (aPTT): 54.9 s (53.1–56.6) vs 49.6 (47.8–51.3); p < 0.01.
Generally, a higher number of COVID patients had at least one episodes of bleeding: 127 (58%) vs 215 (50), p = 0.04; also considering the days on ECMO, COVID group had a significant higher rate of bleeding: 548/3619 days (15%) vs 654/5852 (13.5%), p = 0.03. However, the average of days with bleeding during the ECMO stay was similar between the two groups either includying (14% of days with bleeding in COVID group versus 13% in the Others group, p = 0.58) or excluding patients without any bleeding.
The severity of bleeding episodes was also similar between the groups. COVID group (548 bleeding episodes): Type 1 n 330 (60%), Type 2 n 172 (32), Type 3 n 36 (7); Type 4 n 9 (2); OTHER CAUSES group: Type 1 n 399 (61%), Type 2 n 191 (29), Type 3 n 57 (9); Type 4 n 7 (1); p value = 0.38.
As expected comparing to other series, COVID patients had a longer duration of ECMO support: 20.7 days (18.3–23.1) vs 13.1 (11.7–14.6); p < 0.01.
Finally, patients on VV ECMO for COVID-19 had a worst outcome: lower rate of successful weaning [120 patients (55%) vs 325 patients (75%) in the OTHERS group; p < 0.01.
Conclusions: In two synchronous population of VV ECMO patients for ARF due to COVID-19 or other causes, we confirm that COVID-19 is associated with more bleeding. This tendency is also sustained by the occurrence of prolonged ECMO support.

Physical function measures in ICU survivors, where to now? A scoping review
I. Du Plessis[1], S. Hanekom[1], A. Lupton-Smith[1]
[1]Physiotherapy, Stellenbosch University, Stellenbosch, South Africa
Correspondence: A. Lupton-Smith
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001256

Introduction: There is growing evidence describing the long-term morbidity experienced by critical illness survivors. A major contributing factor to this morbidity is impaired physical function. (Needham et al., 2012; Yuan, Timmins and Thompson, 2021) Consensus is yet to be reached on which physical function measures should be used in this population. (Needham et al. 2017) The heterogeneity and inconsistencies in measurement of physical function in this population makes it difficult for researchers to fully understand and quantify problems in physical function.
Objectives: This review aimed to describe which physically tested measurement instruments have been used in longitudinal studies of critical illness survivors to determine impairments, activity limitations and participation restrictions related to physical functioning.
Methods: A scoping review was conducted using the methodology as per the Joanna Briggs Institute (2015). An electronic database search of EbscoHost, Web of Science and Scopus was conducted from inception to August 2022. Two reviewers independently applied the inclusion and exclusion criteria to all titles, abstracts and articles. Extracted data included year of publication; country; age of participants; follow up timeframes and physical measurement instruments used. Instruments were further classified and coded according to the International Classification of Functioning (ICF).
Results: Sixty four articles published between 1995 and August 2022 were included. Majority of studies arose from high income countries. Thirty-nine different outcome measures were identified and used at variable follow-up intervals (1–60 months). Most studies (52, 81.3%) included multiple follow-up points and were completed within a year, few studies (12, 18,7%) extended beyond a year. Based on the ICF framework, 11 (28.2%) instruments measured impairments and 28 (71.8%) activity limitations. The most frequently measured physical impairment was muscle strength (61, 95.3%), frequently measured with manual muscle testing (30, 46.9%) and/or dynamometry (30, 46.9%). The six minute walk test was the most frequently used instrument in the activity and participation domain, used in 30 (46.9%) studies. Only one (2.5%) instrument addressed all components of the activity/participation domains, majority focused on one aspect, namely mobility. Instruments (3, 7.6%) that addressed several subdomains of activity/participation were seldom used in studies.
Conclusions: Multiple tools are used to report on functional deficits experienced by survivors. The tools measure either impairments or activity/participation limitations. All domains of physical functioning are seldom measured concurrently. Most studies only report on physical function within the first year of survival. Moving forward, consensus is needed on which tools to use to allow for comprehensive understanding of physical functioning in survivors and inform the development of intervention studies.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001257

Introduction: Individuals with severe COVID-19 are at risk of developing prolonged symptoms. Well-performed studies presenting long-term data on mental health and fatigue among patients with critically ill COVID-19 are scarce.

Objectives: To investigate patient-reported symptoms of mental illness and fatigue at 3 and 12 months after critical COVID-19 with respiratory failure, and to describe the dynamics of symptoms during this time. A secondary aim was to investigate risk-factors for post-COVID mental illness and fatigue at 12 months.

Methods: Data from the prospective, multicenter SWECRIT COVID-19 study in southern Sweden was used. For this study patients ≥ 18 years with PCR-confirmed COVID-19 requiring critical care and a P/F-ratio ≤ 40 kPa were included at six intensive care units between May 2020 and May 2021. At 3 and 12 months after acute COVID-19, survivors were invited to a clinical follow-up. Patient-reported symptoms were assessed with the Hospital Anxiety and Depression Scale, the Post-traumatic Stress Disorder Checklist version 5 and the Modified Fatigue Impact Scale. Significant symptoms were identified using established cut-offs and changes were identified by use of reference values for a minimally important difference (MID). Potential risk factors were analyzed by using multivariable logistic regression and included acute disease severity, comorbidities and functional outcome as assessed by the Glasgow Outcome Scale Extended.

Results: 262/301 (87%) survivors participated in the 3-month follow-up and 215/300 (72%) at 12 months. Symptoms of mental illness were common at both 3 and 12 months; anxiety in 33% vs. 28%, depression in 30% vs. 22%, and post-traumatic stress disorder in 17% vs. 13%, with no statistically significant difference between 3 and 12 months (Table 1). Fatigue was the most common symptom on both occasions, 50% vs. 40%, with a statistically significant difference between 3 and 12 months ($p < 0.001$). The improvement in fatigue reached the threshold for a MID (median 38 vs. 33, MID ≥ 4). The dynamics of symptoms are seen in Figure 1. Poorer functional outcome and sleeping difficulties were risk factors for symptoms of mental illness and fatigue at 12 months.

Conclusions: Survivors of critical COVID-19 with respiratory failure commonly experience symptoms of mental illness and fatigue up to 12 months, with a significant improvement in fatigue between 3- and 12-months. Participants reporting poorer functional outcome and less sleep are at particular risk.

Table 1 (abstract 001257) Median score from the questionnaires included in the study and the number of patients who scored at the cut-off or higher in individual questionnaires at 3 and 12 months. Bold text signifies significant value. A p-value < 0.05 was considered significant. IQR, interquartile range. 3M, 3 months. 12M, 12 months. PTSD, post-traumatic stress disorder

Table 1. Patient-reported symptoms 1 year after critical COVID-19 with respiratory failure.

Outcome	Total score 3M median [IQR]	Above cut-off 3M n (%)	Total score 12M median [IQR]	Above cut-off 12M n (%)	Related samples Wilcoxon Signed rank test, p-value
Anxiety	5 [2-9]	75/229 (33)	4 [2-8]	54/193 (28)	.19
Depression	4 [1-9]	68/229 (30)	4 [1-7]	43/193 (22)	.17
PTSD	11 [5-26]	38/220 (17)	10 [4-22]	25/189 (13)	.09
Fatigue	38 [22-53]	115/229 (50)	33 [16-46]	76/190 (40)	**<.001**

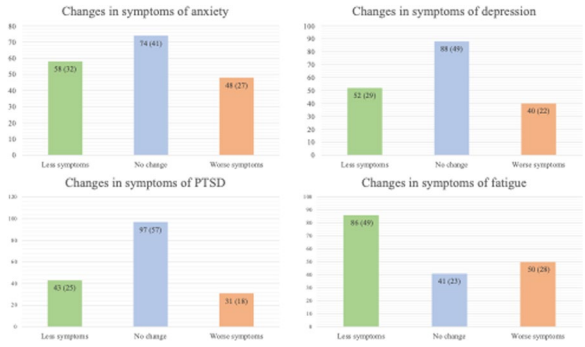

Figure 1 (abstract 001257) Histograms depicting the dynamic of symptoms of mental illness and fatigue between the clinical follow-up at 3 months and 12 months shown as n (%) and categorized by the minimally important difference (MID) in the respective questionnaire. MID for the Hospital Anxiety and Depression Scale: ≥ 2, n = 180. MID for the Post-Traumatic Stress Disorders Checklist: ≥ 6 MID, n = 171. MID for the Modified Fatigue Impact Scale: ≥ 4, n = 177. Abbreviations PTSD, post-traumatic stress disorder

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001259

Introduction: The most effective measure for COVID-19 pandemic containment has been vaccination. All vaccines currently developed have demonstrated their safety and efficacy in preventing new infections, admission to the ICU, and mortality, although their effect on thrombotic events in critically ill patients has not been described.

Objectives: Describe and analyze the incidence of thrombotic complications in vaccinated and not vaccinated patients against COVID-19 admitted to the ICU. Describe and analyze length of ICU and hospital stay and mortality in vaccinated and not vaccinated patients against COVID-19, admitted to the ICU due to severe SARS-CoV-2 pneumonia.

Methods: Multicentre, prospective, descriptive, observational study. All vaccinated and not vaccinated patients against COVID-19 admitted to the ICU due to severe SARS-CoV-2 pneumonia after the start of vaccination in Spain were included. Patients whose vaccination status was unknown were excluded. Full vaccination definition: onset of covid 19 symptoms 14 days after the second vaccine dose.

Results:

Thrombosis, length of stay and mortality outcomes

	Not Vaccinated	Incompletely Vaccinated	Fully Vaccinated
Thrombosis % (n)	23.5 (20)	8.5 (4)	5 (1)
Arterial % (n)	7.1 (6)	0	0
Venous % (n)	16.5 (14)	8.5 (4)	5 (1)
Hospital stay	23 (16–39)	20.5 (15.2–27.5)	26 (13–40.5)
ICU stay	14 (7–24)	9 (5–15)	11 (3–31.5)
Mortality% (n)	29.3 (36)	4.3 (2)	36 (9)

Patients general Characteristics

	Not Vaccinated	Incompletely Vaccinated	Fully Vaccinated
Men %	61.1	57.7	50
Age (IQ range)	62.7 (46.9–67.2)	63 (57.4–72.1)	63 (57.4–72.1)
BMI (IQ range)	29.2 (25–34)	29.4 (25.2–33.8)	28.1 (25–28.9)
HBP %	46.5	27.5	61.5
DM %	30.6	18	30.8
Heart Disease %	14.3	9.8	34.6
Respiratory Disease %	16.9	15.4	19.2
Anticoagulation %	2.2	3.8	0
Antiaggregation %	10.2	3.8	16
APACHE II	10 (7–15)	8 (6–10)	10 (7–13.5)

603 patients admitted to ICU. 399 patients excluded. 204 patients included in the analysis: 78 (38.2%) vaccinated and 26 (12.6%) fully vaccinated. Patient´s general characteristics are described in Table 1. Quantitative variables are expressed as median (interquartile range) and categorical variables are expressed as percentage. Outcomes are described in Table 2.Increase of one unit on the APACHE II score increases the risk of developing thrombosis by 13.2% (OR 1,132; IC 95%: 1,050–1,222; $p = 0{,}001$). The incidence of thrombosis is lower in vaccinated patient but there are not association of thrombosis with vaccination. Not statistically significant relationship between thrombotic events or vaccination with ICU and hospital stay. Not statistically significant association between thrombotic events and mortality. Mortality association with age and vaccination status. For each year that age increases, probability of dying increases by 9.2% (OR 1,092; IC 95%: 1,049–1,136; $p < 0{,}001$). Being fully vaccinated, probability of dying decreases 10.2 times (OR 0,098; IC 95%: 0,018–0,524; $p = 0{,}007$).

Conclusions: In our cohort: The increase in the APACHE II score on admission increases the probability of developing thrombosis. Mortality has no association with thrombotic events. Complete vaccination schedule decreases the probability of dying.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001262

Introduction: Jamaica's first case of COVID-19 was in March 10, 2020 and the Intensive care unit (ICU) one of the major areas affected. A single-center was the primary ICU for COVID-19 patients.
Objectives: To determine the prevalence of, risk factors for AKI and outcome in patients with COVID-19 admitted to the Intensive Care Unit.
Methods: Data from patients admitted to the UHWI ICU with a diagnosis of Coronavirus disease (COVID-19) between March 2020 and November 2021. Data was analyzed using R version 4.1.3 (One Push-Up). The prevalence of AKI was determined, univariate analysis was done to determine factors associated with AKI. Categorical data were compared using the Chi-squared test and continuous data using the t test. Multivariate logistic regression was used to identify factors independently associated with AKI.
Results: One hundred and forty-three patients were included. AKI occurred in 64% of patients, with a prevalence of 12% stage I, 10% stage II and 42% stage III. 31% of AKI patients received dialysis. Independent risk factors for the development of AKI included diabetes mellitus (OR 2.8, $p = 0.029$), obesity (OR 2.5, $p = 0.05$), mechanical ventilation (OR 8.85, $p = 0.002$), hypotension requiring vasoactive agents (OR 4.31, $p = 0.006$). The development of AKI was also associated with an increased length of stay in ICU (8.5 d vs 16 d, $p = 0.00206$) and longer duration on ventilation (4.8d vs 10.2 d, $p = 0.003$).
AKI was associated with higher 30-day mortality, 27% no-AKI vs AKI 85% (OR 14.9, $p < 0.001$).
Conclusions: Critically ill patients with COVID-19 are at very high risk of developing AKI. Developing AKI was associated with poorer outcomes and increased mortality.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001266

Introduction: There have been many studies evaluating different strategies for bloodstream infection (BSI) prevention in intensive care units (ICUs), including single interventions and devices, bundles and protocols. However, other institutional risk factors that could be associated with the risk of BSI have not been deeply explored, especially in low and middle-income countries.
Objectives: To evaluate institutional risk factors (from the perspective of ICU staffing and protocols and infection control services) for BSI incidence in a middle-income country.
Methods: This observational prospective cohort study was nested on the IMPACTO-MR platform, which comprised 51 centers in Brazil, from September 2019 to December 2021. Individual patients' data was prospectively collected and institutional data was collected with surveys. BSI diagnosis was prospectively reported by each center. We fit Cox models with institutional risk factors modelled as fixed effects accounting for patients' confounding variables at baseline. We explored two sets of institutional risk factors: ICU staffing patterns and protocols and infection control services protocols. For ICU staffing, we included an interaction term to allow for their possible dependencies. Results are presented as hazard ratios (HR) with respective 95% confidence intervals (95%CI).
Results: Of 23,026 patients at risk, 828 patients (with 237,764 catheter-days) were diagnosed with BSI. 44 (86.3%) hospitals had a CR-BSI prevention protocol and 38 (76%) had alcohol hand cleansing devices available at all beds. Staff and infection control services factors associated with a lower risk of BSI were semiannual hand hygiene training (HR 0.57, 95% CI 0.43–0.76, $p < 0.001$ compared to single, annual and no training), single use protective gowns (HR 0.69, 95%CI 0.58–0.82, $p < 0.001$), personal protective equipment use training (HR 0.59, 95%CI 0.47–0.0.73, $p < 0.001$), alcohol hand cleansing devices availability in every bed (HR 0.85, 95%CI 0.73–0.99, $p = 0.03$) and family visit duration (hours) (HR 0.94, 95%CI 0.93–0.96, $p < 0.001$). Risk factors for BSI were a higher number of patients per physician (HR 1.13, 95%CI 1.03–1.23, $p < 0.001$), a higher number of patients per bedside-nurses (HR 1.26, 95% 1.15–1.38, $p < 0.001$), which negatively interacted (HR 0.97, 95%CI 0.96–0.98, $p < 0.001$), and a higher proportion of single-bed rooms in ICU (HR 2.13, 95%CI 1.64–2.76, $p < 0.001$). A BSI prevention protocol was not associated with lower risk of BSI (HR 0.85, 95%CI 0.60–1.22, $p = 0.38$), neither was family need to use isolation gowns during visiting hours (HR 1.13, 95%CI 0.93–1.37, $p = 0.22$) or training for preparation of IV medications outside the hospital pharmacy (HR 1.16, 95%CI 0.88–1.55, $p = 0.30$).
Conclusions: Catheter-related BSI prevention can be better accomplished if institutional processes and structure are considered. Avoiding a high number of patients per physician and bedside-nurses may reduce the risk of BSI. Infection control services could further reduce the risk of VAP by routine institutional training and ensuring alcohol availability in every bed. Family presence could also be a protective factor to reduce the risk of BSI.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001267

Introduction: There are a number of ways of extracting information from electronic health records to describe populations of patients with critical illness. These include structured data from national registries such as ICNARC in the UK and big data analytics using datasets such as MIMIC III (1, 2). However, these data reports are usually generic and limited in scope with limited access to health care professionals who cannot influence the dictionary term or phrase configuration. Here, we describe a novel intermediate approach, with more granular data for a local intensive care service using terms reflecting local healthcare professional preferences and patient populations. An extensive but structured list terms within the electronic healthcare record, transformed to an excel heat map representing a longitudinal population phenotype for critically ill patients admitted to a central London ICU.
Methods: Approvals were gained to extract anonymous data from the Intellivue, Critical Care & Anaesthetic (ICCA) database (Philips Healthcare) as part of a service evaluation project. 1000 standard list terms were created in the dictionary of the configuration editor, describing admission organ support; admission diagnosis and past medical history and then all patients screened on admission against the list terms between January 2019 and current date (increasing over time). Terms were structured into categories and found using the search option of the informatics system. Terms were refined overtime. The data extracted from ICCA were pivoted against the admission month of each patient. These totals were then represented by an excel colour code as a percentage of total admissions. A further SQL report ran to ensure no patients or fields were missed by the screening team.
Results: 100% of ICU admissions are represented with no missing data between Jan 2019 and present. Figure 1 shows an example of the phenotype as presented through admission list terms. The association between Covid 19 and hypertension, diabetes, and obesity is demonstrated. The drift in disease characteristics can be seen over time. The consequences of the pandemic are also visible in both presenting disease and comorbidities (Fig. 2) with clear sustained spikes in patients presenting with drug overdose/acute psychosis, parasuicide as well as history of prior mental health; significant psychosocial background, frailty following the pandemic.
Conclusions: Here we have demonstrated a novel use of a SQL extraction of list terms to reveal a simple granular longitudinal phenotype, structured in months, before during and after the COVID 19 pandemic. The phenotype of the population of patients admitted to critical care, provided a unique representation of the pandemic and its aftermath. Standard list term extraction could be translated to reflect any facets of critical illness and supportive care workflow, specific to the local context. Natural Language processing could also be used to try and replicate the phenotypic profile and reduce the burden of data entry. The phenotype of the ICI could also be used in targeting resources and research.

Comparison of SAPS 3, APACHE II, SOFA, and EPM Scoring Systems in Predicting Hospital Mortality in Patients of a Quaternary University Hospital ICU: a retrospective cohort analysis

J. E. Guerra Souza[1], A. G. Almeida Barros[1], C. Gomez Ravetti[1], T. Bragança Ataíde[2], R. Detoffol Bragança[1], J. L. Lima Silva[1], P. Santos Oliveira[3], L. Leite Viana[1], P. Frizera Vassallo[1], A. P. Figueiredo Neves[1]

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001268

Introduction: Scoring systems such as the Simplified Acute Physiology Score (SAPS) 3, Acute Physiology and Chronic Health Evaluation (APACHE) II, Sequential Organ Failure Assessment (SOFA), and the Epimed Mortality Prediction (EPM) model, which is based on machine learning, are widely used to predict mortality in critically ill patients.

However, the ability of these scoring systems to accurately predict hospital mortality for patients originating from diverse populations has yet to be established. Consequently, assessing their performance in a general (clinical and surgical) ICU cohort of a quaternary university hospital is essential. Moreover, comparing traditional scoring systems with machine learning-derived models is crucial to understand their potential advantages and limitations.

Methods: A retrospective analysis was conducted on a cohort of 864 patients admitted to the general ICU of a quaternary university hospital in 2022. Data on patient demographics, comorbidities, and interventions were collected. SAPS 3, APACHE II, SOFA, and EPM scores were calculated within the appropriate timeline from ICU admission. The primary outcome was hospital mortality. Discrimination and calibration of the scoring systems were assessed using C-statistics. COVID-19 patients were excluded.

Results: The study population comprised 864 patients, with a mean age of 56.55 (SD 16.9579). The observed in-hospital mortality rate in the dataset was 21.78%. The area under the curve (AUC) values for APACHE II, SOFA, EPM, and SAPS 3 were 0.708 (95% CI 0.676 to 0.739), 0.758 (95% CI 0.728 to 0.787), 0.847 (95% CI 0.821 to 0.870), and 0.835 (95% CI 0.808 to 0.859), respectively. Pairwise comparisons of ROC curves were conducted to evaluate the differences in discriminative ability between the scoring systems. The comparison between EPM and SAPS 3 showed no significant difference ($p = 0.2507$). However, comparisons between other pairs of scoring systems, such as APACHE II and SOFA or SOFA and SAPS 3, demonstrated statistically significant differences in their AUC values, indicating varying degrees of discriminative ability.

Conclusions: This study provides valuable insights into the performance of SAPS 3, APACHE II, SOFA, and the machine learning-based EPM scoring systems in predicting hospital mortality among patients in a general ICU cohort of a quaternary university hospital. EPM and SAPS 3 demonstrated similar discriminative ability in this cohort, with no significant differences in their pairwise comparison. The results highlight the importance of considering patient-specific factors when applying these scoring systems for risk stratification and clinical decision-making.

Presepsin—a potential biomarker for early detection of bloodstream infection in septic patients

P. Mester[1], S. Schmid[1], C. Kunst[1], K. Gülow[1], M. Müller-Schilling[1], V. Pavel[1]
[1]Department of Internal Medicine I, University Hospital Regensburg, Regensburg, Germany
Correspondence: V. Pavel
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001269

Introduction: Bloodstream infection (BSI) is one of the most severe systemic infections and a leading cause of morbidity and mortality worldwide. Microbiological cultures are used standardly to identify blood pathogens. However, microbiological investigations are time-consuming and have many drawbacks such large sample volume, frequent need for repeated testing and risk of false negative test results after initiation of antibiotic therapy. Procalcitonin (PCT) has been studied as a biomarker for BSI and showed promising results. However, PCT values can be influenced by many pathological conditions like trauma, burns or recent surgery. Therefore PCT is not always reliable as a biomarker for BSI. For an early and targeted therapy new biomarkers are needed to specifically diagnose BSI.

Objectives: Aim of this study was to test the potential of presepsin as a biomarker for BSI in septic patients.

Methods: Levels of presepsin were measured in plasma of patients with different causes of systemic inflammatory response syndrome (SIRS) or sepsis (Sepsis-3, M Singer et al.). The study started in august 2018 and is ongoing. Blood samples were collected within 24 h after admission to the intensive care unit. Until now 79 blood samples from patients with different causes of SIRS or sepsis were included. Blood samples were analyzed by Enzyme-linked Immunosorbent Assay 's (ELISA).

Results: Presepsin was elevated in the plasma of 99% of the patients with SIRS or sepsis. 42 patients (53.20%) were diagnosed with a bloodstream infection using standard microbiological cultures and in 37 cases (46.80%) no pathogen could be isolated in blood. There was a significant difference between plasma of patients with bloodstream infection and without BSI. Presepsin was elevated in patients with BSI. In addition, it was analyzed whether the presepsin concentration is associated with the number of bacterial species in blood. With an increasing number of blood germs, the presepsin levels in SIRS/sepsis patients also increased. Statistical significance was observed between the values from patients with multiple blood pathogens and those with negative blood cultures. Patients with blood pathogens had higher presepsin plasma levels.

Conclusions: Although many stand-alone biochemical markers have been studied for early detection of BSI in critically ill septic patients, C-reactive protein (CRP) and PCT remains the most frequently used markers. Though C-reactive protein (CRP) is an acute phase reactant it is not specific for BSI. Furthermore, although some studies showed the abilities of PCT in detecting bacterial infections in septic patients, a normal or lower PCT values can't always rule out BSI, since PCT levels can be elevated also in other pathological conditions like metastatic cancers or neuroendocrine tumors.

Our study shows that presepsin could be a new useful biomarker for the early detection of BSI in septic patients, regardless of the cause of sepsis.

Major surgery induced impairments in monocyte and lymphocyte crosstalk predispose to post-operative infections in vitro

R. Loye[1], T. A. C. Snow[1], A. V. Waller[1], F. Ryckaert[1], A. Cesar[1], D. Brealey[2], J. Whittle[3], M. Singer[1], N. Arulkumaran[1]

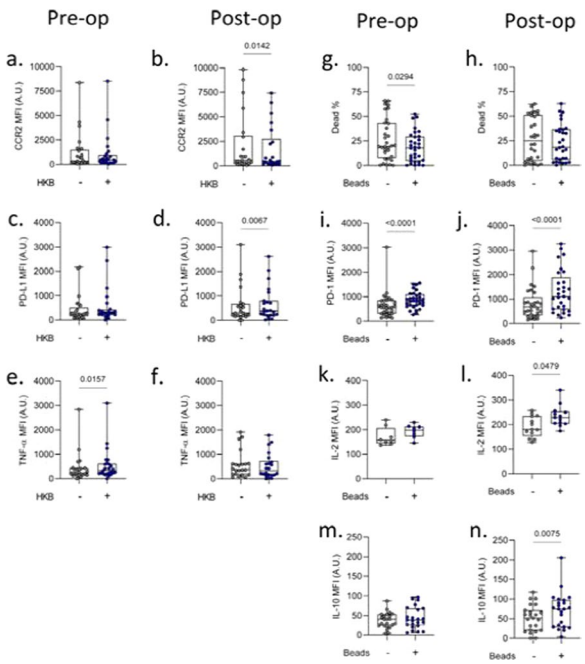
Introduction: Sterile inflammation induced by major surgery results in activation of the immune system. Several studies have explored the immunophenotype of patients who subsequently develop post-operative infections. However, few, if any, have assessed the in vitro dynamic immune response to an infectious stimulus pre- and post-operatively. We hypothesised that changes to the immune system following surgery impairs the immune response to a subsequent infectious challenge, predisposing patients to secondary infections.

Objectives: To identify differences in the in vitro immune response to an infectious challenge in high-risk surgical patients before and 24 h following surgery.
Methods: We conducted a prospective study in which peripheral blood mononuclear cells (PBMCs) from 32 patients undergoing major abdominal surgery were isolated. PBMCs were collected before and 24 h following surgery. PBMCs were stimulated with heat-killed bacteria (HKB) for 24 h to assess monocyte phenotype, or with CD3-CD28 beads for 48 h to assess lymphocyte phenotype. Immune cell phenotype was assessed using flow cytometry.
We assessed classical monocyte antigen presentation (HLA-DR, CD86, CD80), chemotaxis (CCR2 and CXCR4), intracellular cytokines (IL-1ß, IL-6, IL-10, and TNF-α), and T-cell suppression (PD-L1). In lymphocytes, we assessed cell death, checkpoint inhibitor (PD-1), differentiation and proliferation (IL-2R, IL-7R), intracellular cytokines (IL-2, IL-10, and IFN-γ), and activation (CTLA-4 and CD28).
Results: Following HKB stimulation, monocytes isolated prior to surgery demonstrated an increase in intracellular TNF-α ($p=0.0157$), which was not evident in monocytes following surgery. On day one post- surgery, monocytes demonstrated a reduction in CCR2 ($p=0.0142$) and an increase in PD-L1 ($p=0.007$), which were not evident in samples isolated prior to surgery.
An increase in CD4 and CD8 lymphocyte PD-1, IL-2R, CD28, and IFN-γ were evident following stimulation in samples taken both before and following surgery. CD4 lymphocytes isolated prior to surgery demonstrated an increase in cell viability following stimulation which was not evident following surgery. Following surgery, CD4 lymphocytes demonstrated an increase in IL-10 which were not evident prior to surgery. CD8 lymphocytes demonstrated similar changes on stimulation before and after surgery.
CD19 cells demonstrated an increase in cell viability, CD28, and decrease in PD-L1 following stimulation before and after surgery. Following surgery, IFN-γ was increased in CD19 cells, which was not evident prior to surgery.
Conclusions: Differences in immune response to infectious stimuli were seen in vitro before and after surgery. The implication of these changes on post-operative infectious complications needs to be determined. Mechanisms underpinning these changes may facilitate the identification of therapeutic interventions.



Changes in monocyte (a.-f.) and CD4 lymphocyte (g.-n.) immune function following heat killed bacteria (HKB) or CD3-28 bead stimulation. Data expressed as individual dots ($n=32$), horizontal line represents median, box inter-quartile range, whisker range, and compared using Wilcoxon test with p-values < 0.05 shown.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001271

Introduction: Cerebral vasospasm (CVS) is an important cause of mortality and long-term disability after aneurysmal subarachnoid hemorrhage (aSAH). A myriad of drugs has been studied and milrinone has been suggested as an effective and safe treatment for severe CVS in combination with calcium channel blockers.
Objectives: Comparison between intra-arterial verapamil (IA-V) and IA-V combined with intravenous perfusion of milrinone (IV-M) to treat CVS on long-term neurological outcome.
Methods: Retrospective analysis of all adult patients with CVS as a complication after aSAH admitted from 1st January 2018 to 30th June 2022 at a Neurocritical Care Unit of a University Hospital. CVS was defined by elevated cerebral blood flow velocities using transcranial Doppler. Patients treated with selective IA-V boluses were compared with those submitted to IA-V combined with continuous IV-M infusion. Therapeutic approach was based on individualized clinical evaluation, multimodal neuromonitoring and angiographic findings. Favorable functional outcome, defined by Glasgow Outcome Scale (GOS) of 4 or 5, was evaluated at 28 days, 3 and 6 months.
Results: CVS was diagnosed in 91 (45.7%) of 199 patients with aSAH, 61 females (67%), mean age of 53 years (SD ± 12.5). Hunt and Hess score 4 or 5 was observed in 32 (35.2%) and Fisher score 3 or 4 in 82 (90.1%). Delayed cerebral ischemia (DCI) was observed in 45%. Oral nimodipine was administered over 21 days to all patients. Regarding CVS rescue therapies, 28 patients (30.8%) were treated with IA-V and 30 patients (33.0%) with IA-V combined with IV-M. No pharmacological treatment was performed in 33 patients (36.3%) since vasospasm evaluated by transcranial Doppler wasn't clinically significant or wasn´t angiographically confirmed. There were no differences regarding age ($p=0.70$), Fisher grade ($p=0.55$), Hunt and Hess grade ($p=0.47$), and DCI development between the two therapeutic groups. Comparing patients treated with IA-V to those submitted to IA-V plus IV-M, a favorable GOS was observed, respectively at 28 days, 3 and 6 months, in 32.1% vs. 13.3%, 48.1% vs. 33.3% and in 61.5% vs. 47.8%. However GOS wasn't significantly different at 28 days ($p=0.08$), 3 months ($p=0.26$) and 6 months ($p=0.33$) after the ictus regarding the therapeutic approach.

Conclusions: In the studied population the addition of IV-M to IA-V didn't significantly influence short- and long-term functional outcome in CVS after aSAH.

Introduction: During the COVID-19 pandemic, many similarities in clinical presentation were noted between SARS-CoV-2 and other viruses causing seasonal influenza. Nevertheless, some studies showed that ICU length of stay and mortality were higher in COVID-19 patients.
Objectives: Aim: to compare clinical characteristics and outcomes of critically ill hospitalized patients with COVID-19 in comparison with other viruses.
Methods: We conducted a retrospective monocentric study in the ICU of Zaghouan's regional hospital in Tunisia, including critically ill patients hospitalized for severe viral pneumonia from October 1st 2022 of to February 28th 2023. Patients were selected and matched according to similar demographic characteristics. Two groups were secondary individualized G1 = COVID-19 and G2 = patients with other viruses. Were collected epidemiological, clinical, therapeutic and evolving data.
Results: We included 60 patients (30 patients in each group). Viruses identified in G2 were respectively H1N1/pdm 2009 (n = 16), H3N2 (n = 4), influenza B (n = 4), rhinovirus (n = 5), parainfluenza virus (n = 1). Mean age were respectively 51 ± 13.9 years in G1 and 50.9 ± 15.4 years in G2. Gender ratio was respectively 2 in G1 and 1.5 in G2. Group 1 had a higher median APACHE II score (10 [2–28] in G1 vs 6[0–23] in G2, $p < 0.05$). Comorbidities were lesser observed among the other viruses than COVID-19 patients (21.7% vs 25.83%;$p = 0.18$). Hypertension was statistically higher noted in G2 ($p = 0.02$). However, chronic respiratory diseases were higher in G1 ($p = 0.03$).
At admission, PaO2/FiO2 ratio was lower in patients with COVID-19 (152 [82–202] in G1 vs 189 [67–330]; $p = 0.018$). Noninvasive ventilation was initially used in both groups (86% in G1 vs 80% in G2; $p = 0.3$) for a similar duration 3 [1–8] vs 1 [1–6]; $p = 0.48$). Orotracheal intubation was needed in 30% in G1 vs 33% in G2 ($p = 0.5$). Vasoactive agents were more needed in G1 ($p = 0.38$). No differences in healthcare associated infections occurrence ($p = 0.55$) and in median length of ICU stay between both groups were found (5[2–33] vs 3[1–32]; $p = 0.52$). Mortality rate was similar between both groups 21% in G1 vs 23% in G2 ($p = 0.38$).
Conclusions: Pneumonia related to COVID-19 and other viruses seems to be similar in terms of need for mechanical ventilation, length of stay and mortality. Larger studies are needed to further examine the differences between COVID-19 and other viruses.

Topic: Acute respiratory failure and mechanical ventilation

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001273

Introduction: Community-acquired pneumonia (CAP) is a major cause of hospital admission and mortality in adults both in high-income (HIC) and low-and-middle-income countries (LMICs). In LMICs, the accelerated demographic transition has produced an aging population associated with a high rate of co-morbidities and non-communicable diseases. In addition, immunization rates are sub-optimal and the inequities in the healthcare system make timely access to a hospital bed and intensive care a challenge. Therefore, it is not surprising that international cohort studies that evaluate the outcomes of hospitalized patients with CAP demonstrate that hospital outcomes (namely mortality rates) are worse in LMICs as compared to HICs.
Finally, although the hospitalization of adults due to community-acquired pneumonia represents a major challenge for policymakers, clinicians, and public health experts in LMICs, few large cohort studies or population-based studies from these regions are available.
Objectives: The primary objective was the age-adjusted hospitalization rate per 100,000 population. Secondary objectives comprised the crude number of hospital admissions and in-hospital deaths, the age-adjusted in-hospital mortality rate per 100,000 population, age-adjusted in-hospital and ICU lethality rates, ICU admissions by age group, percentage of pneumonia age-adjusted hospital and ICU admissions by age-group.
Methods: A retrospective analysis of hospital admissions from the Brazilian Universal Healthcare System was performed. The data is available on the Information Technology Department of the Brazilian Universal Health System website. We assessed the Authorization for Hospitalization database, where each register includes details about an inpatient, including age, demographic information, admission cause (code from the 10th revision of the International Statistical Classification of Diseases and Related Health Problems: ICD-10) and patient outcome. For count data (crude number of hospital admissions and in-hospital deaths), the AAPC was calculated using log-linear Poisson regression, considering the year as the single predictor (the reference year was 2011). To the previous Poisson model for age-standardized rates, we added the age-adjusted denominator as an offset variable. We calculated the AAPC from 2011 to 2019 and 2019 to 2021, as well as the percentage change (%Δ) over these periods. Comparing both intervals, it is possible to determine whether the COVID-19 pandemic had an impact on the outcomes. We defined 2 age groups (WHO definition): Elderly (> 60 years old) and non-elderly.
Results: From 141,923,885 hospital admissions included in the study, 79,149,709 were adults > 20 years old and after the filter with CAP codes from ICD-10, 3,626,315 admissions were analyzed (Figure 1). A decrease in the absolute number of CAP admissions was observed from 2011 (362,159) to 2019 (353,591) about 2,37% (Fig. 2) with the exception of the elderly group (older than 60 years old). A decrease in the age-adjusted rate of CAP admissions was also observed in the same period, from 286/100,000 in 2011 to 218/100,000 in 2019 (Fig. 2). The absolute number of in-hospital deaths increased by 36.05%, from 46,615 (2011) to 59,337 (2019). The in-hospital lethality increased from

2011 (6.59%) to 2019 (8.66%) by 31,54%. Lethality in ICU admissions decreased over the time by 12.1% in contrast to a 27.74% increase in non-ICU (Fig. 3). In the period 2020–2021 compared to 2019, during the COVID-19 pandemia, it could be observed: a decline in CAP hospital admissions, higher ICU occupation and non-ICU lethality (Fig. 2 and 3).

Conclusions: CAP causes high burden among hospitalized adults in Brazil. Hospitalar CAP admissions in non elderly patients decreased over the years, ICU admitted patients have high mortality rates mainly the elderly group. 2020 and 2021 CAP admissions had an important decrease, probably because of the Health System overload due to COVID-19 pandemia.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001274

Introduction: Hospital-acquired bloodstream infections (HABSI) are frequent in the intensive care unit (ICU) and are associated with a high mortality. Patients with cirrhosis are highly vulnerable and prone to infections. Data on HABSI in critically ill cirrhotic patients are lacking.

Objectives: We aimed to describe the differences in the epidemiology of HABSI between cirrhotic and non-cirrhotic patients in terms of patients' characteristics, source of infection, microorganism distribution and mortality using a large multicontinental database.

Methods: We used high quality data from the prospective observational Eurobact-2 study. We compared the distribution of HABSI sources and microorganisms for cirrhotic and non-cirrhotic patients. The association between *Enterococcus faecium* and cirrhosis was studied using a multivariable mixed logistic regression model. The

association between cirrhosis and mortality was assessed by a multivariable frailty Cox model.
Results: A total of 1059 HABSI patients from 101 centers from all continents were included, of which 160 had cirrhosis. The source of HABSI in cirrhotic patients was predominantly abdominal (35.6%) whereas it was pulmonary (18.9%) for non-cirrhotic patients ($p < 0.01$). Of the 1196 microorganisms identified, 42.3% of the HABSI in cirrhotic patients were caused by Gram-positive species compared to 33.2% in non-cirrhotic patients ($p = 0.02$). HABSI in cirrhotic patients were most frequently caused by *Klebsiella* spp (16.5%), coagulase-negative Staphylococci (13.7%) and *E. faecium (11.5%). E. faecium* HABSI was significantly more observed in cirrhotic patients (11.5% *versus* 4.5%, $p < 0.01$). After adjustment to possible confounding factors, cirrhosis was associated with a higher risk of *E. faecium* HABSI (Odds ratio 2.5, 95% CI 1.3–4.5, $p < 0.01$). Cirrhotic patients with HABSI had an increased mortality hazard ratio (HR) compared to non-cirrhotic patients with HABSI (HR 1.3, 95% CI 1.01–1.7, $p = 0.045$).
Conclusions: Critically ill cirrhotic patients with HABSI have a different epidemiology compared to non-cirrhotic patients with more Gram-positive and especially more *Enterococcus faecium.*

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001275

Introduction: Polytrauma is a leading cause of death around the world. Septic complications are predominant in this group of patients and inflammation biomarkers were propposed as predictors of mortality.
Objectives: to asssess prognostic value of two biomarkers: C reactive protein (CRP) and white blood cells count (WBC) in critically ill polytrauma patients.
Methods: We conducted a retrospective monocentric study including polytrauma patients admitted to the ICU in Zaghouan's regional hospital during the year of 2022. The CRP and WBC counts were monitored daily by a blood test during the ICU stay. We collected epidemiological, clinical, therapeutic and evolving data. Patients were divided in two groups: G1: survivors and G2: deceased.
Results: We included 50 polytrauma patients among them 21 (42%) were deceased. Mean age was 41 ± 17 years with a male predominance (96%). Median APACHE II and SAPS II were respectively 8 [4–18] and 19 [7–47]. All patients had head trauma, 60% had associated thoracic trauma and 14% an abdominal trauma. A surgical treatment was indicated in 14% of patients. Median WBC and CRP levels at admision were respectively 13,703 [8750–16350]/mm3 and 26 [5–80] mg/l. Monitoring of WBC and CRP levels until discharge showed an initial increase (Day 2/3) of the two biological parameters followed by a secondary decerease (Figure 1). In G2, we observed a second rise in WBC and CRP levels respectively at day 5 and day 7 simultaneously with the occurrence of a health acquired infection ($p < 0.05$).
Orotracheal intubation was more needed in G2 (31% vs 100%; $p < 0.05$) with a median duration of mechanical ventilation of 3 days [1–6] vs 6 days [1–9] ($p < 0.05$). Patients in G2 had a longer ICU length of stay (2 days [2–4] vs 5 days [1–9]; $p < 0.05$).
Conclusions: Kinetics of inflammatory biomarkers in polytruma patients seems to be associated with worse prognosis.

A review of antibiotic selection in ventilator associated pneumonia
R. Araujo Silva[1], R. F. Gomes[1], S. Salema Travassos[1], G. Jesus[1], S. Cameiro Croca[1], J. M. Ribeiro[1]
[1]Intensive Medicine Department, Centro Hospitalar Universitário Lisboa Norte, Lisboa, Portugal

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001276

Introduction: Ventilator associated pneumonia (VAP) is a common hospital acquired infection in critically ill patients, associated with significant morbidity and mortality. Some current guidelines recommend combining two broad spectrum antibiotics as the first line therapy for the management of early onset VAP (EOV). However, there is growing concern that the widespread use of broad-spectrum antibiotics may contribute to the development of antimicrobial resistance. In this study, we aim to assess the suitability of such antibiotic strategy for the treatment of early (EOV) and late onset VAP (LOV).
Methods: A cohort of patients admitted to a single center, intensive care unit (UCI) between May 2020 and November 2021, diagnosed with VAP was retrospectively selected. EOV was considered when the diagnosis was established 2–5 days after invasive mechanical ventilation (IMV) and LOV if the diagnosis was considered more than 5 days after IMV. Thorough clinical characterization, first line antibiotic choice and later treatment adjustments were recorded and descriptive statistical analysis was performed.
Results: 183 patients were diagnosed with VAP, 30 were diagnosed with EOV and 153 with LOV, 74,3% of whom were male, and median age was 61 years (IQR 21). A SAPS II score of 34 was recorded for EOV vs 37 for LOV. Patients with EOV had a SOFA score at admission of 4 for EOV vs 6 for LOV. The median time from IMV to diagnosis was 5 days for EOV and 11 days for LOV. Among patients diagnosed with EOV, 50% were also infected with SARS-CoV-2. In patients with EOV, initial antibiotic therapy choice was adequate in 19 patients (63%). 3 patients (10%) required antibiotic spectrum broadening and downgrading was possible in 8 patients (27%). Amoxicillin-clavulanate (AAC) resistant microorganisms was found in a minority of patients ($n = 3$). One fifth ($n = 7$) of patients with EOV met diagnostic criteria for septic shock, but a ACC-resistant agent was isolated in only 1 patient.
Conclusions: Our analysis revealed that prevalence of AAC-resistant microorganisms in EOV is low, even in patients with septic shock. This finding strongly suggests that, in our specific patient population, the initial choice of two long-spectrum antibiotics to treat EOV as recommended by some guidelines may not be necessary.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001277

Introduction: Prolonged intensive care unit (ICU) stay is known to be associated to physical, cognitive, and psychological disabilities in surviving patients. Frailty on ICU admission has been previously associated with mortality and to a lower health-related quality of life after an ICU stay, but its impact on long-stay ICU patients remains unclear.
Objectives: We conducted a study to investigate the association between frailty and poor outcomes in long-stay ICU patients, defined as patients hospitalized for more than 7 days in the ICU. The primary objective was to identify an association between frailty and mortality. The secondary objective was to determine the physical, psychological and cognitive outcomes at 6 months in frail patients compared to non-frail patients.
Methods: We screened all patients identified as long-stay ICU patients from the 1st May 2018 to the 1st May 2021. Frailty was assessed using the clinical frailty scale (CFS), with a score of ≥ 5 indicating frailty. Patients were separated into two groups according to their CFS on ICU admission. A descriptive analysis of patients' characteristics on ICU admission according to their frailty status was performed. We then investigated the association between frailty and mortality using a graphical representation with Kaplan–Meier curves. Finally, a Cox model adjusted to known mortality risk factors in that setting was performed. In surviving patients at 6 months, psychological, physical, and cognitive sequelae and health-related quality of life were assessed using descriptive statistics and multiple linear regressions.
Results: During the study period, we enrolled and followed up 531 long-stay ICU patients, including 353 non-frail and 178 frail patients, for up to 6 months or until death. Frail patients were older, had more comorbidities, and presented with more severe disease on ICU admission. They had a higher mortality rate compared to non-frail patients (61/178 vs. 62/353, $p<0.01$). In the multivariate Cox model, frailty was independently associated with death (HR 2.1 (1.5–3.1), $p<0.01$). At 6 months, frail patients had more dependency for daily activities (73% versus 56%, $p=0.02$) and required more nursing help at home (54% versus 31.7%, $p<0.01$). In the multivariate linear regressions, frailty was associated with poorer physical health-related quality of life ($p=0.03$). However, there was no association between frailty and mental health-related quality of life, depressive symptoms, post-traumatic stress disorder and cognitive outcomes.
Conclusions: Our study found an association between pre-admission frailty and mortality in long-stay ICU patients. Compared to non-frail patients, surviving frail patients are more dependent and have poorer physical health-related quality of life 6 months after their ICU stay, but not necessarily poorer mental health-related quality of life. The CFS, an easy and reliable tool, can be used to assess outcomes in long-stay ICU patients and assist in determining their treatment plan and goal of care.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001278

Introduction: Predicting the outcome of trauma helps clinician to prioritize patients and provide timely and effective treatment. Various scoring systems have been proposed to predict mortality of trauma patients.
Objectives: to identify among three scoring systems: MGAP (mechanism, Glasgow coma scale, age, and arterial pressure), ISS (injury severity score) and RTS (revised trauma score) the best predictive score of mortality in critically ill trauma patients.
Methods: We conducted a retrospective monocentric study including polytrauma patients admitted to the ICU in Zaghouan's regional hospital during the year of 2022. MGAP, ISS and RTS scores were calculated upon presentation in the emergency room. A cut-off for the best score predicting mortality was determined using ROC curve. Epidemiological, clinical, therapeutic and evolving data were collected.
Results: During the study period, 50 patients were included. Mean age was 41 ± 17 years with a male predominance (96%). Median APACHE II and SAPS II were respectively 8 [4–18] and 19 [7–47]. Smoking (63%) and alcoholism (34%) were the most common underlying habits. Seventy-eight percent of patients had no comorbidities. Orotracheal intubation was indicated in 56% of patients with a median length of mechanical ventilation of 5 days [1–8]. Vasoactive agents were used in 42% of cases. Mean ICU length of stay was 19 ± 12 days. Means MGAP, ISS and RTS were respectively 21 ± 5, 36 ± 24 and 6 ± 1. A cut-off value of 33 in ISS was found to be predictif of need for vasoactive agents (Se = 71.4% and Sp = 69.2%) and mortality (Se = 66.7% and Sp = 65.4%). A cut-off value of 19.5 of ISS was found to be predictive of mechanical ventilation (Se = 92.9% and Sp = 68.4%). ROC curves demonstrated that ISS has the best predictive value of need to mechanical ventilation, vasoactives agents and mortality with areas under curve respectively of 0.929, 0.777 and 0.677 (Figure 1).
Conclusions: In critically ill polytrauma patient, the present study demonstrated that ISS score was the best predictive score of mechanical ventilation, need for vasoactive agents and mortality.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001280

Introduction: Dysregulated inflammation and inflammation-driven endothelitis appear to be major pathophysiological contributors to acute heart failure (AHF) and cardiogenic shock (CS) (1, 2). The identification of key players in the resolution of inflammation response, such as lipoxins (LXs) and their FPR2/ALX receptor (3, 4), has led to new potential treatment targets.

Objectives: Since no data on human AHF is yet available, we aimed at characterizing LXs and their FPR2/ALX receptor both in human AHF and CS patients, as well as evaluating their correlation or association with endocan (a biomarker of endothelitis in AHF and CS with prognostic value (2)), cardiac biomarkers and prognosis.

Methods: This study was approved by the Health Ethics Committee of our hospital. Blood and urine samples of AHF (n = 23) and CS (n = 25) patients were collected at days 1–2 (admission), 3–4 and 5–8. Blood donors (BD) were used as controls (n = 22). We quantified serum and urinary lipoxin A4 (LXA4), 15-epi-LXA4 and endocan by ELISA and peripheral blood mononuclear cell FPR2/ALX receptor expression by qRT-PCR. Plasma B-type natriuretic peptide (BNP) and high-sensitivity troponin I (hs-trop I), prognostic scores (APACHE II, SAPS II) and mortality were also analysed. Correlation and multivariate analysis were performed.

Results: At admission there were no differences in serum LXA4 or 15-epi-LXA4 between groups. However, both urinary LXA4 and 15-epi-LXA4 were higher in AHF (U-LXA4, ng/mg creatinine, BD: 0.28 ± 0.08; AHF: 1.19 ± 0.24; CS: 0.45 ± 0.11; $p < 0.001$, AHF vs BD; U-15-epi-LXA4, ng/mg creatinine, BD: 1.89 ± 0.41; AHF: 6.19 ± 1.17; CS 3.34 ± 0.94; $p < 0.001$, AHF vs BD and $p < 0.05$, AHF vs CS). At admission, S-Endocan was significantly higher in AHF (S-Endocan, ng/ml, BD: 1.45 ± 0.17; AHF: 6.12 ± 1.85; $p < 0.001$ vs. BD) and even higher in CS (CS: 12.94 ± 1.88; $p < 0.001$ vs. BD; $p < 0.010$ vs. AHF), whereas U-Endocan was only significantly higher in CS patients (U-Endocan, pg/mg creatinine, CS: 62.48 ± 36.97; $p < 0.01$ vs. BD).

During hospitalization, a decreasing profile in LXs was observed only in AHF (days 3–4 vs days 1–2: S-LXA4, ng/ml: 0.11 ± 0.02 vs 0.15 ± 0.01, $p < 0.05$; S-15-epi-LXA4, ng/ml: 0.63 ± 0.22 vs 1.97 ± 0.68, $p < 0.05$; U-LXA4, ng/mg creatinine: 0.47 ± 0.21 vs 1.19 ± 0.24, $p < 0.01$; U-15-epi-LXA4, ng/mg creatinine: 2.74 ± 0.84 vs 6.19 ± 1.17, $p < 0.01$), but no significant reductions were observed for S-Endocan and U-Endocan values in both patient groups.

FPR2/ALX expression was significantly raised at admission (BD: 0.87 ± 0.10; AHF: 1.90 ± 0.39; CS: 3.81 ± 1.21; $p < 0.01$, CS vs BD) and decreased along hospitalization only in CS (days 3–4 vs days 1–2: 1.41 ± 0.29 vs 3.81 ± 1.21, $p < 0.05$). Noteworthy, FPR2/ALX expression was inversely correlated with APACHE II ($r = -0.69$; $p < 0.001$), SAPS II ($r = -0.79$; $p < 0.001$) and BNP ($r = -0.43$, $p < 0.05$) only in AHF patients. Multivariate analysis confirmed the negative association of FPR2/ALX expression with thecardiac biomarkers BNP ($\beta = -0.00003$, 95% CI: − 0.001 to − 0.000007; $p < 0.05$) and hs-trop I ($\beta = -0.00003$, 95% CI: − 0.00005 to − 0.000007; $p < 0.01$) and the prognostic scores APACHE II ($\beta = -0.093$, 95% CI: − 0.153 to − 0.034; $p < 0.01$) and SAPS II ($\beta = -0.053$, 95% CI: − 0.089 to − 0.016; $p < 0.01$) only in AHF patients. Also, in the same group of patients, FPR2/ALX expression was negatively associated with S-Endocan ($\beta = -0.041$, 95% CI: − 0.073 to − 0.008; $p < 0.05$) and U-Endocan ($\beta = -0.002$, 95% CI: − 0.004 to − 0.00028; $p < 0.05$), while hospital survival was associated with significantly higher expression of FPR2/ALX ($\beta = 1.298$, 95% CI: 0.255 to 2.342; $p < 0.05$).

Conclusions: CS patients appear to have defective resolutive response as suggested by unchanged LXs profile and higher FPR2/ALX expression. The inverse correlations/associations of FPR2/ALX receptor with endocan, cardiac biomarkers and prognostic parameters only in AHF patients suggest that it exerts a protective role in these patients.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001282

Introduction: Sepsis has long been an ambiguous medical dilemma, leading to innumerable casualty despite of energy and resources human dedicate to fight it. By introducing sublingual microcirculation for evaluating sublingual microcirculatory system, we established a reliable noninvasive strategy for better approaching sepsis patients, but with application limited by time consuming measurement required for qualified image to study. Here we try to facilitating its clinical application with shorter frames needed study yielding same clinical information by introducing better image analysis tools.
Methods: Sublingual microcirculation evaluation was applied over adult medical intensive care unit in tertiary hospital as routine daily standard of care. Each adult patient was measured with sublingual microcirculation evaluation by 60 frames matching with 100 frames individually. All the 100-frames sublingual microcirculation video clips were found qualified with *Massey's scoring* system, and all the 60-frames were found qualified with *Massey's scoring* system except the length of videos. This was a nationwide, propensity score-matched case–control study of patients admitted to hospitals between January 2000 and December 2012 with primary diagnosis of first AMI. Among the 186,112 first AMI patients, 72,924 patients with diabetes were identified. The clinical information for the same patient yielding from both version of video clips were interpreted by Micro-Tools, and all the data were compared.
Results: Totally 18 patient was measured, with totally 112 video clips from 60-frames study and 104 video clips from 100 frames study were collected. By further interpretation with Micro-Tools, the image quality for duration, illumination, stability, focus, pressure, and contents were all found no statistical difference (p value = 1). Further clinical information including small vessel FOV (p value = 0.079), TVD (p value = 0.95), CBV (p value = 0.813), FCD (p value = 0.659), PPV (p value = 0.197), RBCv (p value = 0.948), cHct (p value = 0.554), tRBCp (p value = 0.977) were all found no statistical difference in between 60-frames study and 100 frames study, as well as RBCv SD (p value = 0.581) and cHct SD (p value = 0.552). Shorter-frames study had non-inferior clinical information in compared to standard-frames versions.
Conclusions: This study demonstrated shorter-frames study had non-inferior clinical results in compared to standard-frames versions by Image analysis tools with Micro-Tools.

Deceased donor transplantation during COVID times—success story from state in India

R. Muralidharan[1]
[1]critical Care, KIMS Health Hospital Trivandrum, Thiruvananthapuram, India
Correspondence: R. Muralidharan
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001283

Introduction: In India, live donor transplantation is more common than deceased donortransplantations. The enactment of The Transplantation of Human Organ andtissue Act in India in the year 1994 legalized organ donation after brainstemdeath. The Government of Kerala in association with Donation and TransplantationInstitute (DTI Foundation) of Spain implemented transplant procurementmanagement model (TPM model) in the state in the year 2019. KNOS (Keralanetwork for organ Sharing), a local networking organization under Governmentacts as a public, private provider interface, ensuring a transparent and equitableorgan allocation.
Methods: Government medical colleges and private transplant centers appointed an in-hospital transplant procurement manager (TPM) to coordinate potential donorsat intensive care units. The TPM became actively involved in the deceasedorgan donation (DDP) process. The cornerstone of the success was early andproactive identification of potential donors. An educational and international cooperation approach based on theimplementation of a specialized program for healthcare professionals accordingto the DTI Foundation training model started in 2019. It includes on-site training, international internship, hospital visits and DTI´s l experts visiting Keralahospitals to exchange best practices.
Results: Following the initiation of TPM in various hospitals across Kerala, whencompared 2020 Vs 2019, a 60% increase was observed from 30 to 50 organstransplanted in the same period of time even against Covid pandemic effectsworldwide.
Conclusions: The collaboration between local and international organization, the hospital-based organ procurement units headed by Transplant procurement managers (TPM) and the role of government-run networking organizations in improving.
the deceased donor transplantation played a key role for good outcomes ofdonation and transplant programs. When the COVID 19 pandemic resulted inthe suspension of the transplant programs across the country, the deceaseddonation and transplantation activity in Kerala were going unabated.

Fluid stewardship in ICU—'ROSE' yet to blossom in India?

R. Muralidharan[1]
[1]Critical Care, KIMS Health Hospital Trivandrum, Thiruvananthapuram, India
Correspondence: R. Muralidharan
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001285

Introduction: To find out the need of fluid stewardship in post surgical critically ill patientswho requires ICU admission post operatively of the age more than 18 yearsadmitted in multidisciplinary ICU in a tertiary care centre in South India.
Objectives: Intravenous fluids are not benign. They are the most commonly used drugsused in Intensive Care unit. Fluid stewardship is the concept of covering allthe aspects of fluid therapy from procurement ordering, safe storage, prescription administration and monitoring of fluids through education andaudit of the different fluid requirement scenarios.Errors in prescribing are very common. Various surveys and audit haveshown that many staffs prescribing intravenous fluids don't have the know.
how to calculate the requirements of electrolytes and water requirements aswell as the composition of various fluid choices as per the individual needs. Management of fluid therapy rarely reported to have produced harm forpatients. But evidences suggest as many as one in five patients receiving fluidtherapy found to have complications or mobility due to in appropriateadministration of fluids might be too little or too many of fluids.In this era of less is more policy and applying 5RS (resuscitation reducedmaintenance replacement, redistribution and reassessment) of resuscitation.We need to have stewardship to count ongoing prescription strategy like twobags of normal saline, one bag of dextrose so on to prescription strategy to 70kg man requiring 0.9% sodium chloride 0.45% of sodium chloride and 5%dextrose solution like. So we need to demystify the fluid management similarto that of antibiotics to counter the ill effects of fluid therapy keeping in mindprimum non nocere means (first, do no harm).
Methods: To find out the pattern of prescribtion of fluid therapy in post operative patientsrequiring ICU admission and prescribing doctors knowledge about theelectrolyte components of various available fluid choices. Post surgical patients admitted in the MDICU who needs the inclusion criteriaincluded in the study with matching baseline characteristics were included

andtheir fluid prescriptions were analysed on type offluids, flow rate, duration offlow electrolyte status urine output and volume status using a check listwhichincludes lung ultrasound findings like b lines. Along with that the knowledge ofthe prescribing doctor were taken using a five minutes personal interviewchecklist which gives an idea of about the know how of composition of fluidsand patients electrolyte and fluid status awareness and how they educatedthe nurse in charge to alter the fluid administration.
Results: The percentage of patients getting pre fixed fluid therapy calculated after the100% educational intervention given by the intensive care physician for thetarget group of health care workers included in post surgical ward using PDSAstrategy.
Conclusions: After completion of intervention and completion of 25 samples it seems thatthere is statistically significance difference between the previous and currentprescription strategy and incidence of b lines and amount of fluid ordered fromthe ICU in the post surgical patients requiring ICU admission.

The Impact of pediatric intensivists on the management of severe pediatric diabetic ketoacidosis

E. Park[1]
[1]Jeonbuk National University Children's Hospital, Jeollabuk-do, Jeonju-si, Republic of Korea
Correspondence: E. Park
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001288

Introduction: The impact of pediatric intensivists on the management of pediatric patients with diabetic ketoacidosis (DKA) is yet to be studied.
Objectives: We aim to evaluate the effect of pediatric intensivist staffing on DKA outcomes in pediatric intensive care units (PICU).
Methods: This study was a two-institution retrospective review of DKA patients admitted to ICU between 2013 and 2023. Pediatric patients (< 18 years of age) were included in the study if they met ∟ severe DKA criteria on PICU admission. The patients were subsequently divided into two groups based on the presence of the pediatric intensivist. The primary outcome was ICU length of stay (LOS). The secondary outcome was the complication of DKA management, the complication of DKA, hospital LOS, duration of insulin infusion, time to DKA resolution, and mortality.
Results: 32 patients admitted to the PICU with a mean age of 11.50 years (range 0–18 years) were included; 18 (56.3%) were male. Both groups had no significant difference in BMI, HbA1c, initial bicarbonate, pH, and blood glucose level. Patients managed by pediatric intensivists had significantly shorter ICU LOS (116.83 vs. 57.67 h, p = 0.012). Otherwise, there was no significant difference in the median (IQR) time to DKA resolution and hospital LOS between both groups. But complication during DKA treatment was significantly decreased in the intensivist group than in the control group (52.6% vs. 7.7%, p = 0.011).
Conclusions: Management of DKA patients by pediatric intensivists reduces the ICU LOS with significant improvement in treatment complications.

The effects of early mobilization in mechanically ventilated adult ICU patients: systematic review and meta-analysis

L. Wang[1], X. Ou[1]
[1]Department of Critical Care Medicine, West China Hospital of Sichuan University, Chengdu, China
Correspondence: L. Wang
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001290

Introduction: Mechanically ventilated patients in intensive care units (ICUs) usually suffer from short- or long-term complications, which are associated with increased mortality and mechanically ventilated duration, longer length of stay in ICU and hospital, reduced quality of life and increased utilization of medical care[1]. The systematic early mobilization has been commonly advocated as a promising intervention to improve ICU patient outcomes[2]. There is evidence from several studies could demonstrate its feasibility that early mobilization increases muscle strength, reduces the incidence of ICU-acquired weakness and delirium rate, shortens the length of ICU stay and hospitalization[3–5]. However, numerous studies found early mobilization with no or inconclusive evidence for a benefit. Therefore, there is considerable controversy regarding the benefits and adverse effects of mechanical ventilation on early activity in adult ICU patients.
Objectives: We conducted a meta-analysis of RCTs to comprehensively assess the benefits and adverse effects of early mobilization in critically ill mechanically ventilated patients.
Methods: We searched RCTs published in Medline, Embase, CENTRAL (from inception to November 2022). According to difference of timing and type, we divided intervention groups into systematic early mobilization group, late mobilization group and standard early mobilization group. The primary outcome was mortality. The secondary outcomes were ICU length of stay, duration of mechanical ventilation and adverse events.
Results: Nine RCTs combined total of 1756 patients were included. We found early mobilization had no impact on 180-day mortality (RR 1.09, 95% CI 0.89–1.33, p = 0.39) Figure 1 (a). Systemic early mobilization reduced the length of stay in ICU (MD -2.18, 95% CI -4.22– − 0.13, p = 0.04) and the duration of mechanical ventilation (MD -2.27, 95% CI -3.99– − 0.56, p = 0.009) (Figure 1 (b-c)), but it may increase the incidence of adverse events in patients compared with standard early mobilization (RR 1.99, 95% CI 1.25–3.16, p = 0.004) (Figure 1 (d)).
Conclusions: Early mobilization have no significant effects on short- or long-term mortality in mechanically ventilated adult ICU patients, but systematic early mobilization could reduce the ICU length of stay and duration of mechanical ventilation.

Figure 1. (a). Forest plot for early mobilization on effect mortality in the included studies. **(b).** Forest plot for early mobilization effect on ICU length of stay in the included studies. **(c).** Forest plot for early mobilization effect on duration of mechanical ventilation in the included studies. **(d).** Forest plot for early mobilization effect on adverse events in the included studies.

Introduction: Intensive care unit (ICU) patients often experience decreased consciousness or cognitive impairment. Sepsis is one of the major causes of these conditions in the ICU. Electroencephalography (EEG) is a valuable tool for detecting sepsis-associated encephalopathy in ICU patients. It is critical to predict the neurological outcomes of these patients.
Objectives: This study was performed to investigate the EEG findings and search for correlations between EEG abnormalities and prognostic scores of patients with sepsis.
Methods: We conducted this study by reviewing the medical records of a total of 145 sepsis patients who undergo EEG monitoring in the ICU through Neurology consultation. We reviewed neurologic examination, including the Glasgow Coma Scale motor scoring and EEG data. They were treated according to the international guidelines for sepsis. The medical history, seizure, inflammatory biomarkers (CRP and WBC), and prognostic scores for sepsis (sequential organ failure assessment [SOFA]), Acute Physiology and Chronic Health Evaluation (APACHE)II scores, Simplified Acute Physiology Score (SAPS)II scores were analyzed. The neurologic outcomes were grouped based on the modified Rankin scale (mRS) on discharge and 6 months after discharge, and categories 4, 5, and 6 were considered poor outcomes.
Results: The source of infection was the chest for 100, the urinary tract for 19, the abdominal cavity for 13, and soft tissue for 13 patients. Of the patients, 43% (63/145) had poor outcomes (mRS: 4–6) including a vegetative state or death. We did not find any significant associations between EEG abnormalities and inflammatory biomarkers (CRP and WBC). EEG patterns, including background suppression, burst suppression, and generalized periodic epileptiform discharges ($p < 0.001$), were significantly associated with prognostic sepsis scores or poor neurologic outcomes.
Conclusions: We found that EEG findings were very closely related to the overall prognosis and long-term neurologic outcomes of sepsis patients.

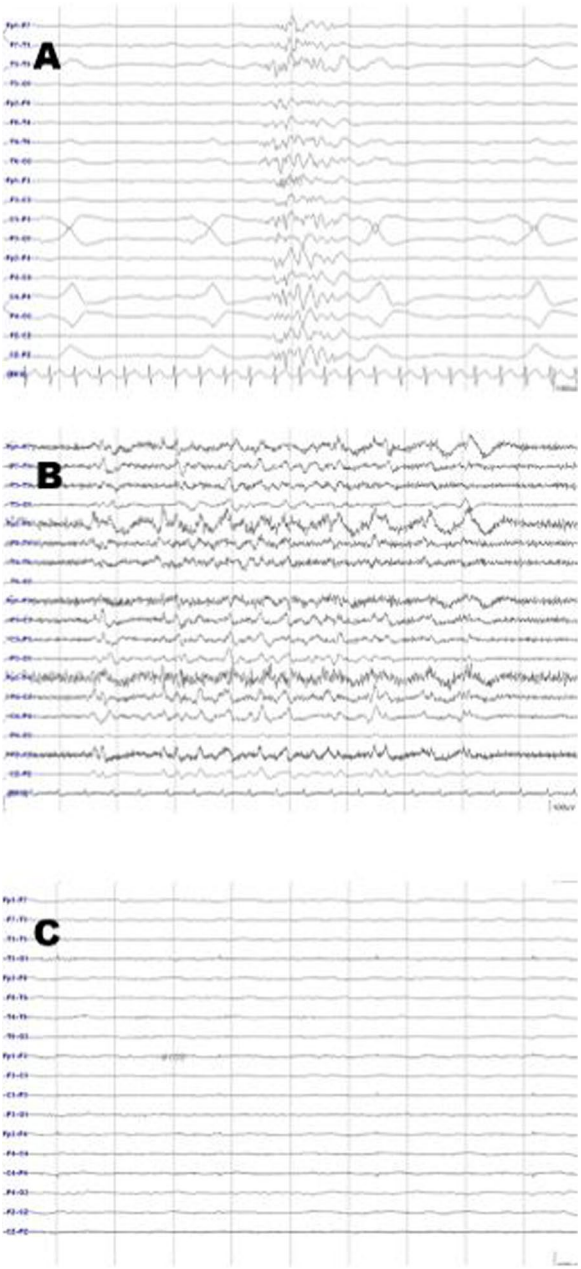

Figure 1 (abstract 001291) Currently known specific electroencephalogram findings with sepsis associated encephalopathy patients. a) Burst-suppression pattern, b) Periodic EEG patterns, c) Generalized background suppression

Table 2 (abstract 001291) Bivariate correlation between EEG and other variables of interest Spearman's rho coefficient analysis

	Spearman's Rho	P value
Age	-0.194	0.237
Serum CRP	0.204	0.212
WBC	0.007	0.968
SOFA	0.499	0.001
MRS	0.534	0.000

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001295

Introduction: During the COVID-19 pandemic, numerous studies found an association of disease severity with obesity and other metabolic risk factors, including diabetes, hypertension, and smoking. Within the respiratory management of the patient with obesity, there are various challenges associated with the greater amount of adipose tissue and its direct repercussion on the diaphragm and rib cage, together with a state of low-intensity chronic inflammation; which favors a deleterious prognosis in these patients. The prolonged requirement of ICU stay increases the risk of nosocomial infections, such as ventilator-associated pneumonia (VAP).
Objectives: In this study we can examine the relationship between obesity and the severity of COVID-19 pneumonia, as well as the impact of VAP.
Methods: Observational, descriptive and cross-sectional study of patients admitted to the ICU from January 2020 to December 2020 with COVID-19 and requiring invasive mechanical ventilation. 221 patients with positive cultures, clinical picture or radiological changes suggestive of VAP were included. For quantitative variables, they were expressed as mean and standard deviation, as well as free distribution median and interquartile range, using the Kolmogorov Smirnov normality tests; for the qualitative ones, it was expressed in frequency and percentage, using the X2 or Fisher's exact test. Kaplan Meier survival curves were performed. Assigning a value of $p < 0.05$ as statistically significant.
Results: A total of 208 patients were analyzed. 77 women (34.8%), 144 men (65.2%). The median age of the total was 56 (47–64.5). BMI of 31 with SD 6.3, $p = 0.020$. LOS of 23 (18–30) $p = 0.034$, ventilation days 18 (14–25) $p = 0.001$; the days ICU stay, 19 (15–24) $p = 0.276$. The most frequent pathogen was Acinetobacter baumannii MDR, followed by Pseudomonas aeruginosa. The median survival was reached on day 23 with an omnibus of $p = 0.003$ 95% CI 20.4–29.5, a strong correlation R2 0.73 (73%), on day 23 of hospitalization, the days of mechanical ventilation explain an R2 89% associated with dying after day 23 (95% CI 18.7–25.2 $p = 0.005$), with a Hazard Ratio of 1.64, that is, the higher the BMI > 31, the greater the risk of dying after 23 days of mechanical ventilation assistance and days hospitalization. Mean survival was reached after 23 days of hospital stay in the ICU with a $p = 0.003$. R2 0.73.
Conclusions: In our study, obese patients with a BMI > 31 who required ventilatory management due to COVID-19 and who had nosocomial pneumonia had higher mortality at 23 days of hospital stay.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001296

Introduction: The linear relationship between brain tissue oxygen tension (PbtO2) and cerebral blood flow (CBF) and the difference between arterio-venous oxygen content (i.e., cerebral oxygen utilization) has been well described. However, how arterial oxygen pressure (PaO2) can modulate PbtO2 and brain metabolism in the absence of tissue hypoxia remains poorly reported.
Objectives: To investigate the relationship between PbtO2, PaO2 and lactate to pyruvate ratio (LPR), assessed by cerebral microdialysis (CMD) in patients with traumatic brain injury (TBI).
Methods: For this study, patients with severe adult (> 18 years) TBI, undergoing multimodal neuromonitoring according to local practices, were eligible if: a) PbtO2 always > 20 mmHg; b) available LPR from CMD; available PaO2. For each PaO2 value, the corresponding LPR and the mean PbO2 value over the preceding 20 min were used. Also, the BOx Ratio (PbtO2/PaO2) and the oxygen metabolism ratio (OxMR = PaO2/LPR) were computed. Correlation among variables was assessed using Pearson's r coefficient.
Results: Among 26 patients with available data, 7 patients met the inclusion criteria for final analysis. Median age was 40 [IQR 37–45] years; mean cerebral perfusion pressure over time was 91.7 ± 14.5 mmHg, while median PbtO2 values was 25 [21–29] mmHg and BOx ratio 0.23 [0.19–0.29]. The number of combined measurements were 93 (11 [9–17] per patient). LPR had a stronger correlation with PaO2 levels (r = -0.351 [95% confidence interval, 95%CI − 0.484 to − 0.149] and a weaker correlation with PbtO2 values (r = -0.266 [95%CI − 0.434 to − 0.034]. There was no correlation between the BOx Ratio and LPR, while the OxMR was significantly correlated with PbtO2 (r = -0.266 [95%CI − 0.434 to − 0.034].
Conclusions: In patients without tissue hypoxia, the OxMR significantly correlated with PbtO2 values, suggesting this ratio could help to better understand the relationship between tissue oxygenation and metabolism.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001298

Introduction: Veno-arterial Extracorporeal Membrane Oxygenation (VA-ECMO) has been implemented as rescue in case of refractory cardiogenic shock (CS) or during resuscitation (extracorporeal cardiopulmonary resuscitation, e-CPR). Exposure to hyperoxemia is common during VA-ECMO, but its impact on mortality and neurological outcome remains unclear.
Methods: We conducted a systematic review and metanalysis (PubMed and Scopus) investigating the effects of exposure to hyperoxemia on mortality and neurological outcome in patients supported by VA-ECMO. Whenever provided, we used the Odds Ratio (OR) adjusted for confounders. Results are reported as OR and 95% confidence interval (CI). Subgroup analyses were conducted according to indication for VA-ECMO and cut-off of hyperoxemia.
Results: Data from 11 observational studies were included. Ten studies reported data on mortality (6 on e-CPR, 4 on CS), only 4 on neurological outcome (eCPR only). As shown in Tables below, exposure to hyperoxemia was associated with higher mortality (OR:1.81, 95%CI 1.22–2.71; p = 0.003;I2 = 81%) and worse neurological outcome (OR:1.97, 95%CI 1.30–2.96; p = 0.001;I2 = 0%). This association remained valid the subgroup analyses conducted according to the cut-off of hyperoxemia (> 200 or > 300 mmHg, Tables 1.1 and 1.2) or to the indication for VA-ECMO (Tables 2.1 e 2.2), although the association with mortality remained uncertain in the eCPR population (p = 0.07). The analysis using adjusted OR only confirmed the increased mortality (OR 1.72 [1.00–2.97], p = 0.05) and poorer neurological outcome (OR 1.99 [1.18–3.37], p = 0.01) in patients exposed to hyperoxemia.
Conclusions: Exposure to hyperoxemia after initiation of VA-ECMO is associated with increased probability of poor neurological outcome and mortality. Clinical efforts should be made to avoid severe hyperoxemia during VA-ECMO support.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001299

Introduction: Despite international guidelines recommend prophylactic and therapeutic measures for presumed or proven infections, invasive fungal infections still mean diagnostic and therapeutic challenge in critically ill patients.
Objectives: Evaluation of the connection between guideline adherence and outcome in critically ill patients receiving antifungal therapy.
Methods: We retrospectively collected the clinical data of patients receiving antifungal therapy for at least two days in 2013–2014 and 2017–2018 in a tertiary intensive care unit. Guideline conformity was assessed retrospectively by two independent experts. In case of disagreement, a third independent expert's opinion decided.
Results: 107 patients were enrolled, 52 and 55 from the two study periods, respectively. The median age was 68 years (IQR: 61–78), the median SAPS II score was 59.5 (IQR: 42.75–74.25). Pulmonary or abdominal source was present in 35.5% and 55.1%, respectively. In 41.1% of the cases the fungal infection was proven by culture or serology.
Guideline adherence was higher in 2018, guideline-based therapy was prescribed in 52.7% vs. 26.9%, respectively, p = 0.007. The rate of proven infections was also higher in the latter period (50.9% vs. 30.8%, respectively, p = 0.034), but less pulmonary infections were seen (23.6% vs. 48.1% in 2018 and 2014, respectively, p = 0,008). Although the median SAPS II score was higher in 2014 (62.00 (IQR: 49.00–78.00) for 2014 and 45.00 (IQR: 35.00–75.00) for 2018, respectively, p = 0.002), we haven't found significant difference between the two periods in 28 days mortality.
Comparing the prophylactic and targeted therapy groups, patients with proven fungal infection were more likely to have bloodstream infections, the escalation rate, and 28 days mortality (24.2% vs. 54.8%, p = 0.001) was higher in that group. Clinicians were more likely to follow the guidelines in case of antifungal prophylaxis: adequate dosage, proper duration of therapy and fully guideline-based therapy (55.6% vs. 18.2%; p < 0.001) was significantly more frequent in the prophylactic group.
Risk factors for 28-days mortality were assessed in separate logistic regression models in the prophylactic and targeted therapy group. Inappropriate fungal prophylaxis was independently associated higher 28-days mortality (OR = 7.62; 95% CI = 1.77–32.81; p = 0.006). However, guideline adherence showed no beneficial impact on 28 days mortality in patients with proven fungal infection.
Conclusions: Our retrospective analysis shows that guideline adherence is beneficial in the prophylaxis of invasive fungal infections, but individual therapy, based on expert clinician's opinion is reasonable, and non-inferior in targeted therapy compared to strict guideline-adherence.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001301

Introduction: After a prolonged intensive care unit (ICU) stay, patients are characterized by an increased mortality and morbidity.
Objectives: The primary aim of this study was to assess the prognostic value of nutritional status, body mass composition and muscle strength, as assessed by body mass index (BMI), bioelectrical impedance analysis (BIA), handgrip (HG) test, and biological features allowing estimation of the prognostic inflammatory and nutritional index (PINI), on one-year survival at the end of a prolonged ICU stay.
Methods: This was a multicenter prospective observational study. Survivor patients, older than 18-year-old, with ICU length of stay > 72 h, were eligible for inclusion. BIA and HG were performed at the end of the ICU stay. Malnutrition was defined by BMI and fat-free mass index. The primary endpoint was one-year mortality. Multivariable logistic regression was performed to determine parameters associated with mortality.
Results: 572 patients were included with a median age of 63 years [53.5;71.1], BMI of 26.6 kg/m^2 [22.8;31.3], SAPS II of 43[31;58] and ICU length of stay of 9 days [6;15]. Malnutrition was observed in 142 (24.9%) of the patients. During the one-year follow-up after discharge, 96 (18.5%) patients died. After adjustment, a low HG test score (aOR = 1.44 [1.11;1.89], $p = 0.01$) was associated with one-year mortality. Patients with low HG score, malnutrition and PINI > 20 had a one-year death rate of 42%. Conversely, patients with none of those parameters had a one-year death rate of 6.93%.
Conclusions: BIA, HG and PINI score at the end of ICU stay could be used to predict one-year mortality. Their performances to identify patients eligible for a structured recovery program could be studied.

Introduction: Abdominal normothermic regional perfusion (A-NRP) in controlled donation after circulatory death (cDCD) is recommend in preference to in situ cooling and rapid procurement (1B). This procedure requires experience and the availability of extracorporeal membrane oxygenation (ECMO), that sometimes is limited to tertiary hospitals. In order to provide support with A-NRP in centers with cDCD programs but without ECMO access, the region of Madrid created a A-NRP team. Our center, with VV and VA ECMO experience, is a part of a one week-on/one week-off roster.
Objectives: Describe the experience of our center as part of the Mobile ECMO team since the program begun.
Methods: Descriptive and retrospective study (April 2017-December 2022). We included all Mobile ECMO team outings. We studied demographic data, ICU length of stay and the reasons for withdrawal of life-sustaining treatments (WLST) of the donors. Number of organs evaluated and the reasons for discard, ECMO run and complications related with ECMO canulation were also reported.
Results: Our ECMO Mobile team was mobilized 41 times to ten different hospitals during the period studied. A-NRP was successfully performed in 37 cases.
Of the 37 utilized donors 21 (59%) were male with mean age of 58 ± 14 years. The reasons for WLST were anoxic encephalopathy following cardiac arrest (n = 17, 46%), catastrophic brain injury after ischemic/hemorrhagic cerebrovascular event or traumatic brain injury (n = 16, 43%), terminal respiratory illness (n = 3, 8%) and one case (3%) after euthanasia. Mean ICU length of stay was 9 ± 8 days.
Cannulation problems were reported in 15 cases (40%) with 4 hemorrhagic complications during vessels cannulation and 11 events of non-progression of the aortic balloon that needed surgical cross clamp of the aorta before A-NRP commencement.
Mean warm ischemia times were 15 ± 6 min. Mean duration of the A-NRP was 82 ± 27 min.
Of the 64 kidneys, 32 livers and 11 bilateral lungs evaluated 58 kidneys, 18 livers and 7 bilateral lungs were finally implanted. The main reason for discard was unfavorable visual assessment and surgical complications and only in one case because of prolonged warm ischemia time.
Conclusions: The establishment of a Mobile ECMO team is feasible across the region of Madrid. This program allows to potential cDCD donors from hospitals without ECMO technology be evaluated for A-NRP, increasing the pool of organs suitable for transplantation.
Cannulation problems are common but in most of the cases the A-NRP is possible, that emphasized the fact that experience and dedicated team is the cornerstone to achieve good results.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001303

Introduction: European population is aging and the burden on the intensive care unit (ICU) admissions of very old patients (age ≥ 80 years) is also rising, representing approximately one fourth of all ICU admissions. [1] Despite the advances in the support for older critically ill patients, the long-term morbidity and mortality rates remain substantial. [2] Chronological age alone is an insufficient predictor of outcome from critical illness, as there is often significant variation in physiological changes in older people.[3] Frailty has become recognized as an important prognostic indicator in critically ill patients in contrast with age. [4].
Objectives: The aim of this study is to identify the impact of frailty on the length of mechanical ventilation, length of stay (LOS) in the ICU and in the hospital and on ICU and hospital mortality in very old patients.
Methods: In a single center, this observational study included all very old (≥ 80 years) patients admitted to a general ICU between the 1st of January and the 31st of December of 2022. Demographics, SAPSII, SOFA, duration of mechanical ventilation, use of vasopressors and measurement of frailty using the Clinical Frailty Scale (CFS) were collected. The analyses were performed with the SPSS (R) statistics (vs 25) using t-test, correlation coefficients (Pearson) and survival analysis (log-rank test). Significant was defined if $p < 0.05$.
Results: A total of 59 patients (47.5% male) with a mean age of 85.7 ± 4.3 years were included in this study. The mean CFS of 4.68 ± 1.55 points and more than half of the patients (50.8%) were classified as frail (CFS ≥ 5). Admission was unplanned in 89.8% (n = 53) of the patients. Either SAPSII and SOFA total had a non-significant correlation coefficient with CFS ($p = 0.35$ and $p = 0.448$, respectively). ICU-mortality was 35.6% and the hospital mortality was 47.5%. A total of 26 (44.1%) patients were mechanical ventilated and mean duration of ventilation was 8.8 ± 7.0 days. The ICU LOS in frail (CFS ≥ 5) patients 7.13 ± 5.89 days and 11.86 ± 9.96 in non-frail (CFS < 5) which was found to be significant ($p = 0.005$) and ICU mortality was higher in the frail patients ($p = 0.013$). There was no significant difference between frailty and the duration of mechanical ventilation or hospital LOS or hospital mortality. In the ICU the non-frailty population has significantly survival likelihood (log-rank test, $p = 0.008$).
Conclusions: Among very old patients (≥ 80 years) admitted to the ICU, frailty (CFS ≥ 5) was associated with a shorter LOS in the ICU but increased ICU-mortality. Frailty did not correlate with the severity illness score (SAPSII) and organ disfunction (total SOFA). These findings may indicate that the use and the impact of CFS in the ICU setting as a predictor of mortality is not fully studied. In conclusion, the admission of geriatric patients to the ICU is increasing and frailty is an emerging prognostic factor for the outcome in the ICU which may play an important role in the clinical evaluation of very old patients but with a high dependency of the local policy of admission and discharge.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001304

Introduction: Cardiac disease is the most common cause of death in the peri liver transplantation (LT) period. Patients with end-stage liver disease are at increased risk of liver specific cardiovascular complications such as portopulmonary hypertension and cirrhotic cardiomyopathy (CCM), in addition to the risk of common cardiac comorbidities prevalent in the general population. Echocardiography is an integral part of the cardiovascular assessment for LT work up. We conducted a service evaluation and improvement project to standardise echocardiographic assessment for LT in our institution.
Methods: A single centre, retrospective evaluation of echocardiograms in adults who underwent liver transplant assessment in a large tertiary LT centre in the UK between the 09/07/2021 and 28/10/2022. Following initial evaluation, a standardised set of parameters were implemented in order to optimise quality of assessment. Echo reports pre and post intervention were compared to assess whether the parameters for a complete assessment were reported.
Results: A total of 93 and 133 patients were identified in the pre and post intervention group respectively. Complete cardiac evaluation including comments on LV, RV systolic and diastolic function, presence of pulmonary hypertension (PH) and regional wall motion abnormality (RWMA) occurred in 5/93 (5.4%) of the pre-intervention compared to 28/133 (21.1%) in the post intervention group. LV ejection fraction was consistently reported across both time periods; 89/93 (95.7%) and 130/133 (97.7%) respectively. Improvements in reporting were seen relating to PH and RWMA occurring in 26 (28%) vs 79 (59%); and 38 (41%) vs 100 (75%) respectively. However, there was no change in diastolic function reporting, 36 (39%) vs 54 (41%). CCM was diagnosed in 0 patients pre-intervention, and 3/54 (5.6%) patients post intervention in those with complete systolic and diastolic assessments. PH was ascertained pre and post intervention in 1/26 (3.8%) and 5/79 (6.3%) respectively, necessitating subsequent diagnostic right heart catheterisation.
Conclusions: Overall, echocardiography reporting for LT assessment improved following implementation of standardised reporting criteria. However, determination of diastolic function and cirrhotic cardiomyopathy remain areas requiring further improvement. Given the increased risk of cardiac dysfunction in these cohort of patients, complete reporting in pre-assessment investigations is essential and needs to be emphasised.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001306

Introduction: Assessment of fluid-responsiveness (FR) is crucial in critically ill patients. Ultrasonographic assessment of inferior vena cava collapsibility (IVCc) and left ventricular outflow tract velocity time integral (LVOT-VTI) variability are commonly utilized non-invasive tests (1). However, several obstacles may preclude their use due to suboptimal ultrasound window. Appealing alternatives for the FR assessment might be the variability of aortic velocity time integral (Aorta-VTI) in the suprasternal window, or the internal jugular vein collapsibility (IJVc) (2).
Objectives: To determine feasibility of alternative ultrasound methods for FR assessment.
Methods: We performed a prospective observational single-centre study on 40 healthy volunteers. We first evaluated the feasibility of suprasternal Aorta-VTI variability [(Velocitymax—Velocitymin) / Velocitymean] and of IJVc [(Diametermax—Diametermin) / Diametermax], and then their ability in predicting FR. As comparators, other parameters investigated were the LVOT-VTI variability and the IVCc (from both subcostal and transhepatic window, both in M-mode and with the aid of automated border detection). FR was determined according to changes in cardiac output (CO) between its baseline (time of recording of parameters), and the highest value of CO registered within two minutes after the passive leg raising (PLR) manoeuvre.
A cut-off of a 10% increase in CO was used to define FR. Values of CO were obtained with the non-invasive continuous CO monitoring (Clearsight, Edwards Lifescience, US). Analysis was conducted with the evaluation of the Area Under the Receiver Operating Characteristic Curve (AUC-ROC); correlation between variables was conducted with Pearson r coefficient.
Results: The feasibility to obtain measurements of suprasternal Aorta-VTI variability and of the IJVc were 95% and 97.5%, respectively. The highest value of AUC among the ROC curves was seen for the LVOT-VTI variability (0.85; cut-off 10.1%, sensibility 90%, specificity 75%), whilst the performance of all other methods was poor (Table 1). Suprasternal aortic-VTI was the only method showing a significant correlation with the LVOT-VTI ($p = 0.005$; moderate degree $r = 0.47$). Conversely, IJVc had no correlation with the all the IVCc measurements (subcostal or transhepatic, M-mode or automated border detection).
Conclusions: In a population of healthy volunteers, we found excellent feasibility for the calculation of suprasternal Aorta-VTI variability and of the IJVc. However, their predictive value for estimating FR seems to be of limited value. Such indexes should be evaluated in critically ill patients. In particular, the correlation of suprasternal Aorta-VTI variability with the LVOT-VTI variability seems promising.
Table 1 (abstract 001306) .

Method	AUC value
LVOT-VTI	0.85
Suprasternal Aortic-VTI	0.50
IJVc M-Mode	0.52
IVCc subcostal in M-mode	0.52
IVCc subcostal in automated border detection	0.61
IVCc transhepatic in M-Mode	0.56
IVCc in automated border detection	0.66

Introduction: Metformin intoxication causes lactic acidosis inhibiting Krebs' cycle and oxidative phosphorylation. The Extracorporeal Treatment In Poisoning group recommends Continuous Renal Replacement Therapy (CRRT) to remove metformin in critically ill patients (1). From 2012, KDIGO guidelines recommend using Regional Citrate Anticoagulation (RCA) due to its lower risk of bleeding than systemic heparin (2). Metformin inhibits citrate metabolism in the Krebs' cycle3; therefore, the risk of citrate accumulation can be supposed with scarce evidence from the literature (4). The direct measurement of citrate is rarely available, and its accumulation is usually estimated by T/I calcium ratio.
Objectives: The aim of the present case series is to describe how the physiochemical approach to acid–base could safely exclude significant citrate accumulation.

Methods: Three patients admitted to the Intensive Care Unit (ICU) with a diagnosis of Metformin-associated Lactic Acidosis (MALA) and treated with CRRT (Baxter International SA, Zurich Switzerland) were studied (Table 1). A mathematical model was developed to simulate the expected citrate accumulation occurring during Continuous veno-venous hemofiltration (CVVH) set as follows: blood flow 150 ml/min, RCA with citrate of 18 mmol/L at 1500 ml/h, post-dilution replacement flow 1500 ml/h, no weight loss. The potential citrate blood accumulation was indirectly monitored as a Total-to-Ionized calcium ratio (*T/I ratio*) above 2.5 and by calculating the Strong Ion Gap (SIG) to identify an increased concentration of Unmeasured Anions (UA).
Results: All three patients showed a resolution of MALA. The SIG calculated after 48 h of treatment was always below 6 mEq/L (Figure 1). In the absence of any metabolism, the estimated citrate accumulation should have been 7 mmol/L after 48 h of CVVH, corresponding to 21 mEq/L of SIG. The *T/I ratio* was consistently lower than 2.5, and the systemic ionized calcium concentration was above 0.90 mmol/L.
Conclusions: Our data support the safety of the use of diluted citrate during CRRT treatment in patients with metformin intoxication. Monitoring the SIG could be an additional valuable tool to detect and monitor citrate accumulation in this context.

Table 1 (abstract 001307) Patient characteristics at ICU admission.

Variables	Patient 1	Patient 2	Patient 3
Age (year)	66	66	71
Sex	Female	Male	Female
Weight (Kg)	70	75	75
Charlson Comorbidity Index	7	6	6
Metformin concentration (mcg/mL)	28.0	10.5	82.5
Chronic Kidney Disease	No	Yes	No
Creatinine (mg/dL)	8.1	4.1	9.0
Urea (mg/dL)	140	114	190

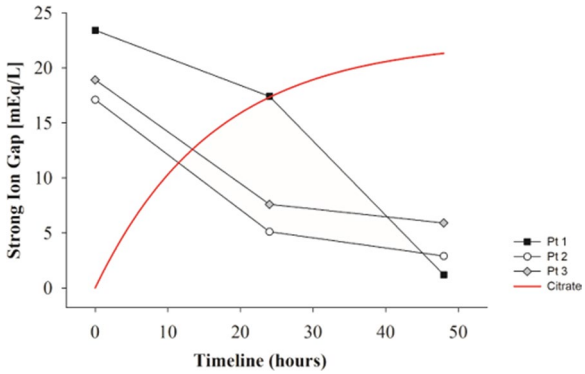

Figure 1 (abstract 001307) SIG in the three patients and calculated citrate accumulation with no metabolism (red line)

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001308

Introduction: The prevalence of ICU-acquired hyponatremia is about 15%, and it is associated with poor outcomes and increased mortality (1). About 10% of patients admitted to the intensive care unit (ICU) receive continuous renal replacement therapy (CRRT) (2,3), exposing them to large exchanges of volume and rapid electrolyte shifts.
Objectives: The aim of the present study was to describe variation in sodium concentration ([Na+]) during continuous veno-venous hemofiltration (CVVH) and assess the incidence of hyponatremia after 48 h of CVVH treatment.
Methods: Oligo-anuric ICU patients with clinical indications for CRRT (PrimsmaMax, Baxter) were enrolled. The CRRT was performed in CVVH modality, with 150 ml/min of blood flow. Regional anticoagulation was achieved with diluted citrate (Prismocitrate 18/0; Gambro) at 1500 ml/h. Phoxilium (Baxter Healthcare Spa) or Multibic 2 K (Fresenius Medical Care, Germany) was employed as replacement solutions and administered post-dilution at 1500 ml/h. Of note, all three solutions have a declared [Na+] of 140 mmol/L. [Na+] was measured by direct ion-selective methods (RAPIDPoint 500 Blood Gas System, Siemens Healthcare Diagnostics) at the beginning of CVVH treatment (T0) and after 3, 6, 12, 24, 48, and 72 h. Osmolality was measured by the freezing point at T0 and after 24, 48, and 72 h.
Sodium variations were analyzed via one-way ANOVA for repeated measures or one-way ANOVA for repeated measures on Ranks, using Bonferroni's or Dunn's correction for post hoc analysis, respectively. A binomial test was performed to compare the incidence of hyponatremia with the expected incidence reported in the literature (*i.e.,* 15%). Data are reported as mean ± standard deviation.
Results: Twenty-six patients aged 62 ± 14 years were enrolled. Three patients were hyponatremic (130 ± 2 mmol/L), seven patients were hypernatremic (151 ± 4 mmol/L), and sixteen normonatremic (141 ± 3 mmol/L). Overall, [Na+] decreased from 142 ± 7 to 135 ± 3 mmol/L ($p < 0.001$) in 48 h (Figure 1). After 48 h of CVVH, a higher than expected prevalence of hypoosmolar hyponatremia (133 ± 1 mmol/L, 295 ± 9.6 mOsm/L) was recorded (69% vs. 15%, $p = 0.02$) (Fig. 2).
Conclusions: During CVVH, we observed after 48 h a significant decrease in [Na+] and a high incidence of hyponatremia, confirmed by osmolality.

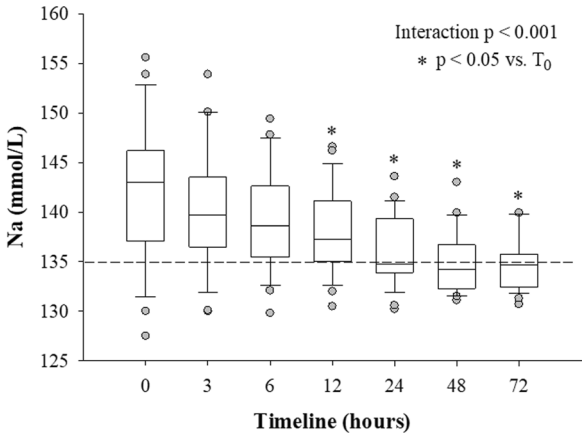

Figure 1 (abstract 001308) Change in sodium concentration during CVVH treatment

Mortality risk in covid-19 veno-venous extracorporeal membrane oxygenation—experience of a Portuguese tertiary hospital

F. Sequeira[1], A. Marques[1], L. Linhares[1], R. Freitas[1], E. Sousa[1], P. Martins[1]
[1]Intensive Care Unit, Centro Hospitalar e Universitário de Coimbra, Coimbra, Portugal
Correspondence: F. Sequeira
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001311

Introduction: Veno-venous extracorporeal membrane oxygenation (VV-ECMO) has become an established therapy to support ARDS in COVID-19 patients failing conventional management. However, this therapy has several potential serious complications, with an estimated incidence of in-hospital mortality after ECMO initiation of 48% (Data from the Extracorporeal Life Support Organization) and is also a limited resource. More accurate predictors of prognosis of COVID-19 patients on ECMO are needed to understand which patients can benefit from this support.
Objectives: The aim of the study was to determine predictors of mortality in patients with COVID-19 supported with ECMO.
Methods: A retrospective observational cohort study of COVID-19 VV-ECMO patients, cannulated between April 1, 2020, and December 31, 2022, at a tertiary center. The primary outcome is in-hospital mortality.
Results: Forty-seven patients (mean age 51.68 ± 11.41, male 68.09%) received VV-ECMO for severe COVID-19 related ARDS.
Before ECMO initiation, median body-mass index was 35.8 ± 7.94 kg/m^2, mean Simplified Acute Physiology Score (SAPS) II was 37.70 ± 14.94, mean Sequential Organ Failure Assessment (SOFA) score was 7.64 ± 2.54, mean PaO2/fraction of inspired oxygen ratio was 80.85 ± 21.90, most patients received prone positioning (89.36%) and non-invasive ventilatory support before endotracheal intubation (61.70%). The median duration until ECMO initiation was 3.7 days ± 4.3. The median duration of ECMO support was 21.13 days ± 14.41.
The most frequent post-cannulation complications were ventilator associated pneumonia (n = 32; 68.09%), bleeding complications (n = 20; 42.55%), bloodstream infections (n = 11; 23.40%) and thrombotic complications (n = 8; 17.02%).
Mortality was 38.30% (n = 18). In patients who died, the median age was 59.28 ± 7.54, 15 male, duration until ECMO was 3.3 days and the median duration of ECMO support was 23 days.
Predictors of mortality were advanced age (OR 1.187, 95% CI 1.066–1.323, p = 0.002), SAPS II (OR 1.056, 95% CI 1.006–1.108, p = 0.026) and SOFA (OR 1.659, 95% CI 1.150–2.395, p = 0.007) were associated with increased risk of mortality. High BMI was not a predictor of mortality (OR 0.87, 95% CI 0.73–1.028, p = 0.1).
Youden's test showed that the best cutoff value of age to predict mortality was 54.5 (sensitivity 83.3%, specificity 72.4%) and AUC 0.83, best cutoff value of SOFA was 8 (sensitivity 83.3%, specificity 55.2%) and AUC 0.75, best cutoff value of SAPS II was 33 (sensitivity 66.7%, specificity 69%) and AUC 0.70.
Conclusions: As expected, age, SOFA and SAPS II were identified as individual predictors of mortality of COVID-19 patients submitted to VV-ECMO treatment.
Other parameters that we anticipated in the clinical setting as important predictors of mortality (namely PaO2/FiO2), did not prove relevance.
Adding to the discussion and in line with literature elevated BMI was a protective factor.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001312

Introduction: COVID-19 coagulopathy is associated with poor prognosis, characterized by a significant increase in fibrinogen (Fib), D-Dimers and a normal or slightly altered platelet count, prothrombin time and activated partial thromboplastin time. A state of "hypercoagulopathy" (HyperC) and "hypofibrinolysis" (HypoF) coexists, only detected by viscoelastic tests (VET). Extracorporeal membrane oxygenation (ECMO), often used as a rescue therapy in SARS-CoV-2 infection, is associated with coagulation abnormalities including life-threatening hemorrhage, thrombosis, and thromboembolic events, triggered by contact of blood with a foreign surface and the resulting activation of both coagulation and inflammatory pathways.
Objectives: We aim to evaluate and characterize the longitudinal hemostatic profile during ECMO in COVID-19 using VET- ROTEM®.
Methods: Prospective, nonblinded, non-randomized study. Consecutive recruitment of adult COVID-19 patients admitted to our hospital's ICU, during a 6-month period. Patients with thrombosis in the previous 3 months, pregnancy, hormone therapy, and congenital coagulopathies were excluded. Patients were tested every 5 days, at discharge and in complications.
Results: We observed a progressive decrease in plasma levels of Fib throughout hospitalization, as the patient progressed to discharge. The CFT-ExTem is < 45 in 4 patients until the 3rd sample (15th day of ECMO, on average). The MCF-FibTem is > 22 and the MCF-EXTEM is > 68, especially in the first 3 samples in all patients. CT-ExTem is never < 45 and LI60-EXTEM is never < = 3.
Evaluation of hemostasis using viscoelastic tests in patients with SARS-COV-2 infection on ECMO

	Hemostasis lab tests	
	1st sample	last sample
FvW:RC	244.0 (68.4) 250.0; (221.0/250.0)	265.0 (110.9) 274.5; (226.0/ 313.5)
CT-ExTem	77.1 (17.0) 83.0; (63.0/84.0)	105.0 (24.8) 114.0; (95.5/ 119.0)
CFT-ExTem	48.7 (11.1) 46.0; (41.0/ 55.0)	89.7 (15.6) 92.0; (82.5/ 98.0)
MCF-ExTem	71.9 (3.6) 72.0; (70.0/74.0)	63.3 (3.1) 64.0; (62.0/ 65.0)
MCF-FibTem	33.2 (6.9) 33.0; (29.0/ 34.0)	15.7 (6.7) 14.0; (12.0/ 18.5)
LI60-ExTem	88.3 (33.1) 99.0; (99.0/100.0)	98.0 (1.7) 97.0; (97.0/ 98.5)

Conclusions: Data analysis of patients under ECMO support (see Table): n = 9, there were no deaths, bleeding complications in 4 (44,4%) patients and thrombotic complications in 2 (22,2%) patients.
Patients have the usual HyperC status described in COVID during the first 15 days of ECMO, especially due to MCF-Extem and MCF-Fibtem parameters. After this initial phase, patients present no longer a HyperC profile in Rotem®, which may have 2 causes: 1) decrease in Fib plasma levels throughout the course of the disease, probably related to control of inflammation pathways; 2) consumption/activation of platelets and other clotting factors by contact of blood with a foreign surface of extracorporeal circuit. There are HyperC parameters that are never altered: CT-Extem and CFT-Extem, which are highly dependent on the presence of heparin, never < 45. Additionally, LI60-EXTEM is never compatible with HypoF.
These findings may lead one to think that in patients on ECMO, the baseline state of COVID is "compensated" by the hyperfibrinolysis associated with this technique, due to lysis/consumption of platelets and clotting factors by the filter, and/or by regional anticoagulation of the circuit.

Alveolar-arterial oxygen gradient is a better marker of respiratory inssuficiency and hypoxemia in comparison with PaO2/Fio2

A. Montoro[1], J. P. Vázquez[2], A. Sierra[2], J. I. Amigo[2]
[1]ICU, Angeles Hospital Lomas, Mexico, Mexico; [2]ICU, Angeles Hospital Lomas, HUIXQUILUCAN, Mexico
Correspondence: A. Montoro
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001313

Introduction: Alveolar-arterial gradient can be useful as a predictor of hypoxemia, as well as an index of the ventilatory function. It can also defined the mechanism of hypoxemia as shunts or V/Q, leading to be of inmense help for the physician in decision making, also in diagnosis. Because of it describes the ventilatory function, it can predict severe cases of respiratory insufficiency despite some signs and symptoms are normal, or even if the PaO2/Fio2 index is normal.
Objectives: The aim of this study is to evaluate the D (A-a)O2 to determine respiratory insufficiency in comparison to the PaO2/Fio2.
Methods: Retrospective, in patients admitted at Hospital Angeles Lomas in México between March 2022 to March 2023. We retrospectively recollected clinical and arterial blood gas analyses at the admission. Respiratory insufficiency was defined by clinical and symptoms correlated and with the PaO2/Fio2. All the patients were divided in two groups, with respiratory insufficiency and no respiratory insufficiency.
Results: Overall, 60 patients were included in this study. Of these patients 41 (64%) were male and 19 (29.7) were female. 41 patients (68.33%) had respiratory insufficiency and hypoxemia, of this 90% reported dyspnea and only 6 (9.4%) were reported of COPD as respiratory comorbidity. Lineal regression showed that patients with respiratory insufficiency and hypoxemia were significantly more likely to be diagnosed or detected with D (A-a)O2 than PaO2/Fio2 (Pvalue 0.001 and 0.663 respectively).
Conclusions: Hyopxemia and respiratory insufficiency are one of the main pathologies in ICU admissions. To be accurate we can measure with several devices, but not all of this are very accurate. Alveolar-arterial oxygen gradient D (A-a)O2 is more useful than PaO2/Fio2 to identify a patient with respiratory insufficiency and hypoxemia and even can be useful to predict need of icu admission and predict the outcomes and mortality.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001315

Introduction: Nosocomial central nervous system (CNS) infections require rapid effective antimicrobial therapy. Reaching appropriate concentrations in CNS remains challenging because of blood- brain barrier and cerebrospinal fluid (CSF) turnover. The main goal of this multicenter prospective study was to explore PK/PD of Linezolid (LNZ) in CSF and efficacy of current dosing regimens in CNS infections.
Methods: Twenty five patients with external ventricular drainage (EVD) treated with LNZ by 600 mg every 12 h (two doses (2D), n = 17) or 8 h (three doses (3D), n = 8), for a CNS or other site infection. Blood and CSF samples were collected after steady-state (3–5 days), at predetermined sampling times. LNZ plasma data were first modelled by a population pharmacokinetic analysis. Thereafter, plasma parameters estimated and corrected for protein binding of 31% were fixed to fit unbound CSF concentrations. In the final model, parameters for both plasma and CSF data were simultaneously estimated. Then, Monte Carlo simulations were conducted to determine the probability of target attainment (PTA) and the cumulative fraction of response (CFR) in CSF of current dosing regimens against methicillin-resistant Staphylococcus aureus (MRSA) and methicillin-resistant Staphylococcus epidermidis (MRSE)[1].
Results: A two-compartment (one for plasma and one for CSF) linear model was found to be the most appropriate. LNZ was widely distributed into the CSF with a mean ratio of AUCCSF/AUCplasma of 90% for unbound concentrations. No difference in the penetration of LNZ into the CSF was observed between patients with and without meningitis. PTAs (AUC/MIC > 100) were greater than 90% only for MICs ≤ 0.5 mg/L after administration of.
the standard dosing regimens, suggesting no efficacy against MRSA and MRSE infections (CFR ≤ 13% and 70%, respectively).
Conclusions: Our results confirmed that 100% of unbound form of LNZ diffuse in CSF at steady-state [2- 4], which could allow a plasma therapeutic drug monitoring to estimate the free concentration of LNZ in CSF to adapt treatments. However, according to our results, none of the studied dosing regimens reached widely the PKPD target. For the usual dosing regimen, linezolid CSF concentrations seem insufficient to treat MRSA and MRSE with MICs upper than 0,25 mg/L in ICU patients with CNS infections.

PTA (AUC/MIC > 100) and CFR of linezolid in CSF fo

Daily dose	1 200 mg	1 800 mg

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001316

Introduction: Percutaneous tracheostomy (PT) is a widely performed procedure in intensive care units (ICUs). The use of ultrasound (US) prior to tracheostomy is described as a tool that can minimize some of the potential complications of this procedure. There are scant reports in the literature regarding the description of the technique. We present the ultrasound protocol of our unit, permormed by intensivists as well as the findings of anatomical alterations encountered.
Methods: Retrospective descriptive study. Neck ultrasounds performed prior to PT were evaluated between July 2010 and March 2023 in the ICU of Hospital Regional Concepción, Chile. The USs were performed bedside by an intensivist in all patients in which the requirement for PT was defined. The indication for PT was made according to local protocols and adjusted to clinical guidelines. The technique includes a review of airway characteristics, venous and arterial vessels, and masses. Specific search for vascular alterations or masses on the path of puncture, presence of goiter and presence of masses or nodes and deviations of the trachea (Figure 1). According to the findings, ultrasounds were classified into three groups: (1) Neck US suitable for standard PT technique (2) Neck US suitable for PT with precautions (3) Neck US contraindicates PT (Fig. 2). Findings that contraindicated PT were arterial structure, large caliber venous structure or mass on the puncture path and major tracheal deviation.
Results: During the study period, 820 ultrasound evaluations for PT were performed. They were distributed as follows: 782 patients (95.37%) group 1, 26 (3.17%) group 2, 12 (1.46%) group 3. The main findings were vascular (19), followed by masses (13) and deviations of the trachea (6). In group 2, alterations were 10 veins and 2 arteries between the trachea and the skin but lateral to the puncture path; 5 peritracheal adenopathies; 5 minor tracheal deviations (3 due to adenopathy, 1 post-surgical retraction, 1 unknown cause) and 4 goiters. In group 3, the alterations were 3 elongations of the brachiocephalic trunk, 3 large caliber arteries and 1 vein in the puncture path; 3 masses on the puncture path; 1 major tracheal deviation; 1 multinodular goiter. The PTs performed in group 2 had no immediate or ICU-stay complications. Of the PTs group 3, 10 were successfully performed surgically. The remaining 2 cases corresponded to brachycephalic trunk elongation and aberrant artery with a larger caliber in the tracheostomy region. After evaluation by otorhinolaryngology with secondary image, it was decided to maintain the orotracheal tube until extubation. The group of all altered USs (2 and 3) had no special characterization in age, sex, or external anatomical features of the neck.
Conclusions: The presented method for screening altered structures using ultrasound prior to percutaneous tracheostomy, is simple to perform, reproducible, and identifies important alterations that can condition severe complications of this procedure.

Ultrasound protocol prior to percutaneous tracheostomy
1. Hyperextension neck position
2. Linear transducer 7-12 Hz
3. Trachea review: location relative to the midline, transverse diameter measurement, distance from the skin, visualization of tracheal rings.
4. Blood vessels review: visualization of anatomical vessel trajectory, Doppler for the puncture trajectory, ruling out brachiocephalic trunk elongation.
5. Masses review: thyroid (goiter, masses), masses in the puncture trajectory, or lateral masses that alter the trachea trajectory.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001317

Introduction: Apart from their oxygen-carrying capacity, synthetic haemoglobin-based oxygen carriers (HBOCs) can also scavenge reactive oxygen species (ROS). They may therefore play a useful role in mitigating reperfusion injury following resuscitation from hypoxic insults in addition to providing an alternative to blood transfusions. HBOCs typically scavenge nitric oxide (NO), elevating blood pressure. While higher doses result in adverse outcomes related to excessive vasoconstriction (1), low doses that only marginally raise Hb levels and novel recombination techniques may be both safe and efficacious.
Objectives: To examine the safety profile of a novel, genetically engineered, recombinant and homogenously PEGylated HBOC given at low dose to instrumented healthy rats.
Methods: Under brief anaesthesia, healthy male Wistar rats ($n = 12$, approx. weight 300 g) underwent tunnelled central venous and carotid artery access. The lines were connected to a tether system that enabled free movement and access to food and water in their cages upon recovery. The animals were then randomised to receive either an intravenous bolus of HBOC (8.33 mL/kg) or Ringer's Lactate (RL). At pre-specified timepoints, blood pressure and temperature were recorded, and blood samples taken for blood gas analysis, organ function (troponin, creatinine, urea, bilirubin, albumin, ALT, CK and triglycerides), and inflammatory markers (IL-6, IL-10, C3a and C5a). Echocardiography was performed at baseline and at study end (24 h) under anaesthesia.
Results: The novel recombinant HBOC was well tolerated by the rats with no change in behaviour or appearance. No significant differences were found in lactate, acid–base balance, oxygenation variables and electrolytes. Cardiorespiratory function, temperature, weight, and markers of inflammation and organ function markers were similar at study end for both groups. The only exceptions were an increase in aortic blood flow peak velocity ($P = 0.047$) and a clinically insignificant rise in creatinine ($P = 0.04$) in HBOC treated rats (Figure 1). The engineered mutations of the current HBOC, targeting promotion of oxidative reactions and NO scavenging, did result in no impact on the blood pressure.
Conclusions: An intravenous bolus of our novel recombinant homogenously PEGylated HBOC did not result in any of the toxicity effects previously reported with higher doses of other HBOCs. We are now progressing to studies assessing its impact on ischaemia–reperfusion injury.

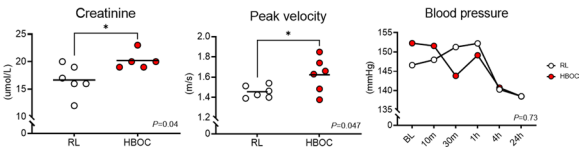

Figure 1 (abstract 001317) Creatinine, peak velocity, and blood pressure. RL: Ringer's Lactate; HBOC: Haemoglobin-Based Oxygen Carrier; BL: Baseline; h: hour; m: minute. All times stated for blood pressure are from the onset of i.v. drug infusion. Peak velocity and creatinine were performed at 24 h. *P < 0.05

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001321

Introduction: Medical nutrition in the Intensive Care Unit (ICU) needs to be tailored to meet patients' needs. It is not well established whether patients with SARS-Cov2 Acute Respiratory Distress Syndrome (ARDS) present differences compared to other ARDS patients in terms of calories – protein intake.
Objectives: We aimed to assess current clinical practices in terms of delivering protein support in critically ill patients with respiratory failure due to SARS-Cov2 or other severe ARDS etiologies.
Methods: We prospectively included mechanically ventilated patients due to SARS-Cov2 ARDS (ARDScov) or ARDS of other etiologies (ARDSot) who were hospitalized in the ICU of a tertiary hospital during the SARS-Cov2 pandemic period (2020—2021). The primary outcome of the study was the protein-intake/protein calculated demand ratio (pi/pc); this ratio was defined as the daily protein intake to daily caloric demands calculated by the European Society for Clinical Nutrition and Metabolism (ESPEN) formula.
Results: A total of 150 patients were included; 75 patients with severe ARDScov and 75 with severe ARDSot. The median (IQR) pi/pc was significantly lower ($p = 0.04$) in the ARDScov group 0.423 (0.33;0.52), compared to ARDSot (0.597, 0.40;0.79). Serum albumin values (mg/dl) measured on the first ICU day of were similar between the two groups (3.03, 2.9;3.1 vs 3.0, 2.8;3.2). Serum albumin (mg/dl) was significantly lower in ARDScov patient group on the seventh ICU day (2.54, 2.4;2.6 vs 2.79, 2.6;2.9 respectively, $p = 0.01$). ARDScov patients reached 42.43% (35.5;49.37) of the ESPEN recommended target compared to ARDSot patients who reached on average 64.92% (51.9;77.94) ($p = 0.001$). In ARDScov group, the pi/pc correlated significantly with the number of regurgitation episodes during ICU hospitalization ($r = 0.30$, $p = 0.02$).
Conclusions: This study shows that accomplishing recommended by ESPEN targets among patients with COVID-19 may be challenging. A specific strategy of nutritional intervention in SARS-Cov2 ARDS patients may be helpful to improve outcomes.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001322

Introduction: In infectious disease pandemics such as coronavirus disease 2019 (COVID-19), the number of severely ill patients requiring intensive care increases rapidly, and there is concern that the standard health care delivery system cannot provide the necessary medical care. Therefore, a flexible system must be established to prepare for a pandemic even in non-pandemic times. With centralization of the health care delivery system, which has been an issue in Japan, hospitals may be able to provide more advanced medical care; on the other hand, with the increased number of patients due to a pandemic, it may not be possible to treat all patients. Not only intensive care physicians but also various specialists in intensive care units need to conduct medical procedures such as mechanical ventilation and extracorporeal membrane oxygenation (ECMO) for severely ill patients. Thus, during the COVID-19 pandemic, severe cases had to be treated at nearby or family medical institutions that do not ordinally handle severely ill patients.
Objectives: To examine the severe infectious disease medical system during a future pandemic, an analysis of the trends in the health care delivery system for severe COVID-19 patients in Japan was conducted.
Methods: We analyzed data published by the Japanese government from January 2021 to February 2023. The number of hospitalized COVID-19 patients in all hospitals in Japan was collected using mainly the Gathering Medical Information System (G-MIS), and the number of positive COVID-19 cases in all medical facilities in Japan was collected by a law using mainly the Health Center Real-time Information-sharing System on COVID-19 (HER-SYS). We used the values obtained on the last Wednesday of each month.
We analyzed the relationship between the number of hospitalized COVID-19 patients and the number of hospitals that handle hospitalization of COVID-19 patients.
Results: The median total number of positive COVID-19 cases per day was 24,125 (interquartile range: 3,116–73,258), total number of hospitalized COVID-19 patients on ECMO or ventilators (HE) was 259 (93–387), and number of hospitals with HE was 129 (64–173). The total number of HEs showed a strong positive correlation with the number of hospitals with HE (correlation coefficient: 0.958 (95% confidence interval: 0.905–0.981), $p < 0.001$). Regarding the total number of HEs in each hospital, the proportion of hospitals with 1–4 HEs was negatively correlated (-0.935 (-0.971 to -0.857), $p < 0.001$), and the proportion with ≥ 5 HEs positively correlated, with the total number of HEs (0.935 (0.857–0.971), $p < 0.001$).
Conclusions: As the number of patients with severe COVID-19 increases, the number of hospitals providing care for such patients is also increasing. Our results suggest that the number of severe cases during a pandemic did not exceed the number of patients that can be handled at hospitals in Japan, which may be because a sufficient health care delivery system was in place.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001324

Introduction: Alterations in brain microcirculatory (BMC) in patients with sepsis and septic shock have not been well studied. The phenomenon could be studied by Using enhanced-contrast brain ultrasound (CEUS) with microbubble contrast administration., we prospectively investigated the clinical impact of brain microcirculation (BMC) alterations in patients with sepsis and septic shock.
Objectives: We studied (a) If CEUS could detect BMC alterations in sepsis (b) If these alterations are associated with alterations in global brain perfusion and cerebral autoregulation disturbance? (c) If these alterations are associated with cerebral complications and worse outcome?
Methods: For three days, mean arterial pressure, cardiac index (by transthoracic echocardiography), cerebral blood flow (by echo-color duplex of the carotid and vertebral arteries), brain autoregulation and the mean flow velocities of the middle cerebral arteries (by transcranial echo-color doppler) were simultaneously evaluated in 58 patients with sepsis. CEUS assessed BMC alterations with the changes of the time-intensity perfusion curves variables (including time-to-peak and

peak-intensity) in different regions of interest of brain parenchyma. Brain injury was confirmed on computed tomography or magnetic resonance imaging. Coma and delirium were evaluated using the Glasgow Coma Scale or the Confusion Assessment method in the ICU, respectively.
Results: There was no difference between survivors and non-survivors in cardiac index, mean arterial pressure, cerebral blood flow and the mean flow velocities of the middle cerebral arteries over three days. The non-survivors developed more BMC alterations with prolonged time-to-peak ($p < 0.01$) and decreased peak-intensity ($p < 0.01$) in the left lentiform nucleus and left white matter of the temporo-parietal region of the middle cerebral artery. Non-survivors also developed more frequently coma, delirium in the ICU and had more frequently impaired brain autoregulation and signs of brain injury on imaging than survivors (all $p < 0.01$).
Conclusions: In patients with sepsis, non-survivors developed more brain complications than survivors, and this was associated with more severe microvascular alterations in the brain.

Figure1: Ultrasound techniques to evaluate brain perfusion in patients with sepsis

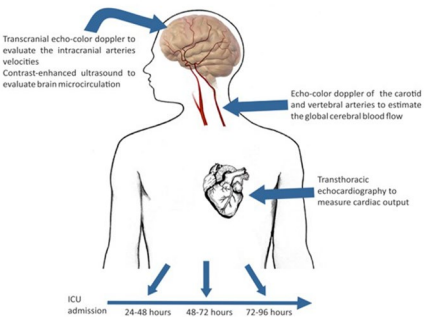

Figure 2: Time-to-peak (seconds) evolution of three regions of interest of brain parenchyma of the left side between non-survivors and survivors.

Introduction: Introduction—Sepsis is defined as the dysregulated host response to infection resulting in organ dysfunction and, in some cases, death. Survivors frequently develop cachexia and myopathy which impairs recovery and increases long term mortality. In conditions akin to sepsis, including burn injury and cancer-associated cachexia, this has been attributed to catabolism driven by hypermetabolism due to a process called 'browning'. Browning describes the switch of energy-storing white adipose tissue to a thermogenic energy-burning brown adipose tissue-like phenotype. Browning is characterised by increased mitochondrial density, multiloculation of lipid droplets and expression of thermogenic mechanisms including the canonical marker of browning—uncoupling protein 1, aka 'thermogenin'. Identification and prevention of browning may reduce muscle wasting in survivors of sepsis.
Objectives: Establish whether browning of white adipose tissue occurs and drives hypermetabolism and muscle wasting in survivors of an animal model of sepsis.
Methods: Experimental sepsis was induced in rats using intraperitoneal zymosan which causes a prolonged inflammatory insult. Immunofluorescence and body and muscle mass were used to identify cachexia and myopathy. Expression of thermogenic browning mechanisms were studied in epididymal (eWAT) and retroperitoneal adipose tissue and (rpWAT) using thermal imaging, high resolution respirometry, RNA-sequencing and Western blot. Mitochondrial function and adipose tissue architecture was interrogated by multiphoton imaging of live adipose tissue explants.
Results: Rats with zymosan peritonitis developed a sepsis-like illness with a mortality of 17% at 14 days. Compared to sham animals, sepsis survivors developed hypermetabolism, cachexia and myopathy with reduced muscle mass and myofibre thickness. Oxygen consumption of eWAT and rpWAT per milligram of tissue was elevated at days 3, 7 and 14 of sepsis recovery, however, when controlled for lipid droplet size or mitochondrial or cell number, the increase was abolished. Compared to sham, RNA sequencing of rpWAT showed inflammation and down regulation of genes related to oxidative phosphorylation and thermogenesis at 14 days after septic insult. UCP1 protein was not expressed. Notably, SERCA2 mRNA and SERCA2 protein were increased, suggesting increased calcium cycling. Multiphoton microscopy showed neither increased mitochondrial density nor lipid multiloculation consistent with browning. The NAD (P)H pool was, however, more oxidised in tissue from animals recovering from sepsis, potentially indicating increased or altered metabolism.
Conclusions: Hypermetabolism, cachexia and myopathy in the recovery phase of experimental sepsis are not caused by classical browning. Calcium cycling mechanisms in adipose tissue may be implicated. The findings are counter to many established studies and merit further investigation.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001326

Introduction: Patients undergoing invasive mechanical ventilation (MV) accumulate tracheal secretions below and above the endotracheal tube (ETT) cuff. Tracheal suctioning is required to prevent complications due to secretion retention, but such a procedure is not free from risks. To promote secretion clearance, a new cuff controller device has been recently developed [1]. The cuff controller, synchronized with the mechanical ventilator, performs an artificial cough maneuver with a fast cuff deflation/inflation cycle within the inspiratory time, thus generating a gas flow around the ETT cuff towards the mouth (artificial cough flow).
Objectives: To assess safety and efficacy of the device in promoting secretion clearance.
Methods: The study was approved by the local Ethical Committee. Adult subjects, admitted to general intensive care unit and undergoing invasive MV, were enrolled. At enrollment, a first deep mouth aspiration was performed and the device was connected to the ETT cuff, target pressure 25 cmH2O. A sigh (total inspiratory pressure 35 cmH2O, inspiratory time 2 s, once per minute) was introduced in the ventilatory settings for device activation. The ETT cuff deflation/inflation cycle lasted around 1.2 s. The artificial cough maneuver was consecutively performed 3 times and then a second mouth aspiration was performed in order to assess the primary outcome, represented by the presence or absence of oral secretions (Responders and Non-Responders, respectively). Safety was evaluated as the presence of adverse events during each maneuver. Study population was described according to clinical and demographic characteristics assessed at enrollment. For each maneuver, artificial cough flow was estimated as the leaked volume (residual volume at end-expiration measured by the ventilator) divided by 1.2 s.
Results: We enrolled 30 patients (66.7% males, mean age 60.1 ± 18.5 years, mean body mass index 26.0 ± 7.2) and half of them undergoing controlled ventilation. Device activation was feasible for all patients and two adverse events were recorded (reactive cough and transient hypotension resolved with volume infusion). For two patients, the primary outcome was not evaluated due to logistical issues. The second mouth aspiration detected secretions in 22 patients (Responders 78.6% of 28). Demographical and clinical characteristics did not statistically differ between Responders and Non-Responders. Prevalence of Responders did not differ according to the ventilation mode ($p = 0.6483$). Artificial cough maneuvers produced a mean cough flow of 17.9 ± 10.4 L/min and no statistical difference between mean cough flow was detected between Responders and Non-Responders ($p = 0.8011$) (Figure 1).
Conclusions: Our study showed that the tested ETT cuff controller was safe and feasible and it was able to promote tracheal secretion transfer to the mouth.

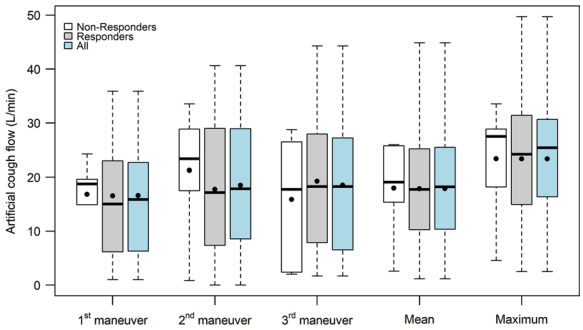

Figure 1 (abstract 001326) Boxplot of artificial cough flows during device activation
Figure shows the distribution of artificial cough flow observed during each maneuver (1st, 2nd and 3rd maneuver) and the distribution of mean and maximum value observed among the three maneuvers.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001328

Introduction: Non-invasive respiratory support, such as high flow nasal oxygen (HFNO) or non-invasive ventilation (NIV), have the potential to reduce the risk of invasive mechanical ventilation in hypoxemic patients with COVID-19. However, randomized clinical trials demonstrate conflicting results, the number of included patients is limited, and real-world practice data remain scarce.
Objectives: To determine whether an approach that includes HFNO or NIV is superior to conventional oxygen therapy (COT) in reducing the risk of invasive mechanical ventilation in hospitalized hypoxemic patients with COVID-19.
Methods: We emulated a target trial using the National COVID Cohort Collaborative data on COVID-19 patients [1]. We included adult hypoxemic patients (P/F ratio ≤ 200 mmHg) within their first 24 h of hospital admission with a SARS-CoV-2 infection. Pregnant patients, patients with hypercapnia ($PaCO2 > 45$ mmHg), or a do not resuscitate order were excluded. We compared three treatment arms: HFNO, NIV, and a control group with only COT, started within a grace period of six hours after meeting the eligibility criteria. The primary outcome was intubation within 28 days. We censored patients if they had a hospital transfer or an unknown hospital discharge destination. Subgroups were based on BMI, respiratory rate, P/F ratio, and PaCO2. We used the

inverse probability censored weighted (IPCW) Aalen-Johansen estimator to estimate the 28-day cumulative incidence of intubation for the three arms.
Results: Of the almost 5 million patients admitted to the hospital with COVID-19, 10.894 met the eligibility criteria, of which 1.274 initiated HFNO, 641 initiated NIV, and 8.655 did not start HFNO/NIV within the grace period. The unadjusted cumulative 28-day risk of intubation was 48% in the HFNO arm, 57% in the NIV arm, and 24% in the COT arm. With an initial, albeit still incomplete, adjustment, the 28-day risk of intubation was 38% for the HFNO arm, 51% for the NIV arm, and 20% for the COT arm. These correspond to risk differences of 18% (HFNO vs COT), -13% (HFNO vs NIV), 31% (NIV vs COT). The restricted (at day 28) mean time to intubation was 7 days for HFNO, 12 days for NIV, and 3 days for COT. Results will be bootstrapped for reliable confidence intervals and analysed for the subgroups.
Conclusions: We observe a trend among hypoxemic patients with COVID-19 that NIV as initial treatment increases 28-day cumulative incidence of intubation compared to HFNO or COT.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001330

Introduction: Trauma is one of the major causes of death worldwide. Severed injured patients will be triaged by the trauma team activation criteria (TTAC) to receive immediate care from a trauma team.
Objectives: This research aimed to identify the mortality rate and predictors for the mortality of patients who met the TTAC.
Methods: This is a retrospective cohort study that collected data from a trauma registry. All patients who arrived at the emergency department and met the TTAC within 1 h after arrival were eligible. The initial vital signs, initial clinical examination, and laboratory results were collected. The univariable analysis was performed and the parameters were selected for multivariable analysis and the predicting score was derived from the coefficients.
Results:: A total of 878 patients were eligible for the cohort. The 28-day mortality rate was 15.7%. The multivariable analysis showed that age $\geq$ 60 years (OR 8.6, 95%CI 4.2–17.5, $p < 0.001$), GCS $\leq$ 8 (OR 6.0, 95%CI 3.3–11.1, $p < 0.001$), Base excess (BE) ≤ -10 mEq/L (OR 9.6, 95%CI 5.2–17.9, $p < 0.001$). The SAB score comprised of age $\geq$ 60 years = 1, GCS $\leq$ 8 = 1, and BE ≤ -10 mEq/L = 1. At the cut point of 2, the score had a sensitivity, specificity, positive predictive value, and negative predictive value of 52%, 94%, 60%, and 92%, respectively.
Conclusions: The SAB score can be a tool to classify trauma patients who met TTAC into a higher tier for more intensive management.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001331

Introduction: PICS is a syndrome that involves the alteration of different spheres such as emotional, physical and neurocognitive. It has been demonstrated that critically ill patients who have been admitted to the ICU have increasingly more risk factors to develop PICS such as delirium, invasive (IMV) and non-invasive mechanical ventilation (NIMV), ARDS, multi organ failure, sepsis, cardiac arrest etc.. Most of these patient are not fully recover a year after they ICU discharge, even after 5 years after ICU discharge. It is important to detect and treat PICS.
Objectives: To analyze the prevalence of PICS and the need for outpatient clinic in its diagnosis and treatment.
Methods: Descriptive observational study conducted in the post-ICU outpatient clinic of a 28-bed polivalent ICU. Between 04/2021 and 12/2022. Patients who met at least one of the risk factors for developing PICS (IMV or NIMV > 2 days, ARDS, delirium, cardiac arrest with recovery, sepsis, multiorganic failure) were included. Follow-up was conducted at 1,3,6 and 12 months after ICU discharge. The spheres that comprise PICS (physical, psychological and cognitive) were assessed using validated scales (MRC, MOCA, HADS, Barthel, clinical frailty score, SARC-F score SF-12).

Results: 93 patients at risk of developing PICS were followed in the ICU outpatient clinic. Median age was 62 years old (52–70), 74% (69) male, median APACHE of 17 (13–24), median SAPS III of 52 (45–55) and median Barthel of 100. 73% (68) were admitted due to respiratory failure, 63% (59) due to SARS COV 2.
84% (78) developed PICS. The neurocognitive sphere was the most frequently altered (73%), followed by physical sphere (60%) and psicologycal sphere (18% anxiety and 18% depression) (Figure 1). 40% (37) were affected in two spheres, 28% (26) only one and 17% (16) in all three (Fig. 2). The most frequent combination was neurocognitive and physical impairment (30%), followed by only neurocognitive impairment (21%) and impairment in all three spheres (17%) (Fig. 3). A poor perception of quality of life was found. 84% (78) had global SF12 < 75%, 71% (66) physical SF12 < 75% and 83% (77) mental SF12 < 75%.
60% (56) of the patients were referred to other specialists. The most frequent were 48% (45) to neuropsychology, 20% (19) to mental health, 10% (9) to otorhinolaryngology, 9% (8) to rehabilitation.
Conclusions: There is a high incidence of PICS in patients with risk factors after ICU discharge.
Post-ICU outpatien follow-up is necessary to detect and treat patients with PICS.

Figure 1: Percentage of altered spheres by months.

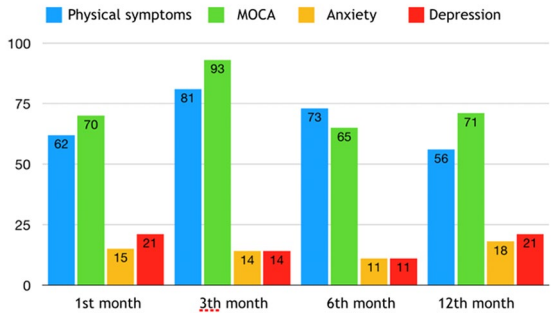

Figure 3: Altered spheres combined.

Introduction: Nosocomial central nervous system (CNS) infection is rare but of bad prognosis, leading to devastating neurological complications and increased rate of mortality. The difficulty in treating nosocomial CNS infection is due to the blood brain barrier (BBB) making it a challenge to attain effective concentration at target site and being effective against multi-drug resistant (MDR) bacteria common in nosocomial CNS infection (1). Meropenem is a broad-spectrum antibiotic recommended in the treatment of nosocomial CNS infection (2).
Objectives: The main objective of our study was to describe distribution of meropenem at target site in patient with acute brain injury.
Methods: We included in a national prospective multicenter study (CPP17-016a/2017- 002993–37), 25 brain injured patients with an EVD and treated with meropenem for CNS or other infections. Blood and CSF were collected at different time depending on the dosing regimen: intermittent infusion (2 g/8 h or 2 g/6 h), continuous infusion (6-8 g/Day) with or without loading dose of 2 g. Total plasma and CSF concentrations (C°) were obtained by a Liquid Chromatography coupled with Tandem Mass Spectrometer. Unbound plasma (Plu) C° was calculated from meropenem protein binding of 2%. From a non-compartmental analysis, C° time profiles of meropenem were obtained. CSF to plasma ratio, of area under the curve (AUC) of C° over time for intermittent dosing (AUCCSF/AUCPlu), of C° at steady state for continuous infusion (CCSF/CPlu), were calculated, representing the rate of meropenem penetration into CSF. We then performed a PK population modelling with a Monte Carlo Simulation (MCS) to obtain probability of target attainment (PTA) and Cumulative fraction response (CFR). PTA

and CFR were performed for patients without CNS infection (type 0) and with CNS infection (type 1).
Results: We included 25 patients after informed consent, (mean age: 54 ± 16,20 years old), and analyzed 114 blood and 135 CSF samples. For all patients (with and without CNS infection) mean AUCCSF/AUCPlu was 0.15 ± 0.12 and CCSF/CPlu was 0.07 ± 0.06. PTA:100%T > MIC was reached in plasma for continuous infusion. For a MIC = 2 µg/ml in patients with CNS infection, PTA in CSF was 40% for 2 g every 8 h, 60% for 2 g every 6 h, 50% for 6 g/Day of continuous infusion after loading dose of 2 g and 65% for 8 g/Day of continuous infusion after loading dose of 2 g. CFR were higher than 90% for all species studied except Pseudomonas aeruginosa in patients with and without CNS infection.
Conclusions: As described in literature, Meropenem poorly penetrates the CSF with a large interindividual variability (3, 4). The appropriate strategy to achieve optimal therapeutic concentrations for an optimal pharmacodynamic efficacy in most of CNS infections with GNB except for Pseudomonas aeruginosa or GNB with high MIC 36 36 seems to be 6 g/day continuous infusion. For intermittent dosing regimen longer duration of infusion should be preferred. For Pseudomonas aeruginosa, higher daily dose of meropenem should be considered and further studies are needed. For a probabilistic treatment 8 g/day should probably be preferred first and in case of identification of a difficult to treat bacteria, a therapeutic drug monitoring of meropenem in CSF could be proposed to avoid treatment failure. The practice of therapeutic drug monitoring should be further studied to be proposed in routine.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001335

Introduction: BACKGROUND: Coronavirus disease 19 (Covid-19) has been one of the most common causes of acute respiratory distress syndrome (ARDS), being responsible for a pandemic with almost 7 million deaths certified. Severe forms of ARDS can be supported with veno-venous extracorporeal membrane oxygenation (VV-ECMO). A specific population where the use of VV-ECMO for Covid-19 ARDS has been repeatedly reported is in young women in the peripartum period.
Objectives: OBJECTIVES: We aimed at performing a systematic review to summarize the results of the current literature on VV-ECMO in peripartum women with Covid-19 ARDS.
Methods: METHODS: We performed web-based search on Pubmed (last update 31.03.2023) to identify relevant articles; the protocol was regularly registered on PROSPERO. We included only articles published in English. Data were inserted independently by two authors (LM, SP) in an Excel database, and cross-checked by two authors (LLV, FS). We primarily focused on maternal and fetal mortality, recording also maternal and gestational age, as well as values of PaO2/FiO2 (P/F) ratio at cannulation, VV-ECMO duration and intensive care unit (ICU) and hospital length of stay (LOS).
Results: RESULTS: Our systematic search retrieved 131 items on PubMed. As reported in Table 1, we finally included 11 studies, including 8 retrospective studies (5 of them being single-center studies, 2 multicenter studies and 1 cohort study), 2 prospective studies (1 of them being single center study and 1 multicenter study), 1 prospective and retrospective cohort study, with a total of 191 patients. Among them, 151 were prepartum and 40 postpartum women (mean age 31 years). Average P/F ratio at cannulation was 72 with a mean duration of VV-ECMO of 22 days. Only 4 studies reported data on ICU and 3 on hospital LOS, with a mean of 43 and 63 days, respectively. The average maternal and fetal mortality were 17.8% (30/168, n = 10 studies) and 20.7% (12/58, n = 8 studies), respectively. Notably, the largest study did not report data on fetal mortality.
Conclusions: CONCLUSIONS: In our systematic review of case series and studies reporting data from pregnant women supported by VV-ECMO for severe ARDS due to COVID-19, we found that maternal and fetal survival stands around 80%. Such results seem rather good considering these were obtained during previously unexperienced pandemic conditions.

Introduction: The rising incidence of Gram-negative bacteria is a global threat (1, 2). Positively charged liposomes are preferentially attracted to the negatively-charged Gram negative bacterial membrane (Figure 1) and can be used to potentially overcome multidrug-resistant bacterial infections by achieving higher target concentrations.
Methods: Meropenem was encapsulated within cationic liposomes. The in vitro antimicrobial efficacy of free (non-liposomal) and cationic liposome-encapsulated meropenem was compared by determination of minimum inhibitory concentration (MIC) against different bacterial strains.
To assess liposomal safety in vitro, healthy volunteer whole blood was incubated with standard or liposomal meropenem for 6 h at therapeutic (10mcg/ml and 30mcg/ml) and supra-therapeutic (100mcg/ml) concentrations. Leucocyte toxicity was evaluated by measurement of reactive oxygen species (ROS) production and cell viability using flow cytometry.
Results: Depending on the specific charge, phospholipid composition, and sizes of liposomes, the efficacy of liposomal meropenem was as high as 125-fold compared to free meropenem (**Fig. 2**). Even at supratherapeutic concentrations, liposomal meropenem formulations were associated with minimal, if any, increase in leucocyte ROS or cell death.
Conclusions: Cationic liposomal meropenem enhanced bactericidal activity in-vitro compared to free meropenem, and were non-toxic in vitro. Assessment of efficacy, safety, and pharmacokinetics of liposomal antibiotics needs to be assessed in an in vivo model of sepsis.

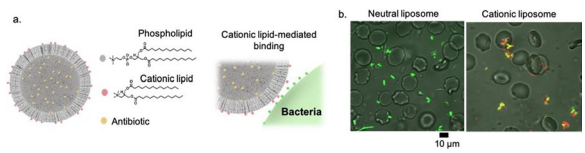

Figure 1 (abstract 001336) (a) Bacterial targeting is mediated by cationic lipids (red), which directs liposome binding to negatively charged lipids in bacterial cells (green). (b) Confocal laser scanning microscopic (CLSM) showing antibiotic liposomes (red) co-localise selectively with E.coli (green) cells and not erythrocytes (bright field)

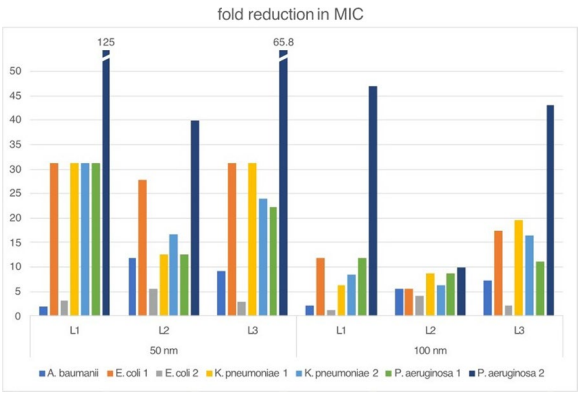

Bars indicating reduction in minimum inhibitory concentrations (MIC, in microg/mL) of three formulations of cationic liposomal meropenem (each at 2 sizes) against free meropenem against laboratory strains of common pathogens.

Introduction: Carotid Endarterectomy (CEA) surgery has an increased risk of postoperative stroke, as well as hyperperfusion syndrome. Thus, postoperative strict control of Blood Pressure is crucial. Our institutional target range is a postoperative systolic BP (sBP) within 130-145 mmHg. The goal of our study was to observe the efficacy of the use of clevidipine to control sBP within the established target range. Our hypothesis was that clevidipine is more effective than standard management in controlling BP.
Methods: This is an observational prospective cohort study. Data from consecutive patients older than 18 years old undergoing carotid endarterectomy were prospectively collected from April 2018 to October 2021. This study was approved by the Institutional Review Board (IRB). The primary outcome was the Area Under the Curve for systolic Blood Pressure (AUC-sBP) normalized per hour

(mmHg x min/h) during the first 6 h postoperatively. It measures the amount and time of sBP being below or above the pre-established target range (130-145 mmHg). Non-parametric test (Wilcoxon rank-sum and Fischer´s exact test) were used to compare the continuous and dichotomic variables between groups. Stata 13.1 was used for data analysis.
Results: Data from 97 consecutive patients were prospectively collected. Clevidipine was used in 44 of them, while for the other 53 patients in the non-clevidipine group, labetalol was used in 38 patients, while 15 patients needed a combination of labetalol plus urapidil to maintain sBP within the pre-established target range. The clevidipine group showed higher baseline sBP (mean ± SD 144 ± 15 vs 140 ± 7 mmHg, SMD − 0.34).
The use of clevidipine was associated with a significantly lower AUC-sBP (mmHg x min /h) compared to the non-clevidipine group (median [IQR], 120 [92–150] vs 240 [240–300] mmHg x min/h, $p < 0.00001$). Results were confirmed after adjusted linear regression analysis (coef. -220 mmHg x min/h (95% CI -293 -146), $p = 0.0001$). The mean total cumulative dose of clevidipine was 58 ± 86 mg, mean ± SD. The mean time of clevidipine use was 14 ± 10 h, mean ± SD. No adverse effects were observed associated with the use of clevidipine.
Conclusions: In our cohort, the use of clevidipine was associated with higher efficacy for Blood Pressure control after Carotid Endarterectomy compared to the use of labetalol or urapidil, without adverse effects observed.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001342

Introduction: Despite utilization of enteral feeding has a highly prominent impact uponcritical care in intensive care units (ICU), serious and maybe even lethal related complicationscan occur because of the poor nasogastric tube (NGT) replacement. NGT is a procedureroutinely performed in patients with enteral feeding and assessing correct nasogastric tubeplacement is vital. Today, chest X-ray is universally accepted as a gold standard to confirm correct positioning of NGT. However, alternative methods are introduced because of some chest radiography related demerits like high financial cost, further time required for X-ray confirmation, as well as multiple radiation exposure in some cases.
Objectives: OBJECTIVES: In the current study, we aimed to evaluate diagnostic accuracyof some of the alternative methods including end-tidal CO2 (ETCO2), pH analysis and point-of-careultrasonography (POCUS) in comparison to chest X-ray.
Methods: We reviewed main alternative methods including end-tidal CO2 (ETCO2), pHanalysis and point-of-careultrasonography (POCUS) and compared them accuracy with chest X-ray. An electronic literature search was conducted until 2023, using PubMed, Web of Sciencesand Scopus. Studies with all epidemiological designs like observational and randomized controltrials were considered.
Results: Our review indicated that sensitivity of POCUS in observational studies wasbetween 0.91% (95% CI, 83–96%) and 100% (95% CI, 97–100%) with specificity ranged from 67% (95% CI, 9–99%) to 100% (95% CI, 74–100%). In an RCT in 118 patients, sensitivity of POCUS was reported 96.5% (95% CI, 88–99.6%) with PPV 98.2% (95% CI, 98.1–98.3%). In astudy the pH measurement was not confirmed as a reliable technique for confirming NGT placement. Another investigation suggested mild diagnostic accuracy in pH with cutoff equal to 4.25 (AUC 0.79, $p < 0.001$). The ROC analysis for ETCO2 with a cut point of 25.5 mmHg reached 1.0 (AUC 1.0, $p < 0.001$).
Conclusions: It seems that ETCO2, POCUS, and pH could be good alternatives for chest X-ray respectively. But strong RCTs with large sample size should be performed for comparing diagnostic accuracy of these methods with each other at the same time.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001343

Introduction: Telomere shortening is associated with an impairment of the immune system, which is explained by the progressive decline in physiological homeostasis associated with aging. The severity of acute respiratory distress syndrome (ARDS) depends on the amount of etiologic substances with corresponding immune reactions, the duration of the appearance of specific immune cells, or the repertoire of specific immune cells that control the substances.
Objectives: Study the impact of telomere length in whole blood from COVID-19 patients at disease onset with the need for invasive and non-invasive mechanical ventilation, need for pronation, days of pronation and worst PaO2/FiO2 in patients admitted to the ICU.
Methods: A cross-sectional prospective study enrolling critical patients with COVID-19 recruited at Tajo University Hospital was carried out from March to September 2020. Blood samples were obtained upon admission to the ICU, prior to connection to any kind of mechanical ventilation. Relative telomere length (RTL) quantification was carried out by monochromatic multiplex realtime quantitative PCR. Telomere length analysis was adjusted for age, gender and BMI.
Results: 72 patients were analyzed. Table 1 presents descriptive information on sample demographic characteristics. Initially, no association was found between the relative length of the telomere and the need for invasive mechanical ventilation (IMV) (OR 2,30; CI 95%: 0,63–8,49). After adjusting for age, gender and weight an association was observed. Patients who required invasive mechanical ventilation had a shorter relative telomere length than those who did not (1,69 vs 1,86), with an OR 11,49 (CI 95%: 1,60–119,05). No associations were found with need for non-invasive mechanical ventilation, need for pronation, days of pronation and worst PaO2/FiO2, in the adjusted and unadjusted models.

Clinical and epidemiological characteristics

A retrospective, single center cohort service evaluation of anidulafungin prescribing during COVID-19 pandemic

C. Meddings[1], F. Hanks[2], D. P. Rahmawati[3]
[1]Critical Care/Pharmacy, Guy's and St Thomas' Hospital, London, United Kingdom; [2]Critical care, Guy's and St Thomas' NHS Foundation Trust, London, United Kingdom; [3]School of Pharmacy, UCL School of Pharmacy, London, United Kingdom
Correspondence: C. Meddings
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001344

Introduction: International guidelines recommend the use of steroids and interleukin-6 antagonists for treating COVID-19 (C-19) in patients requiring respiratory support. (1) However, these agents have been associated with increased risk of fungal infection. (2) Anidulafungin is the first-line antifungal for invasive candidiasis (IC) at Guy's and St Thomas' Adult Critical Care Units (ACCU). Increased anidulafungin consumption was observed during the C-19 pandemic on ACCU and it was unknown if this was due to increased activity or a change in prescribing practices. Therefore, we undertook a retrospective, single-centre service evaluation of anidulafungin prescribing in ACCU to identify the effect of C-19 on guideline compliance and anidulafungin usage.

Objectives: To compare the following between C-19 and non-C-19 cohorts:

1. The Defined Daily Dose of anidulafungin prescribing (DDD/100 bed days) using World Health Organisation DDD methodology. (3)
2. The percentage of suspected versus proven IC at anidulafungin prescription initiation.
3. Compliance of anidulafungin prescribing with ACCU antifungal guideline based on specified risk factors for IC.

Methods: Data collection occurred over three separate 2 calendar month periods: pre-C-19 comparator (January–February 2020), C-19 surge one (April–May 2020) and C-19 surge two (January–February 2021). All patients prescribed anidulafungin and admitted to ACCU were included. Electronic medical records were interrogated and data collected using a pre-defined data collection tool. Statistical analysis was carried out using SPSS v28. A Kruskal Walls H test was used for comparing DDD's, and Chi-square test for patient demographics. P values < 0.05 were considered statistically significant.

Results: A statistically significant increase in anidulafungin DDD was observed between the control cohort and C-19 surge 1 and surge 2 cohorts (3.42 versus 13.62 and 12.91 respectively, p = < 0.001). The indication for anidulafungin prescribing was for suspected IC in the majority of cases, with only two proven infections across all cohorts. The percentage of prescriptions that were compliant with prescribing guidelines was higher in the C-19 cohorts compared to the control (77% and 81%, compared to 60%). Median duration of anidulafungin treatment was 6 days for all cohorts.

Table 1 (abstract 001344) Patient demographics

	Pre-C-19 (n = 15)	C-19 Surge 1 (n = 60)	C-19 Surge 2 (n = 96)	Chi-square test (p-value)
Diabetes	1 (6.7%)	13 (21.7%)	34 (35.4%)	0.027
Immunosuppressive Medication	5 (33.3%)	30 (50%)	86 (89.6%)	< 0.01
Prior antibiotic use	13 (86.7%)	49 (81.7%)	86 (89.6%)	0.058
Vascular access device	11 (73.3%)	51 (85%)	89 (92.7%)	0.058
Total Parenteral Nutrition	3 (20%)	2 (3.3%)	6 (6.3%)	0.062
Abdominal surgery	4 (26.7%)	5 (8.3%)	2 (2.1%)	0.01
Median length of stays (IQR)—day	7 (2–12)	12 (7–20)	13 (8–20)	0.031
Multiple candida colonisation	2 (13%)	9 (15%)	12 (12.5%)	0.906

Conclusions: The increased anidulafungin usage observed in the C-19 cohorts was due to increased prescribing for suspected IC, rather than proven IC, or increased bed days. This is likely due to anidulafungin initiation in patients with ongoing signs of sepsis with no clear source. Potential contributing factors identified include significantly higher rates of diabetes, immunosuppressant use and longer ICU stay in C-19 cohorts. The high DDD, low proven infection rate, and high guideline compliance highlight the limitations of guideline driven anidulafungin prescribing, and the need for rapid molecular diagnostics to identify true IC, facilitating appropriate anidulafungin use.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001345

Introduction: Sepsis-induced acute kidney injury (AKI) is a common and serious complication in critically ill patients, increasing morbidity and mortality rates. This study aimed to explore the characteristics and clinical outcomes of critically ill patients with sepsis-induced AKI.

Methods: We conducted a prospective observational study involving adult patients diagnosed with sepsis according to the third International Consensus Definitions for Sepsis from 19 institutions across South Korea. AKI was defined based on the Kidney Disease Improving Global Outcomes (KDIGO) classification. Baseline creatinine was determined as the lowest value during admission or the calculated value from the Modification of Diet in Renal Disease (MDRD) study equation, assuming a baseline glomerular filtration rate of 75 mL/min/1.73 m^2.

Results: A total of 4,885 patients were included in the analysis. Among them, 3,063 (62.7%) presented with sepsis-induced AKI, with 549 patients in stage 1 and 2,410 in stages 2 and 3. Patients with sepsis-induced AKI had significantly higher baseline serum lactate, procalcitonin levels, and Sequential Organ Failure Assessment (SOFA) scores and required more vasoactive drugs than those without AKI. Non-adherence to obtaining blood cultures and administering broad-spectrum antibiotics within 1 h was associated with the development of AKI. Hospital mortality rates were 41.7% for sepsis patients with AKI and 23.4% for those without AKI. The adjusted hazard ratio (HR) for in-hospital mortality in patients with stage 2 and 3 AKI were 1.35 (95% CI: 1.10–1.67, p < 0.001) and 1.64 (95% CI: 1.33–2.03, p < 0.001), respectively.
Conclusions: Our study revealed a 62.7% incidence of sepsis-induced AKI in adult patients in South Korea. Sepsis-induced AKI was independently associated with longer hospital stays and increased in-hospital mortality rates.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001346

Introduction: Candidaemia is the most common form of invasive candidiasis (IC) and significantly impacts the morbidity and mortality of critically ill patients1. The cumulative incidence of IC in Europe is 7.07 per 1000 intensive care unit (ICU) admissions2. Candidaemia poses both a diagnostic and therapeutic challenge: whilst early initiation of treatment is beneficial, early diagnosis is difficult. Confirmatory cultures take time and the value of more expeditious screening tests remains uncertain3.
Objectives: To analyse the cohort of patients diagnosed with candidaemia for common risk factors, adherence to management guidelines and overall outcomes.
Methods: A retrospective notes review was conducted of all patients diagnosed with candidaemia in our mixed adult ICU between February 2019 and September 2022. Patient demographics, risk factors for candidaemia, biochemical markers of infection, candida score4, candida species cultured, investigations performed, antifungal treatment, in-hospital mortality and length of stay were all collected.
Results: There were 16 patients diagnosed with candidaemia during the study period. The mean patient age was 66 years and 81% were male. 44% of patients were medical admissions whilst 56% were surgical. Admission blood tests, CRP on day of candidaemia diagnosis, candida score and candida species grown are summarised in Table 1. Candida albicans was cultured in 10 patients (62%), whilst candida glabrata, candida dubliniensis and candida tropicalis were grown in 4 (25%), 1 (6%) and 1 (6%) of patients respectively.
Of the 16 patients, those with typical risk factors for candidaemia were as follows: broad-spectrum antibiotics 16 (100%), indwelling central venous catheter 15 (94%), total parenteral nutrition 7 (44%), diabetes 5 (31%), immunosuppression 5 (31%), renal replacement therapy 3 (19%), neutropenia 2 (12%) and pancreatitis 2 (12%) (Table 1).
The recommended investigations for patients with candidaemia include serial blood cultures, echocardiography and fundoscopy. These were received by 11 (69%), 8 (50%) and 5 (31%) of patients respectively. Of the 13 patients with available data, 10 (77%) were managed with antifungal agents: 6 receiving fluconazole (46%) 4 receiving caspofungin (31%) and 2 receiving amphotericin B (15%) (Table 1).
The overall in-hospital mortality was 53%. The average ICU length of stay was 12 days (4–28 days range) (Table 1).
Conclusions: At our centre, the incidence of candidaemia was significantly lower than described in large multicentre studies2, with a similar mortality1. Typical risk factors described in the cohort demonstrate patients at greatest risk of candidaemia and the management demonstrates less than perfect adherence to investigation and treatment guidelines. Utilising this data to power a prospective quality improvement project could aid the recognition, management and prevention of candidaemia in future.

Baseline Data	
Characteristic	**N = 16**[1]
Demographics	**Mean (%)**
Female Sex	3 (19%)
Age (years)	66 (55, 75)
Medical Admission	7 (44%)
Laboratory Tests and Risk Score	**Median (IQR)**
Admission WBC (x10^9/L)	15.7 (8.6, 19.4)
Admission CRP (mg/dL)	136 (20, 254)
Admission Creatinine (µmol/L)	80 (63, 123)
Admission Lactate (mmol/L)	1.5 (0.9, 2.0)
Candida Score	2 (2, 4)
CRP on Day of Diagnosis (mg/dL)	130 (99, 280)
Antifungal Choice	**Mean (%)**
Caspofungin Used	4 (31%)
Fluconazole Used	6 (46%)

The potential role of Neutrophil-Reactive Intensity (NEUT-RI) in ICU diagnosis of sepsis: a retrospective critical illness cohort study

E. M. A. Mantovani[1], S. Pastori[2], V. Roccaforte[2], R. Panella[2], A. Pezzi[1], M. Gotti[1], P. Formenti[1], G. Sabbatini[1]

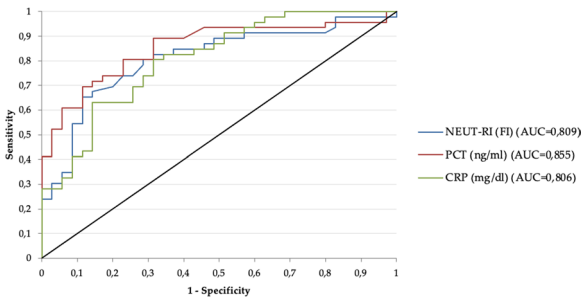
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001347

Introduction: The diagnosis of sepsis is often difficult and belated, substantially increasing the mortality in affected patients. Its early identification allows to choose the most appropriate therapies in the shortest time, improving patients' outcome and eventually their survival.
Objectives: Since neutrophil activation is an indicator of early innate immune response, the aim of the study was to evaluate the role of Neutrophil-Reactive Intensity (NEUT-RI), which is an indicator of their metabolic activity, in the diagnosis of sepsis.
Methods: Data from 96 patients consecutively admitted to the ICU were retrospectively analyzed (46 septic and 50 non-septic patients). Septic patients were further divided between "complicated sepsis" and "non complicated sepsis" according to the severity of the illness. Patients were subsequently classified according to renal function.
Results: For the diagnosis of sepsis, NEUT-RI showed an AUC of 0,826 and a better negative predictive value than Procalcitonin and C-Reactive Protein (87,4% vs 83,9% and 86,6%, $p < 0,001$). Unlike PCT and CRP, NEUT-RI seemed not positively influenced by renal failure ($p = 0,212$). No significant difference in NEUT-RI values was observed according to the severity of sepsis ($p = 0,075$).
Conclusions: In conclusion, the increase in NEUT-RI values could be useful in the early ruling out of sepsis, and it does not appear to be influenced by renal failure. However, NEUT-RI has not proved efficient in discriminating the severity of sepsis at the time of admission. Larger prospective studies are needed to confirm these results.



The Figure shows the area under the Receiver-operating characteristic (ROC) curve for the distinction of inflammatory parameters for detection of sepsis. The areas under the ROC curves are as follows: NEUT-RI (blue

line): 0.80 [95%CI 0.74–0.91]; PCT (red line): 0.85 [95%CI 0.77–0.93]; CRP (green line): 0.80 [95%CI 0.77–0.93; p < 0.001; AUC = Area Under the Curve.

Table 1. Baseline characteristics of the study population, divided by diagnosis of sepsis at ICU admission.

	Septic (n 46)	Non septic (n 50)	*P*
Age (years)	70 [46; 87]	68 [29; 90]	0.172
Male sex, N (%)	24 (56)	28 (58)	0.992
Complicated sepsis N (%)	25 (54.3%)		
Diagnosis:			
Pneumonia, N (%)	23 (50)		
Peritonitis, N (%)	12 (26)		
Urinary tract infection, N (%)	11 (23)		
Coma		11 (22)	
Other neurologic disorders		14 (28)	
Acute pulmonary edema		7 (14)	
Post-surgery monitoring		18 (36)	
SOFA score at ICU admission (points)	7 [4; 8]	6 [4; 8]	0.951
AKI at ICU admission, n (%)	28 (60.1)	21 (42)	0.245
Plasmatic creatinine (mg/dl)	3.51	2.04	<0.001
NEUT-RI (FI)	60.3 [41;112]	49.9 [41.5;63.1]	<0.001
PCT (ng/ml)	56.71 [0.2;250]	2.51 [0.2;56.2]	<0.001
CRP (mg/dl)	17.89 [2.1;42.5]	6.43 [0.1;22.2]	<0.001

SOFA = Sequential Organ Failure Assessment; ICU = Intensive Care Unit; AKI = Acute kidney Injury as defined by KDIGO guidelines; PCT = Procalcitonin; CRP = C-Reactive Protein.

Table 2. Inflammatory parameters in septic vs non-septic patients, and in patients diagnosed of AKI.

	No-AKI	*n*	AKI	*n*	*P*
NEUT-RI (septic)	61.83 [47,1-112] FI	18	59.24 [41-75,2] FI	28	0.212
NEUT-RI (non-septic)	50.35 [41,5-63,1] FI	29	49.39 [44,2-56,4] FI	21	0.589
PCT (septic)	31.03 [0,22-250] ng/mL	18	73.22 [0,23-250] ng/mL	28	0.002
PCT (non-septic)	0.69 [0,2-3] ng/mL	20	5.08 [0,32-28,61] ng/mL	15	0.016
CRP (septic)	13.74 [2,09-37,26] mg/dL	18	20.56 [2,51-42,5] mg/dL	28	0.026
CRP (non-septic)	5.51 [0,13-22,25] mg/dL	24	7.72 [0,7-18,42] mg/dL	17	0.131

AKI = Acute kidney Injury as defined by KDIGO guidelines; No-AKI: normal renal function.

Table 3. Accuracy (AUC), cut-off, sensitivity and specificity of inflammatory parameters for detection of sepsis.

	AUROC (95% CI)	Cut-off	Youden's index	Sens (95% CI)	Spec (95% CI)	PPV	NPV
NEUT-RI	0,826 [0,741-0,912]	≥51,9 FI	0,56	80,4% [68,9-91,8]	76% [64,2-87,8]	65,2%	87,4%
PCT	0,855 [0,771-0,938]	≥2,16 ng/mL	0,58	69,6% [56,3-82,9]	88,6% [78-99,1]	77,3%	83,9%
CRP	0,822 [0,736-0,908]	≥6,91 mg/dL	0,51	80,4% [68,9-91,9]	70,7% [56,8-84,7]	60,6%	86,6%

AUROC = Area Under the ROC curve; Sens = Sensitivity; Spec = Specificity; PPV = Positive Predictive Value; NPV = Negative Predictive Value.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001348

Introduction: Head computed tomography (CT) is a guideline recommended method to predict functional outcome after cardiac arrest (CA), but standardized criteria for evaluation are lacking.
Objectives: The aim of the current study is to validate a standardized approach to radiological evaluations of HIE on CT for prediction of functional outcome in comatose CA patients.
Methods: This is a prospective observational international multicentre substudy of the Targeted Hypothermia versus Targeted Normothermia after out-of-hospital cardiac arrest (TTM2) trial.Patients still unconscious 48 h post-arrest at 13 participating hospitals were routinely examined with CT. Prior to the current study´s initiation, a protocol article was published. Original images were evaluated by eight examiners from four countries blinded to clinical data using a standardized protocol. Qualitative assessment included evaluation of absence/presence of "severe HIE". Radiodensities were quantified in pre-specified regions of interest for calculation of grey-white matter ratios (GWR) at the basal ganglia level. Functional outcome was dichotomized into good (modified Rankin Scale 0–3) and poor (modified Rankin Scale 4–6) at six months post-arrest. Prognostic accuracies for good and poor outcome will be presented as sensitivities and specificities with 95% confidence intervals (using pre-specified cut-offs for quantitative analysis), descriptive statistics (Area Under the Receiver Operating Characteristics Curve), inter- and intra-rater reliabilities according to STARD guidelines.
The TTM2 trial and the TTM2 CT substudy are registered at ClinicalTrials.gov NCT02908308 and NCT03913065.
Results: Of the 473 patients included in the CT-substudy 157 (33%) had a CT > 48 h ≤ 7 days post arrest. 20 CTs were excluded; artefacts (n = 2), infarction (n = 5), intracranial haemorrhage (n = 3), not fulfilling technical requirements (n = 10). Included CTs have now been evaluated and the data is planned to be analyzed in the beginning of May 2023.
Conclusions: The results from this prospective trial will validate a standardized approach to radiological evaluations of HIE on CT for prediction of functional outcome in comatose CA patients.

Checklist - SOP for qualitative analysis in the TTM2 CT-Sub study

Patient: _____ Rater: _____

Prerequisites

Artifacts precluding analysis	☐ yes	☐no
Brain diseases precluding analysis	☐ yes	☐no
Residual contrast agent visible	☐ yes	☐no

Qualitative Analysis

Start using standard brain window and then adapt to optimize visibility of grey-white matter differentiation. *Evaluate axial images at these 4 different levels. Consider the best grey-white-differentiation, best visibility of sulci*

1 - Brain stem + Cerebellum		
Effacement of CSF spaces	☐ yes	☐no
Pseudo-SAH	☐ yes	☐no
White Cerebellum Sign	☐ yes	☐no
2 - Basal ganglia		
Bilateral loss of grey-white distinction	☐ yes	☐no
Bilateral sulcal effacement	☐ yes	☐no
Reversal sign	☐ yes	☐no
3 - Frontoparietal cortex corona radiata level		
Bilateral loss of grey-white distinction	☐ yes	☐no
Bilateral sulcal effacement	☐ yes	☐no
4 - High convexity cortex		
Bilateral loss of grey-white distinction	☐ yes	☐no
Bilateral sulcal effacement	☐ yes	☐no

Result of qualitative analysis

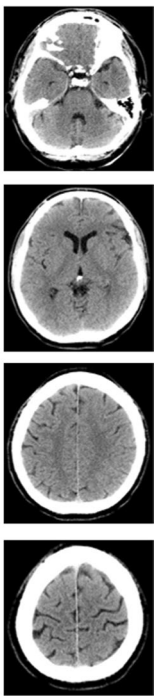
Definite severe HIE: *complete or near complete loss of grey-white distinction in the basal ganglia and in the frontoparietal cortex with additional evidence of brain swelling/sulcal effacement. Consider patient age while evaluating.*

☐ Definite signs of severe HIE
☐ No definite signs of severe HIE

In the clinical setting, would you have diagnosed severe HIE despite the fact that the current SOP's stated criteria for definitive severe HIE are not being met?

☐ yes
☐ no

CT Levels



SOP checklist for qualitative analysis. Standardised operating procedure checklist for qualitative radiological evaluation. CSF; cerebrospinal fluid, SAH; subarachnoid haemorrhage, HIE; hypoxic-ischaemic encephalopathy.

Checklist - SOP for quantitative analysis in the TTM2 CT-Sub study

Grey-white matter ratio (GWR) determination

Before starting GWR determination, perform the qualitative evaluation and enter the results into the electronic case report form.

GWR determination is carried out by manual placement of 8 circular ROIs with an area of 0.1cm^2.

Hounsfield Units should be displayed to ensure ROI placement in an area where radiodensity is representative of that target brain region. Focal hypo- or hyper densities, e.g. resulting from small vascular lesions, calcifications or noise must be avoided.

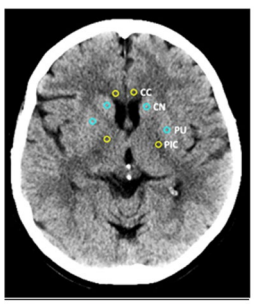


Figure 1 – ROI Placement for GWR determination at the basal ganglia level. Blue – grey matter ROIs, yellow – white matter ROIs. CC; genu of the corpus callosum, CN; head of the caudate nucleus, PU; putamen, and PIC; posterior limb of the internal capsule.

8 ROI basal ganglia GWR (8 BG)

All axial slices containing basal ganglia structures should be evaluated and ROIs placed bilaterally in the slice best representative of that target region. Thus, these 8 ROIs may be placed in different slices:

- Putamen
- Posterior limb of the internal capsule
- Head of the caudate nucleus
- Genu of the corpus callosum

In case of complete loss of grey-white distinction, use ventricles and midline as landmarks. In some patients with severe HIE radiodensity is similar in grey and white matter, exact location of target regions cannot always be determined. Nonetheless, ROIs should be placed and patients should not be excluded from GWR determination. The GWR of the 8 BG model will be calculated with the radiodensities measured at the ROI as follows:

$$8\ ROI\ BG\ GWR = \frac{CN_{right} + CN_{left} + PU_{right} + PU_{left}}{CC_{right} + CC_{left} + PIC_{right} + PIC_{left}}$$

SOP for the quantitative measurement of grey-white matter ratio. Placement of Regions of Interest (ROI) for determination of the grey-white matter ratio (GWR) at the basal ganglia level including 8 or 4 ROIs.12,13 Yellow indicates white matter ROIs and blue indicates ROIs in the grey matter. All axial slices containing basal ganglia structures should be evaluated and ROIs placed bilaterally in the slice best representative of that target region. Thus, these 8 ROIs may be placed in different slices: 1) Putamen (PU); 2) Head of the caudate nucleus (CN); 3) Posterior limb of the internal capsule (PIC), and 4) Genu of the corpus callosum (CC). In case of complete loss of grey-white distinction, use ventricles and midline as landmarks. In some patients with severe HIE radiodensity is similar in grey and white matter, exact location of target regions cannot always be determined. Nonetheless, ROIs should be placed and patients should not be excluded from GWR determination. Crosses indicate the ROIs included in each grey-white matter ratio method: 8 BG (basal ganglia model), 4SI (simple model) and auto GWR (automated GWR determination).

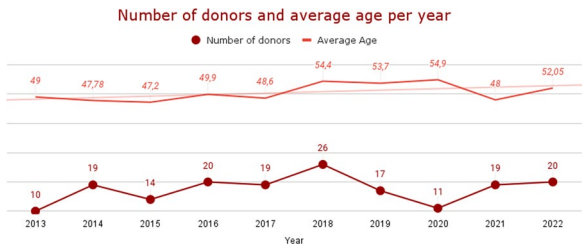
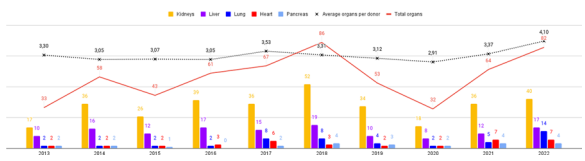
Years in organ donation: asingle center retrospective analysis

J. Martins[1], M. Costa[1], R. Covas[1], L. Costa[1], A. Mesquita[1], J. E. Oliveira[1]
[1]Intensive care medicine department, Braga Public Hospital, Braga, Portugal
Correspondence: J. Martins
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001349

Introduction: Organ donation is an integral part of the intensive care unit activity and it provides valuable healthcare benefits for the population, it is therefore important to keep track and optimize recognition of potential organ donors aswell as the correct management of the dead donor to improve outcomes of organ quantity and quality.
Objectives: The objetives of this study are to characterize the population of organ donors from 2013 until 2022 in an intensive care unit in a tertiary hospital in Portugal aswell as to evaluate the impact of the COVID-19 pandemic on the number of organ donors and organs collected.
Methods: Data was retrospectibly collected from an intensive care unit in the north of Portugal from the year 2013 to 2022 on the number and characterists of brain dead donors aswell as the organs collected.
Results: A total of 175 donors were identified and 579 organs collected averaging 3,30 organs harvested per donor. The mean age of the donors was 50,5 years, ranging from 17 to 74 years old. An upwards trend on the average age of donors and maximum age of donors was noted. The most frequent organ collected were kidneys (58%) followed by the liver (23%). The most frequent gender was male at 109 (62%) donors. A signficant drop in the number of donors can be seen from 2019 until 2022 due to the COVID-19 pandemic.
Conclusions: A trend of increased number of organ donations, increased average age and increased maximum age was present until 2019, the COVID-19 pandemic had an important impact on the number of organ donations until 2022. The number of heart, lung and pancreas colected shows an upwards trend and 2022 was the highest average organs per donor in the 10 years analysis.



Number of donors and average age of donors per year.



Total organs collected and type of organs collected per year and average organs per donor per year.

Correlation of the diaphragmatic function measured by ultrasound in comparison with the force negative inspiratory breath, as predictors of ventilatory weaning in critically ill patients patients in the Intensive Care Unit

J. C. C. Landeros Yañez[1], M. Ugarte[2]
[1]Terapia intensiva neurologica, INNNMVS, Ciudad de México, Mexico; [2]INNN Terapia intensiva Neurologica, INNNMVS, Ciudad de México, Mexico
Correspondence: J.C.C. Landeros Yañez
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001350

Introduction: Background. The diaphragm is the main respiratory muscle and its function in the critically illpatient favors the development of respiratory complications and thus an increase in the numberof days on mechanical ventilation (Esper, 2016). Approximately 20% of patients undermechanical ventilation present difficulties in ventilatory weaning, it is considered that about40% of the mechanical ventilation time is necessary for the ventilatory weaning process (Zhou,2017). In patients under mechanical ventilation the diaphragm muscle can develop weaknessand atrophy, which can lead to prolonged duration of ventilation (Rittayamai, 2019).
Objectives: To determine the diagnostic accuracy of correlates of diaphragm function measuredby ultrasound compared to negative inspiratory force as predictors of ventilatory weaning incritically ill Intensive Care Unit patients.
Methods: A prospective, observational, longitudinal, longitudinal, comparative study ofdiagnostic accuracy was carried out in patients admitted to the intensive care unit. At admission,ultrasonographic measurement of diaphragmatic thickness was taken daily until the withdrawalof mechanical ventilation was evaluated under medical criteria and in compliance with theconditions for ventilatory weaning. The ultrasound was performed in M mode, takingmeasurements of the diaphragm with the linear transducer positioned on the chest wall at theanterior subcostal level. The measurements evaluated were diaphragmatic excursion and: thetime to peak inspiratory amplitude of the diaphragm is defined as the time from the beginningof diaphragmatic contraction in inspiration, at the same time the negative inspiration force isevaluated, together with the usual predictors for ventilatory weaning. Once mechanicalventilation was withdrawn, the patient was monitored for 48 h and success in the withdrawalof mechanical ventilation was considered when the patient did not require mechanicalventilatory support during that period.
Results: During the period evaluated, 50 patients who met the inclusion criteria were included,58% men (29/50), 42% women (21/50), with an age in years of 62 ± 2.8 SD. They had variousconditions: surgical and non-surgical neurological 23 (46%), noncardiothoracic post-surgicalpatient 11/50 (22%), infectious 9/50 (15%), cardiothoracic post-surgical patient 5/50 (10%) andprimary respiratory disorders 2/50 (4%). The need for invasive mechanical ventilation in dayswas 4.6 ± 1.5 SD; spontaneous ventilatory test with T-piece was performed in 49/50 (98%)patients and CPAP/PS in 1/50 (2%) Table 1.Successful withdrawal of mechanical ventilation was reported in 44/50 (88%) patients, failurein 2 (33.3%) neurocritical patients, 2 (33.3%) patients with pathology of infectious origin, 1 (16.6%) non-cardiothoracic post-surgical patient and 1/50 (16.6%) cardiothoracic post-surgicalpatient.
Conclusions: Both diaphragmatic excursion and diaphragmatic peak inspiratory time, measuredby ultrasound, present adequate sensitivity and specificity to predict successful extubation in thecritically ill patient.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001352

Introduction: Trauma patients admitted to the emergency department are frequently characterized by metabolic acidosis, usually sustained by lactic acid and/or unmeasured anions (UA)1. The gold standard to identify and quantify the presence of UA is the Strong Ion Gap (SIG) computation, which, however, requires multiple simultaneous measurements, not always available at the bedside. Alactic Base Excess (aBE) has been recently introduced as a clinical surrogate for the identification of UA2. Indeed, aBE can be easily calculated as it is the sum of Standard Base Excess (sBE) and lactic acid. While aBE is a strong predictor of mortality in septic patients3, no data are currently available regarding trauma.
Objectives: This observational study aimed to identify the association between aBE and SIG in trauma patients and evaluate aBE as a possible marker of injury severity.
Methods: Trauma patients (Age > 13 years) admitted to the Trauma Center of the Niguarda Ca' Granda Hospital in Milan, Italy were enrolled. A blood gas analysis (*RapidPoint 500e, Siemens Healthineers, Milano)* was performed at admission. In addition,magnesium, albumin, and phosphate (*Cobas c702; Roche Diagnostics GmbH, Mannheim, Germany*) were measured. SIG, aBE, and Shock Index (heart rate/systolic blood pressure) were calculated as previously described 1,2,4. Demographic data, medical treatment, and clinical outcomes were recorded. The population was divided in two groups according to the median value of calculated aBE. The clinical parameters of the two groups were compared.
Data are presented as mean ± SD or median [IQR]. Comparison between continuous variables was performed using a t-test or Mann–Whitney test, as appropriate. Categorical variables were compared using Fisher exact test. The association between SIG and aBE was assessed using linear regression analysis.
Results: From February to March 2023, 37 trauma patients were enrolled. Patients had a mean pH of 7.28 ± 0.17, SBE of -5.9 ± 6.5 mmol/L, SIG of 7.9 ± 4.2 mmol/L and aBE of -1.5 [-3.5, 1.5] mmol/L. Overall characteristics of the study population and comparison according to median (-1.5 mmol) aBE are reported in Table 1. Patients with lower aBE were more acidotic, had higher lactate concentrations, and lower BE. Moreover, they were characterized by higher shock index, number of transfused red blood cells, and in-hospital mortality. SIG and aBE were characterized by a negative linear association ($r = 0.80$, $p < 0.001$) (Figure 1).
Conclusions: In trauma patients, aBE seems a useful clinical tool to identify the presence of UA. Our data suggest that aBE might be a marker of injury severity.

Assessing the potential benefit of an extracorporeal membrane oxygenation (ECMO) service

S. Williamson[1], C. Baker[2], J. B. Simon[1], C. Weaver[1], S. Soni[1], R. Stumpfle[1], U. Waheed[1], B. Baharlo[1], P. Patel[1], L. Thakuria[1]

Introduction: Severity of cardiogenic shock (CS) is an important predictor of mortality. The European Society of Cardiology guidelines (1) suggest considering short term mechanical circulatory support (MCS) in the setting of severe cardiogenic shock. There is increasing utilisation of MCS for severe CS, including in cardiac arrest (CA), where it may be implemented alongside standard advanced life support. The 2020 ARREST trial (2) suggested significant survival benefit with extracorporeal cardiopulmonary resuscitation (ECPR).
Objectives: We assessed the number of patients with cardiogenic shock who may have benefited from short term MCS, in our tertiary cardiac centre, which is in the process of exploring the development of a veno-arterial extracorporeal membrane oxygenation (VA-ECMO) programme.
Methods: Using data collated from our Heart Attack Centre, we included patients who had out-of-hospital cardiac arrests (OOHCA), in-hospital cardiac arrests (IHCA) or were identified as having cardiogenic shock by the clinical team, between March 2021 to March 2022. The highest SCAI shock score (3) within 24 h of admission was retrospectively calculated to classify shock severity. Survival to discharge rates were obtained. Additionally, patients presenting with OOHCAs were assessed against ARREST trial inclusion criteria.
Results: 83 Patients with cardiogenic shock were identified in this period. 45 patients were admitted following OOHCA, 28 after IHCA and a further 10 patients had cardiogenic shock without cardiac arrest. As demonstrated in Figure 1, the survival rate decreased with worsening SCAI shock score.

Table 1 (abstract 0001353) Survival to discharge of severe cardiogenic shock

Aetiology	Number of patients with SCAI D or E	Survival to discharge
IHCA	19	3/19 (15.8%)
OOHCA	23	12/23 (52%)
CS	5	3/5 (60%)
Total	47	18/47 (38%)

Mortality amongst 47 patients with severe shock (SCAI scores D and E) was 62%. The majority (89%) of patients with severe cardiogenic shock were cardiac arrests, 8 of which would have met ARREST trial criteria. Survival rates are shown in Table 1.
Conclusions: We identified 8 patients/year who met ARREST trial inclusion criteria. Assuming their stated 43% survival with ECPR, 3 additional patients may survive annually in our centre with emergency MCS. Whilst acknowledging that continuing work is required to further refine the selection criteria for MCS in shock, these data suggest that our heart attack centre would achieve the minimum volume of cases for an ECMO centre as recommended by the Extracorporeal Life Support Organisation (6 cases/year), with the potential to save a small number of additional patients with shock.

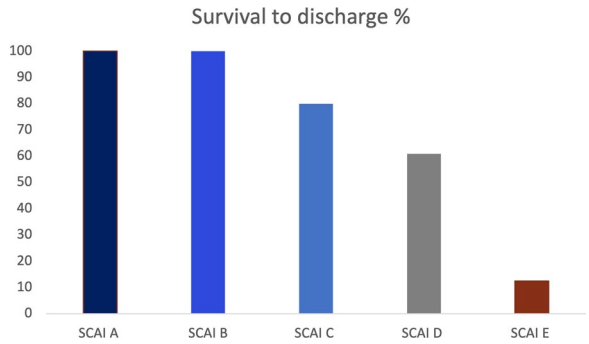

Figure 1 (abstract 001353) Survival to discharge of SCAI categories

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001355

Introduction: Cycling is nowadays a crucial recreational activity and the most common transportation mode in the world. Numerous risk factors, such as road conditions, poor visibility, adverse weather, unlit conditions, and other geometric factors, contribute to bicycle crashes. While a vast majority of past studies focused on bicycle crashes that occurred at junctions, relatively little research has examined segment crashes.
Objectives: This study aims to examine the risk factor for three common crash types on segments: overtaking, rear-end, and door crashes.
Methods: By analysing British Stats19 accident data (1991–2020), our study evaluated bicycle overtaking, rear-end, and door crashes on segments. Independent variables of interest include age and sex of cyclist and crash partner, lighting condition, speed limit, crash partner's vehicle type, crash day, and crash time. Multivariate logistic regression models were employed to estimate adjusted odds ratios (AORs)

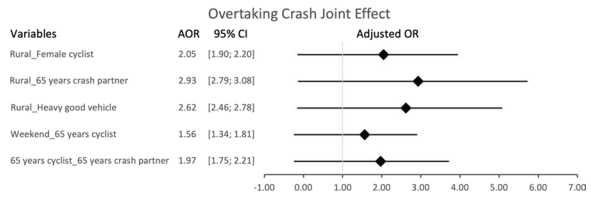
between potential risk factors. We further investigate joint effects of the variables with statistical significance.

Results: A total of 127,637 bicycle segment crashes were analyzed, of which 18,350 (14.4%) were overtaking crashes, 44,962 (35.2%) were rear-end crush, and 6,363 (5.0%) were door crush.

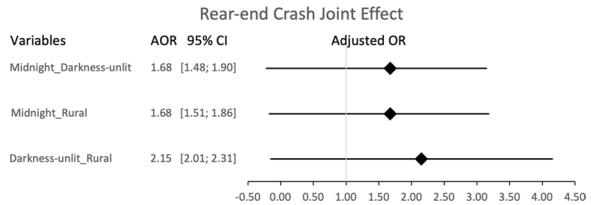
In overtaking crashes, bus/heavy good vehicles as crash partner was found to be a contributory factor (AORs = 2.87; 95% CI = 2.47–3.23). Other risk factors include elderly crash partners (AORs = 2.01; 95% CI = 1.94–2.09) and rural areas with speed limit ≥ 40mph (AORs = 2.34; 95% CI = 2.16–2.32). For rear-end crashes, darkness and unlit conditions (AORs = 1.49; 95% CI = 1.40–1.57) and rural areas (AORs = 1.32; 95% CI = 1.28–1.35) increase crash risks. As for door crashes, urban areas with speed limits up to 30 mph (AORs = 16.19; 95% CI = 13.51–19.38) and taxi as crash partner (AORs = 2.69; 95% CI = 2.31 –3.15) were risk factors.

Several joint effects were identified to be significant, including rural area and elderly crash partner (AORs = 2.93; 95% CI = 2.79–3.08) in overtaking crashes and darkness and rural area (AORs = 2.15; 95% CI = 2.01–2.31) for rear-end crashes.

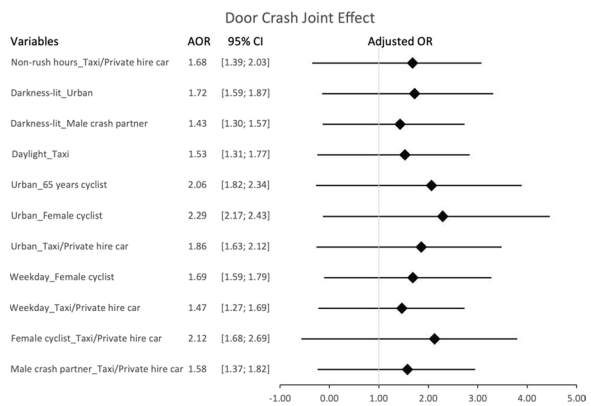
Conclusions: Crucial risk factors include bus/heavy good vehicles, elderly drivers of crash partner, and rural areas for overtaking crashes; darkness with unlit conditions and rural areas for rear-end crashes; urban areas and taxi as crash partner for door crashes.



Joint effects in overtaking crash.



Joint effects in rear-end crash.



Joint effects in door crash.

Prior nutritional status and survival outcomes in patients with sepsis: a population-based cohort study

I. Hwang[1], S. In-Ae[1]
[1]Department of Anesthesia and Pain Medicine, Seoul National University Bundang Hospital, Seongnam-si, Republic of Korea
Correspondence: I. Hwang
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001356

Introduction: Nutritional status is an important factor affecting health-related outcomes in hospital-admitted patients. However, the association between nutritional status and survival outcomes in patients with sepsis remains unclear. We aimed to examine whether nutritional status is associated with mortality among patients with sepsis.

Methods: This population-based cohort study used data from a nationwide registration database. Adults who were diagnosed with sepsis from 2018 to 2020 and underwent standard health examinations before hospital admission for sepsis were included. Nutrition scores were evaluated using the Nutritional Lifestyle Assessment Tool in South Korea.

Results: Overall, 2,482 patients with sepsis were included in this study. The 90-day and 1-year mortality rates in patients with sepsis were 26.8% (664/2,482) and 34.2% (848/2,482), respectively. In the covariate-adjusted multivariable logistic regression model, a 1-point increase in nutrition score was associated with a decrease in 90-day mortality in patients with sepsis (odds ratio [OR]:0.98, 95% confidence interval [CI]: 0.97, 0.98; P = 0.025). In the covariate-adjusted multivariable Cox regression model, a 1-point increase in nutrition score was associated with a decrease in 1-year mortality in patients with sepsis (HR: 0.99, 95% CI: 0.98, 0.99; P = 0.035). In the subgroup analyses, a 1-point increase in the nutrition score was associated with decreased 90-day and 1-year mortality in the underweight group (< 18.5 kg/m^2).

Conclusions: Better nutritional status before hospital admission was associated with improvements in 90-day and 1-year mortality rates among patients with sepsis. This association was more evident in underweight patients (BMI < 18.5 kg/m^2). Our results suggest that adequate dietary intake, along with healthy eating habits, might be a protective factor against mortality among patients with sepsis.

Increased plasma calprotectin is associated with 90-day mortality and worse functional outcome in COVID-19 patients admitted to the intensive care unit

I. Didriksson[1], M. Spångfors,[2], A. Frigyesi[3], G. Lilja[4], H. Friberg[5], A. Schiopu[6]
[1]Departement of Anesthesia and Intensive Care Medicine, Skånes universitetssjukhus Malmö, Malmö, Sweden; [2]Department of Anaesthesia and Intensive Care, Kristianstad Hospital, Kristianstad, Sweden; [3]Departement of Intensive and Perioperative Care, Skånes Universitetssjukhus Lund, Lund, Sweden; [4]Department of Clinical Sciences Lund, Neurology, Lund University, Lund, Sweden; [5]Department of Clinical Sciences, Intensive and Perioperative Care, Lund University, Lund, Sweden; [6]Department of Translational Medicine, Lund University, Department of Internal Medicine, Skane University Hospital, Lund, Sweden
Correspondence: I. Didriksson
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001358

Introduction: Calprotectin is a pro-inflammatory alarmin and a biomarker of neutrophil activation. Previous studies found that increased calprotectin is associated with an unfavourable prognosis in unselected populations of COVID-19 patients.
Objectives: We aimed to assess calprotectin as a possible outcome predictor in COVID-19 patients admitted to the intensive care unit (ICU).
Methods: This prospective study included 498 COVID-19 patients admitted to six ICUs in Sweden between May 2020 and May 2021. Blood samples were collected on admission and day 7. Calprotectin was analysed after study completion. Functional outcome was assessed by the Glasgow Outcome Scale-Extended (GOSE). Univariable logistic regressions were performed for calprotectin on day 0 and day 7, dichotomised at the median value. Calprotectin dynamics were calculated as calprotectin change between days 0–7. The study outcomes were mortality and functional outcome at 3 months.
Results: Total 3-month mortality was 39%. Good functional outcome (GOSE > 6) among survivors at 3 months was 35%. Calprotectin above median on day 7 was associated with increased mortality, OR 1.20 (95% CI 1.02–1.40), p = 0.025 and fewer patients with GOSE > 6 OR = 0.75 (95% CI 0.60–0.94), p = 0.012. Patients with calprotectin increase between days 0–7 had higher mortality compared to patients with calprotectin decrease (p = 0.045). In addition, the need for invasive mechanical ventilation (IMV) and continuous renal replacement therapy (CRRT) was more prevalent in patients with day 7 calprotectin above median (p = 0.042 and p = 0.007, respectively).
Conclusions: High calprotectin on day 7 and increasing calprotectin after ICU admission are associated with an adverse prognosis in critically ill COVID-19 patients.
Study registration: ClinicalTrials.gov Identifier: NCT04974775.

The impact of a dedicated critical care speech and language therapy service on multidisciplinary team management of patients with a tracheostomy

P. Day[1], B. Martin[2], D. McWilliams[3]
[1]Speech and Language Therapy, University Hospital Coventry and Warwickshire, Coventry, United Kingdom; [2]Speech and Language Therapy, University Hospital Coventry & Warwickshire, Coventry, United Kingdom; [3]Centre for Care Excellence, University Hospital Coventry & Warwickshire, Coventry, United Kingdom
Correspondence: P. Day
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001360

Introduction: The role of Speech and Language Therapists (SLT) within critical care has been increasingly recognised, with national guidance in the United Kingdom recommending all patients with a tracheostomy are seen by a SLT [1,2]. Involvement of SLT for patients with a tracheostomy may reduce the time to cuff deflation and speaking valve use, facilitate weaning from mechanical ventilation, assist with verbal communication and return to oral intake [3]. In April 2022 a newly created, dedicated SLT service was created within Critical Care at University Hospital Coventry and Warwickshire.
Objectives: To evaluate whether the introduction of a dedicated SLT for Critical Care improved outcomes for patients with a tracheostomy.

Methods: All patients admitted to a neuro-trauma critical care unit, undergoing tracheostomy and surviving to Critical Care discharge were included in the analysis. Data was collected prospectively from 1st April 2022 until 31st December 2022 and compared to a historic baseline for the same period. The primary outcome was the proportion of patients decannulated within Critical Care; secondary outcomes included time from tracheostomy insertion to decannulation.
Results: 75 patients met the inclusion criteria and were seen by the SLT team during the evaluation period and compared to 104 patients in the baseline group. Time taken to tracheostomy insertion for the intervention and baseline groups was 14.8 and 14.1 days respectively. The introduction of the SLT team was associated with significant increase in the proportion of patients decannulated within critical care (65% vs 45%, $p < 0{,}001$), with non-significant but potentially clinically important reductions also seen in time to decannulation (21.4 vs 24.1 days) and critical care length of stay (40.1 vs 48.3 days). Whilst there was no baseline for comparison, the 2022 data showed 61% of patients had oral intake established and 78% were able to communicate verbally before Critical Care discharge.
Conclusions: The introduction of a dedicated SLT service as part of the established multi-disciplinary team was associated with an increased rate of decannulation within Critical Care. Whilst potentially important clinical reductions were observed for both time to decannulation and critical care length of stay, these were not statistically significant so should be interpreted with caution.

Introduction: Sepsis is the dyregulated host response to infection leading to organ dysfunction and death. In patients with sepsis, fever and external warming are associated with survival,hypothermia and cooling are associated with mortality. It is unclear why. Mitochondrial function is implicated in sepsis mortality yet can be manipulated by temperature in healthy tissue. We used musce tissue from a septic rat model to investigate whether temperature effects sepsis-induced mitochondrial dysfunction and therefore may contribute to the protective effect of heat.
Methods: Rats received either sham ($n = 5$) or septic ($n = 5$) insult using our established faecal-peritonitis rat model of sepsis. At 6 h organ failure was confirmed by echocardiography and the soleus was removed for ex-vivo studies. Baseline, complex 1 (CI) and complex 2 (CII) stimulated electron transport chain function was measured using High Resolution Respirometry in permeabilised soleus myofibres at 34ºC, 37ºC and 40ºC.
Results: Sepsis caused organ dysfunction demonstrated by reduced cardiac velocity time integral. CII stimulated oxygen consumption was reduced in septic animals compared to sham, but was not statistically significant. In healthy myofibres oxygen consumption following CII stimulation was higher at 40ºC vs 34ºC ($p = 0.006$). In septic myofibres, oxygen consumption was higher at 40ºC following both CI and CII stimulation compared to 34ºC ($p = 0.033$ and $p = 0.025$, respectively).
Conclusions: In ex-vivo studies, external temperature manipulation impacts both healthy and septic mitochondrial function in soleus muscle. Febrile-range temperature, either endogenous or exogenous, may protect or recover sepsis-induced mitochondrial dysfunction. Further studies are ongoing to confirm this and identify a mechanism.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001362

Introduction: One in twenty patients with a solid tumour require ICU admission within 2 years.[1] Critical illness has been demonstrated to significantly impact cancer survivors' long-term health, possibly through disturbance of oncologic treatment administration. Furthermore, the dysregulated inflammatory response experienced during critical illness may negatively impact disease progression.
Objectives: This study aimed to determine the impact of a critical care admission on the rate of solid tumour progression to metastatic disease.
Methods: We conducted a retrospective observational study using UK Biobank data. Adult patients with a solid tumour without metastasis were identified. Patients who survived a critical care admission within two years of diagnosis were compared to a hospitalised cohort. Kaplan–Meier survival analysis and Cox Proportional Hazards assessed differences in rate of metastatic disease, death, and progression-free survival.
Results: Data from 1854 participants with a solid tumour who survived a hospitalisation were analysed: 453 (24.4%) were critical care survivors, and 1401 (75.6%) were hospital survivors. There was a higher rate of metastatic progression in the critical care cohort at one (15% vs. 8%, $p < 0.001$), five (25% vs. 14%, $p < 0.001$), and ten years (26% vs. 16%, $p < 0.001$) (Figure 1).
This was confirmed on adjusted multivariable analysis (HR, 1.46; CI, 1.10–1.95; $p = 0.01$). After adjustment for confounders, critical care survivors had a higher mortality rate (HR, 1.42; CI, 1.22–1.65; $p < 0.001$) and poorer progression-free survival (HR, 1.69; CI, 1.31–2.18; $p < 0.001$).
Conclusions: This cohort study demonstrated that the rate of solid tumour progression to metastasis is higher in critical care survivors compared to a hospitalised cohort.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001364

Introduction: It is unknown whether doctors have realistic perceptions of critically ill patients' prognoses.
Objectives: To survey the ability of Finnish anaesthesiologists to estimate the probability of one-year survival of intensive care patients based on data available at the beginning of intensive care.
Methods: We sent a survey by e-mail to members of the Finnish Society of Anaesthesiologists (n = 1249, of whom an active e-mail address was available for 887). The survey presented a brief description of 12 fictional but real-life-based patient cases. For comparable patients treated in the intensive care unit (ICU), the true one-year survival ranged from 18.2% to 100%, according to data from the national ICU quality registry. For each case, we asked the respondent to estimate the likelihood of the patient being alive one year after ICU admission, choosing from the alternatives 5%, 10–90% in 10% intervals and 95%. Based on the difference between the estimate and the registry data-based realistic probability, we categorised the estimates as perfect (within 10 percentage points of the realistic probability), good (within 20 percentage points) and poor (difference over 20 percentage points).
Results: We received 210 responses and totally 210 × 12 = 2520 estimates. Of the respondents, 43 (20.5%) were specialists working full-time in the ICU, 81 (38.6%) were specialists working occasionally in the ICU, 47 (22.4%) were specialists not working in the ICU and 39 (18.6%) were doctors in training. Of all estimates, 1083 (43.0%) were perfect, 645 (25.6%) were good, and 792 (31.4%) were poor, with 612 (24.3%) underestimating and 180 (7.1%) overestimating the likelihood of survival. The median estimate was perfect in eight cases, good in one case and poor in three cases, underestimating the likelihood of survival in all three cases. At best, for a middle-aged patient with diabetic ketoacidosis, 76.7% of responses were perfect (Figure 1, left panel). At worst, for an 80–84-year-old patient with need for vasopressor support after emergency coronary artery bypass grafting, 63.3% of responses were poor, severely underestimating the prognosis (Figure 1, right panel).
Estimates that were poor made up 26.2% of the estimates made by specialists working full-time in the ICU (with 21.1% underestimating and 5.1% overestimating the likelihood of survival), 29.8% of those made by specialists working occasionally in the ICU (with 23.2% underestimating and 6.6% overestimating the likelihood of survival), 39.0% of those made by specialists not working in the ICU (with 30.0% underestimating and 9.0% overestimating the likelihood of survival) and 31.4% of the estimates made by doctors in training (with 23.1% underestimating and 8.3% overestimating the likelihood of survival).
Conclusions: Underestimating an intensive care patient's long-term prognosis is common. More education about critically ill patients' prognoses is needed.

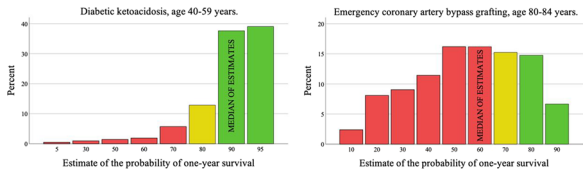

Figure 1 (abstract 001364) Distribution of estimates. The realistic likelihood of one-year survival is between the green bars

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001367

Introduction: Sleep quality in ICU patients is poor. The Odds Ratio Product (ORP) is a continuous index from 0 to 2.5 based on EEG that allows a new sleep classification. The sleep patterns or ORP-Sleep architecture types can be described according to the % of total recording time (TRT) during the sleep study spent in deep sleep (ORP < 0.5) and the % of TRT in full wakefulness (ORP > 2.25). Asynchronies during MV are common and might be related to the level of sedation, but the relationships between sleep and asynchronies during MV in ICU are unknown.
Objectives: To describe the night sleep patterns using ORP and its relationship with the amount and type of asynchronies in a cohort of mechanically ventilated patients.

Methods: Prospective observational study in a single ICU from a University Hospital. A single Sleep study using Prodigy® was performed in a relatively stable phase after ICU admission, simultaneously the waveform from the ventilator were recorded using BetterCare® to detect asynchronies.
Results: 42 patients were included in the final analysis after excluding those patients with lost signals from EEG or ventilator: Age 64 yo (54–76), Females 29%, APACHE II at admission 9 (6–14). During the sleep study: level of sedation RASS -5 (-3 to -5), previous duration of MV was 3 days (2–4.75), most patients were on Volume control ventilation (68%) or Pressure Support Ventilation (19%). The use of sedatives was propofol (54%), midazolam (32%) and dexmedetomidine (12%). Almost all patients were with fentanyl infusion (85%). The amount of deep sleep was 41% "little", 20% "normal" and 39% "excessive". The amount of full wakefulness was 78% "little", 15% "normal" and 7% "excessive". No differences were found between low incidence of asynchronies by Asynchrony Index (AI) < 10% and high incidence by AI > 10% in deep sleep and full wakefulness. Two asynchronies were related to at least normal full wakefulness: Short Cycling (SC) ($p = 0.02$) and Prolonged Cycling (PC) ($p = 0.006$). The reverse trigger asynchrony (RT) was related to excessive deep sleep ($p = 0.001$) (Table).
Conclusions: Most patients had either insufficient or excessive amount of deep sleep, but very little time in full wakefulness. The global incidence of asynchronies (AI) was not related with sleep patterns, but the asynchronies related to inspiratory time and flow were associated with wakefulness, and reverse triggering with an excessive amount of deep sleep.

	Little deep sleep n= 17	Normal deep sleep n=8	Excessive deep sleep n=16	p
IEE, % breaths; median (IQR)	0.2% (0-0.8)	0.38% (0-0.9)	0.15% (0-0.25)	0.2
DT, % breaths; median (IQR)	0.5% (0.1-1.1)	0.77% (0.26-1.1)	0.6% (0.3-0.82)	0.98
SC, % breath; median (IQR)	0.1% (0-0.3)	0.2% (0.1-0.4)	0.2% (0-0.3)	0.69
RT, % breath; median (IQR)	2.3% (0.7-6)	1.3% (0.15-3)	8% (4-18%)	0.001
PC, % breath; median (IQR)	0	0	0% (0-0.005)	0.74

	Little full wakefulness n=32	Normal full wakefulness n=6	Excessive full wakefulness n=3	p
IEE, % breaths; median (IQR)	0.18% (0-0.4)	0.57% (0.2-0.79)	0.02% (0-0.4)	0.18
DT, % breaths; median (IQR)	0.5% (0.14-1.1)	0.77% (0.25-1.1)	0.6% (0.3-0.8)	0.48

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001368

Introduction: Changing trunk inclination affects lung function in patients with ARDS. However, its impacts on PEEP titration remains unknown.
Objectives: Primary aim of this study was to assess, in mechanically-ventilated patients with COVID-19 ARDS, the effects of trunk inclination on PEEP titration. Secondary aim was to compare respiratory mechanics and gas exchange in semi-recumbent (40° head-of-the-bed) and supine-flat position (0°) following PEEP titration.
Methods: Twelve patients were positioned both at 40° and 0° trunk inclination (randomized order). The PEEP associated with the best compromise between overdistension and collapse guided by Electrical Impedence Tomography (PEEPEIT) was set. After 30 min of controlled mechanical ventilation, data regarding respiratory mechanics, gas exchange, and EIT parameters were collected. The same procedure was repeated for the other trunk inclination.
Results: PEEPEIT was lower in semi-recumbent than in supine-flat position (8 ± 2 *vs.* 13 ± 2cmH2O, $p < 0.001$). Moreover, the percentage of alveolar overdistension and collapse at PEEPEIT were significantly higher in the supine-flat position (10 ± 5 *vs.* 5 ± 3%, $p = 0.002$ and 9 ± 5 *vs.* 5 ± 3%, $p = 0.001$, respectively). Semi-recumbent position with optimized PEEP resulted in higher PaO2:FiO2 (141 ± 46 *vs.* 196 ± 99, $p = 0.02$) and lower global inhomogeneity index (46 ± 10 vs. 53 ± 11, $p = 0.008$). A loss of aeration (measured by EIT) was observed only in supine-flat position (-153 ± 162 *vs.* 27 ± 203 ml, $p = 0.007$).
Conclusions: Semi-recumbent position is associated with lower PEEPEIT and results in better oxygenation, less derecruitment, and more homogenous ventilation as compared to supine-flat position.

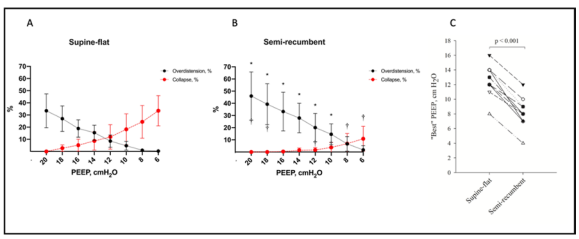

Figure. Overdistension, collapse and "Best" PEEP titration performed in supine-flat and semi-recumbent positions.

The results of collapse and overdistension during PEEP titration performed in supine-flat position and semi-recumbent position are presented in **Panel A** and **Panel B** respectively. Red dots represent the percentage of collapse, while black dots represent the percentage of overdistension. A two-way ANOVA for repeated measures was performed to evaluate the effect of trunk inclination and PEEP both on collapse and overdistension ($p<0.001$ for both). * = $p<0.05$ compared to the percentage of overdistension in supine-flat position for the same PEEP value; † = $p<0.05$ compared to the percentage of collapse in supine-flat position for the same PEEP value. **Panel C** represents the "Best" PEEP based on EIT in supine-flat and semi-recumbent position. Individual pairs of "best" PEEP identified through EIT in the two positions are reported. The p-value refers to the paired-t test. Data of 12 patients are reported, however 2 pairs of patients have the same pair of "best" PEEP values in supine-flat and in semi-recumbent position. As a consequence, data of only 10 patients are visible.

Extracorporeal membrane oxygenation in acute liver failure—case series

M. Zentar[1], S. Patel[2], R. Loveridge[3], T. Pirani[4], C. Willars[5], M. Angelova-Chee[5], A. Vercueil[5], G. Auzinger[6]
[1]Liver Intensive Care, King's College London, London, United Kingdom; [2]Intensive Care Department, King's College Hospital, London, United Kingdom; [3]Critical Care, Kings College Hospital NHS Foundation Trust, London, United Kingdom; [4]Critical care, Kings College Hospital, LONDON, United Kingdom; [5]Critical Care, King's College Hospital, London, United Kingdom; [6]Critical Care, King's College Hospital NHS Foundation Trust, London, United Kingdom
Correspondence: M. Zentar
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001369

Introduction: Despite the increasing number of indications for extracorporeal membrane oxygenation (ECMO), acute liver failure (ALF) is viewed as a contraindication in the majority of circumstances. Severe coagulopathy which invariably accompanies ALF and the high incidence of cerebral oedema significantly increase the risk of bleeding complications and intracranial hypertension. Functional immunoparesis contributes to infection, sepsis and septic shock. Despite an emerging literature on the utility of ECMO in elective liver transplantation there remains a sparsity of data in ALF patients, with or without transplantation.
Objectives: To describe our experience in supporting ALF patients with ECLS and to identify predictors of successful weaning from ECMO.
Methods: Retrospective case review of patients admitted and treated at a tertiary referral liver transplant centre between 2012 and 2022, who presented with ALF and were supported with veno-arterial (VA) or veno-venous (VV) ECMO.
Results: Among 21 patients included, 12 patients (57%) were female. The median age was 31 years (IQR 26–37). In total 16 patients (76%) required VV ECMO and 5 patients (24%) VA ECMO, with a median support duration of 5 days (IQR 4–9). Median INR was 5 (IQR 3.57–7.36), median peak bilirubin was 251uM (IQR 202–380), and median lactate was 11.7 mM (IQR 6.6–14.7). A total of 18 patients (86%) met King's College Hospital poor prognostic criteria with 15 patients (71%) undergoing emergency liver transplantation (ELT), 12 (57%) of whom were bridged to ELT on ECMO. At the time of cannulation 21 patients (100%) required renal replacement therapy and 6 patients (29%) had signs of raised intracranial pressure with fixed and dilated pupils. For patients receiving VV ECMO the median RESP score was -8 (IQR -6 to -11), patients supported with VA ECMO had a median SAVE score of -11 (IQR -11 to -15). Circuit anticoagulation was only used in 7 patients (33%). A total of 15 patients (71%) were successfully weaned from ECMO; 3 VA ECMO (60%) and 12 VV ECMO (75%). Ten patients (48%) survived to hospital discharge; 2 VA (40%) and 8 VV ECMO (50%). Assessment of multiple variables within 24 h of ECMO initiation showed that lower lactate levels (median 10 mM weaned vs 15.35 mM not weaned, $p = 0.014$), lower (VIS) Vasopressor and Inotropic Scores (median 55 weaned vs 133 not-weaned, $p = 0.023$) and an increased number of days on ECMO (median 6 days weaned vs 3 days not-weaned, $p = 0.0025$) were associated with a significantly greater chance of successful weaning. ROC analysis for the above variables were as follows: VIS AUC 82.2% (2.3–100%), Lactate AUC 84.4% (63.9–100%), and Days on ECMO AUC 93.3% (83.9–100%).
Conclusions: ECMO support in ALF is feasible and despite the extreme pathophysiology a significant percentage of patients survived with or without emergency liver transplant. Lower lactate levels, lower VIS and greater number of ECMO days were associated with a greater chance of successful weaning.

A comparison between emergency physicians and radiologists on the accuracy and efficiency of the interpretation of computed tomography of acute appendicitis

CC. Chao[1]
[1]Emergency Department, Taipei Medical University Hospital, Taipei, Taiwan
Correspondence: C.C. Chao
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001372

Introduction: Appendicitis is a common acute abdomen disease seen in the emergency department (ED). Early diagnosis of appendicitis can reduce time to treatment and prevent complications. We compared the interpretation of computer tomography (CT) scan between emergency physicians and radiologists.
Objectives: The aim of this study is to compare the time to and the accuracy of CT scan interpretation between emergency physicians and radiologists.
Methods: This is a retrospective study that enrolled patients with CT scan for suspected acute appendicitis in an academic hospital from July 2019 to May 2020. Analysis on the accuracy of the diagnosis of appendicitis and time from completion of CT scan testing were compared between emergency physicians and radiologists.
Results: A total of 318 patients with appendicitis were included. Patients coming to hospital at off time were younger (Mean Difference = 5; *P*-value = 0.016) and were more common with normal CRP (Chi-square = 11.19; *P*-value < 0.001). Both groups' interpretations of appendicitis were not affected by arrival time and all did differential diagnosis well (Emergency physician

area under curve (AUC) = 0.912 versus Radiologist AUC = 0.911). Time to CT interpretation by emergency physicians was significantly lower than by radiologists (Mean Difference = -217.37 min; *P*-value < 0.001).
Conclusions: The interpretation of abdominal CT scan for acute appendicitis by emergency physicians was more efficient and equally accurate compared to interpretation by radiologists.

Correspondence: R. Hoiland

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001373
Introduction: Following a traumatic spinal cord injury (SCI), there is a period of continued spinal cord tissue hypoxia that contributes to secondary injury. Blood pressure augmentation is employed clinically in an attempt to increase spinal cord blood flow and spinal parenchymal oxygen tension (PO2). However, this strategy does not consistently alleviate secondary spinal cord tissue hypoxia or injury and new hemodynamic management strategies are needed.
Objectives: To investigate the influence of blood pressure augmentation with dobutamine and adjuvant ethyl nitrite (ENO), an oxygen-dependent vasodilator, on hemodynamic management and spinal cord oxygenation following traumatic spinal cord injury (SCI).
Methods: Parallel experiments were conducted in rodent and pig models of high-thoracic SCI: a dose-escalation study with ENO (0–100 ppm) and an acute treatment study (~0 to 4 h post-SCI) involving ENO (50 ppm; rodents only), dobutamine (DOB, 1 ug/kg/min, IV), and combined ENO + DOB administration along with controls (Lactated Ringer's, IV). Rodents underwent a T3 SCI (300 kdyn, no compression) while pigs underwent a T2 SCI (~2600 kdyn, 2 h compression). Mean arterial pressure (MAP; femoral artery) and intraparenchymal spinal PO2 were measured.
Results: Dose-escalation of ENO to 50 ppm increased spinal PO2 from 9 ± 5 to 17 ± 8 mmHg in the rodents (P = 0.043; n = 4) and from 12 ± 2 to 16 ± 3 mmHg in the pigs (n = 2). In the acutely treated rodents, MAP was higher with DOB (84 ± 8 mmHg; P = 0.002; n = 5) and DOB + ENO (79 ± 8 mmHg; P = 0.018; n = 5) compared to controls (63 ± 6 mmHg; n = 5) while ENO increased spinal PO2 compared to controls (23 ± 7 vs. 6 ± 3 mmHg; P = 0.002; n = 5 each group); concurrent DOB infusion further augmented PO2 (+ 6 ± 4 mmHg; P = 0.03; n = 5). In the acutely treated pigs, spinal PO2 was 12 ± 11 mmHg in controls (n = 4), 21 ± 11 mmHg with DOB (n = 6), and 34 ± 23 mmHg with DOB + ENO (n = 5) following decompression. Spinal PO2 decreased from pre-SCI to post-decompression in the control group (-12 ± 15 mmHg) but was elevated in the DOB + ENO group (+ 21 ± 19 mmHg; P = 0.04 compared to the change in controls).
Conclusions: Blood pressure augmentation with dobutamine and adjuvant ethyl nitrite holds promise as an approach to optimize hemodynamic management and spinal cord oxygenation following traumatic spinal cord injury. Such improvements in spinal cord oxygenation may be a method by which we can reduce secondary injury in the spinal cord and improve outcomes for patients that suffer a traumatic spinal cord injury.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001374

Introduction: Isolation of one lung leads to ventilation-perfusion mismatch and increases intrapulmonary shunt, which in some cases may lead to clinically significant hypoxemia and potentially could lead to significant postoperative complications. Recent research has shown that high-flow oxygen insufflation (HFO) could be applying during one-lung ventilation (Duwat A. et al., 2019).
Objectives: This study aims to compare the effectiveness of high-flow oxygen insufflation and continuous positive airway pressure (CPAP) in correcting intraoperative hypoxemia, reducing V/Q mismatch, and preventing postoperative complications and adverse outcomes.
Methods: The study included 67 patients who underwent elective video-assisted thoracoscopic lobectomy and developed hypoxemia during the first 15 min of one-lung ventilation. The patients were randomly divided into two groups: the first group (HFO group) received HFO into the non-ventilated lung to correct hypoxemia, while the CPAP group received conventional CPAP into the non-ventilated lung. Oxygenation parameters were recorded at four time points during the operation: T1 for bipulmonary ventilation, T2 for single-lung ventilation, T3 for implementation of HFO with a flow of 60 L/min (at a temperature of 37 °C) and an initial FiO2 of 0.5 into the non-ventilated lung for the HFO group or CPAP of 5 cm H2O into the non-ventilated lung in the CPAP group. At T4, HFO was applied with a flow of 30 L/min (at a temperature of 37 °C) and an initial FiO2 of 0.5 into the non-ventilated lung in the HFO group, while in the CPAP group, CPAP of 2 cm H2O was applied into the non-ventilated lung. We analyzed PaO2, SaO2, PCO2, Qs/Qt, and surgical team satisfaction with lung collapse by visual analog scale (VAS; 0 is for perfect visualization, 10 is for inability to perform VTS). Postoperative complications and outcomes were analyzed.
Results: At T1 and T2, there were no statistically significant differences between the groups in oxygenation parameters. PaO2 was significantly higher in the HFO group at T3 and T4: 134.5 (126.0; 141.75) mm Hg in the HFO group vs 108.5 (104.0; 114.5) mm Hg in the CPAP group at T3 (p < 0.001) and 118.5 (113.0; 122.25) mm Hg vs 92.5 (89.0;

98.25) in the CPAP group at T4 for the HFO and CPAP groups, respectively ($p < 0.001$). At T4, SaO2 was higher (97% (96; 97)) in the HFO group: 97% (96; 97) vs 94% (94; 95) in the CPAP group ($p < 0.001$). Qs/Qt at T4 was 10.7% (9.5; 15.7) in the HFO group and 21.3% (18.4; 23.9) in the CPAP group ($p < 0.001$). There was a significant difference in surgical satisfaction between the HFO group and CPAP group at T3 and T4: 2.5 (2; 3) in the HFO group at T3, 9 (8; 9) in the CPAP group at T3 ($p < 0.001$); 1 (0; 1) in the HFO group and 5 (4; 5) in the CPAP group ($p < 0.001$). PCO2 did not differ at any time during surgery. Postoperative complications did not differ between the two groups: class III Clavien-Dindo complication developed in one patient in the CPAP group. The need for postoperative respiratory support did not differ between the two groups (Chi-square 0.891, $p = 0.346$). No fatal outcomes were observed in our study.

Conclusions: The use of high-flow oxygen insufflation during one-lung ventilation undergoing video-assisted thoracic surgery allows for effective treatment of hypoxemia similar to the CPAP method and seems to be safe in terms of postoperative complications and outcomes. High-flow oxygenation could provide better intraoperative visualization.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001375

Introduction: Medical training continues to evolve, and theoretical training is currently inconceivable without balanced practices, even more so if we think about complex techniques or procedures such as extracorporeal membrane oxygenation (ECMO), hence the growth of the offered training through clinical simulation. However, the arrival of the pandemic abruptly modified this new training philosophy, having to update the training methods and implement multiple online platforms and supports to maintain training despite the situation caused by COVID-19.

Objectives: The objective of the study was to assess whether differences were detected between two training course models on the use and management of ECMO; one carried out entirely face-to-face and another hybrid with an online theoretical phase and face-to-face practical phase (post-COVID-19 pandemic); in terms of the degree of satisfaction, interest in the contents, integration with the teaching staff and the methodology among the students who received the full face-to-face course compared to those who received the hybrid course model (on-line plus face-to-face).

Methods: A total of 6 theoretical-practical training courses were carried out, including advanced simulation workshops, between 2017 and 2023 (4 face-to-face courses of 22 h and 2 in a mixed online format/3 months plus face-to-face/2 days). Retrospective descriptive study, for which, at the end of the course, a satisfaction survey was conducted with scores between 1 (poor) and 5 (excellent). Statistical analysis was performed with SPSS v24, quantitative variables were used that were expressed as mean and SD, and the comparison of means was carried out using the T-Student test with a pre-established degree of significance of 0.05.

Results: Data from 161 students were analyzed (135 answered the survey, 83.8%). 46 in hybrid modality and the rest in face-to-face modality (courses of 24 to 30 students). Regarding the results, both types of courses, had high evaluations and, it should be noted (Table 1) that, both in the evaluation of the course and in the integration with the teaching staff, there were no statistically significant differences between both group models but that, in the interest in the topics and the valuation of the methodology, a relevant variable for us, did point to differences in favor of the hybrid model.

Questions	Mean face-to-face	Standard desviation face-to-face	Mean Hybrid	Standard desviation hybrid	T-Student
General evaluation of the course	4.73	0.21	4.83	0.27	0.954
Interest in the topics covered	4.06	0.85	4.45	0.47	0.004
Integration of teachers with assistants	4.60	0.64	4.67	0.49	0.532
The methodology has been adequate	4.16	0.73	4.43	0.63	0.044

Conclusions: Both course formats had a high degree of student satisfaction. The modification in the teaching strategy, with hybrid training (online 3 months associated with face-to-face simulation workshops during 2 days) not only was not inferior to the classic model, but its methodology was better valued compared to the classic one.

Correspondence: A. Schweighauser
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001378

Introduction: An increase of invasive and probable invasive group A Streptococcal infections (iGAS and piGAS) in the last year has been described (1). Our aim was to compare the incidence of iGAS and piGAS from 2018 to May 2022 (period 1) with incidence of cases from June 2022 to April 2023 (period 2) in the Cantonal Hospital of Grisons, Switzerland and to describe the cases occurring during the last year.

Methods: iGAS is defined by germ isolation from sterile sites (blood, synovial fluid, peritoneal fluid), whereas piGAS by germ isolation from non-sterile sites (deep skin or retropharyngeal aspirations) requiring one or more of the following: hospitalization for iv. antibiotics, surgery or admission to the Intensive Care Unit (ICU) (2). Streptococcal toxic shock syndrome (STSS) is defined as sudden onset of shock, organ failure and frequently death (3).

We captured all cases of iGAS and piGAS that were recorded in the Swiss Diagnosis Related Groups of our institution and by reviewing the medical records of all hospitalised patients with positive blood culture with group A streptococci from January 2018 until April 2023. Additionally, we summarised comorbidities, clinical presentation, therapeutic approach and outcome of all patients with iGAS and piGAS of our institution since June 2022 differentiating the patients of the ICU from patients of the wards.
Data are expressed as numbers (%) and median (IQR).
Results: During the over four years period from 2018 to May 2022 we identified totally 16 cases of iGAS and piGAS, 7 of them had positive blood cultures. From June 2022 to April 2023, we noted an increase of to a total of 40 cases. There were 22 cases of iGAS (12 treated on the ICU) and 18 piGAS (5 treated on the ICU). The male/female ratio was 2.3.
ICU: Total 17 cases, median age was 58 (39–73) years. The most common clinical manifestation was soft tissue infection n = 12, (71%) with 3 (18%) necrotizing fasciitis. Alcohol n = 5 (29%), drug abuse n = 5 (29%) and obesity n = 3 (18%) were the main comorbidities. All patients received appropriate antimicrobial treatment. Clindamycin was administered in 15 (88%) of the cases. 9 (53%) patients needed surgery with 1 patient requiring limb amputation. 7 (41%) patients developed STSS and 8 (47%) suffered from ARDS. 3 (42%) patients with STSS received Immunoglobulin (IVIG) (4). 28-days mortality was 18%.
NON-ICU: Total 23 cases, median age was 56 (39–71) years. The most common clinical presentation was soft tissue infection n = 15 (65%). The most common co-morbidity was diabetes n = 4 (17%). Regarding iGAS, 9 (40%) of patients did not receive Clindamycin, although indicated (5,6). 16 (70%) patients needed surgery. No patient died.
Conclusions: We noted an increase of piGAS and iGAS in our hospital since June 2022. The clinical presentations were serious: 43% of the patients were admitted to the ICU. Illicit substance, alcohol abuse and obesity were risk factors. Mortality was high. According to the literature adherence to current treatment recommendations is low. Efforts should be undertaken to improve standard of care: Immediate treatment should include clindamycin for iGAS and IVIG for STSS.

Introduction: Few data are available on lung microbiota composition of patients with COVID-19-related ARDS (C-ARDS) receiving invasive mechanical ventilation (IMV). Moreover, limited evidence has investigated the correlation between lung microbiota and respiratory mechanics.
Objectives: We aimed to assess the relationship between lung microbiota composition, respiratory mechanics and clinical outcomes in critically ill patients with C-ARDS.
Methods: This observational study involved two ICUs of a university hospital in Italy from April 1 through December 31, 2020. Lung microbiota was investigated by bacterial 16S rRNA gene sequencing, performed on bronchoalveolar lavage (BAL) fluid samples withdrawn after intubation. The lung bacterial communities were analyzed after stratification by respiratory system compliance/predicted body weight (Crs) and ventilatory ratio (VR). Weaning from IMV and in-hospital mortality were further assessed.
Results: We enrolled 70 C-ARDS patients requiring IMV. Lung microbiota composition (phylum taxonomic level, PERMANOVA test) significantly differed between patients with low Crs vs. those with high (p = 0.010), as well as in case of low-VR vs high-VR stratification (p = 0.012). As difference-driving taxa, Proteobacteria (p = 0.017) were more dominant in low *vs* high-Crs patients, whilst Firmicutes less (p = 0.040). Similarly, Proteobacteria were more dominant in low *vs* high-VR patients (p = 0.013). We further observed lung microbiota diversity as a prognostic factor of in-hospital mortality (HR = 3.31, 95%CI 1.52–7.20, p = 0.048).
Figure: Graphic representation of respiratory mechanics, aerated tiddue and lung microbiota composition in two patients.
Computed tomography scan images of lungs from two representative patients with (A) high Crs/PBW (0.61 (mL/cmH2O)/Kg) and VR (3.64) values or (B) low Crs/PBW (0.43 (mL/cmH2O)/Kg) and VR (1.65) values depicted the distribution of aerated lung tissue, detailed in the respective wave frequency graphs. For each patient, bubble chart shows dominant families in the lung bacterial community. Abbreviations:Crs = compliance of the respiratory system. PBW = predicted body weight. VR = ventilatory ratio.
Conclusions: C-ARDS patients with low Crs/low VR had a Proteobacteria-dominated lung microbiota. Moreover, a more diverse lung bacterial community was more likely a predictor of weaning from IMV and discharge alive from hospital.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001381

Introduction: Severe chest trauma (CT) remains a leading cause of morbidity and mortality. Inadequate pain management has a deleterious effect, increasing the risk of respiratory complications, chronic pain, and prolonged hospital stay. Although opioids are commonly used, their adverse effects limit their use. Regional analgesia (RA), as part of multimodal regimen, has been shown to be beneficial in comparison to opioid-based methods. Thoracic epidural (TEP) is the recommended regional technique in most European protocols, but its use may be limited in critical care. Other techniques, such as continuous erector spinae plane block (CESB), can be a safe and effective alternative.
Objectives: To describe the use of RA in ICU patients with CT and to evaluate its impact on clinical outcomes.
Methods: Single-center retrospective cohort study of all adult patients with CT admitted on a Trauma Center of a tertiary universitary hospital and submitted to RA as part of a multimodal regimen between January 1st 2021 and December 31st 2022.
Primary outcome: variation in opioid consumption following RA.
Secondary outcomes: incidence of RA complications, nosocomial infections, duration of mechanical ventilation, and ICU and hospital length of stay (LOS).
Preliminary analysis included descriptive statistics, along with inferential analysis based on t-tests and chi-square comparisons.
Results: Of the 469 trauma patients admitted, 57 met the inclusion criteria (12.2%). Most were male (87.7%), with a median age of 49 years. 63.2% had comorbidities. Mean Trauma Score and Injury Severity Score was 42.9%; Mean Injury Severity Score was 25.5 and 82.5% of them had a score > than 15 (no significant difference in TEP versus CESB groups). Road traffic accidents were the main mechanism of injury (50.9%) followed by falls (31.6%). 10.5% had isolated CT. Brain, spine, and abdominal trauma were the most common concurrent injuries.
TEP was performed in 75.4% and CESB in the remaining 24.6% patients. Only one complication was documented. Median oral morphine milligram equivalents decreased significantly from 405 (IQR 1020) before RA to 60 (IQR 60) on the fifth day after RA ($p < 0.001$). This reduction in opioid consumption was statistically significant in the TEP group ($p = 0.002$) but not in the CESB group.
Mean hospital LOS was 24.7 days, with 10.1 days in ICU (6.8 of them after RA). 40.35% of patients required mechanical ventilation for a mean duration of 9.73 days, 7**.**35 of which after RA. Incidence of nosocomial infections was 21.4%. Total mortality was 1.7%.No differences were found between TEP and CESB groups for these parameters.
Conclusions: RA is safe and effective for pain relief and avoiding side-effects of opioid based regimens for ICU patients with severe CT. It was associated with a significant reduction in opioid consumption on the 5th day after its initiation, namely with TE. Similar clinical outcomes were observed between TEP and CESB.

Testosterone and sST2 as mortality predictive biomarkers in patients with sepsis induced cardiomyopathy

L. Wang[1], Z. Liying[1]
[1]Department of Critical Care Medicine, Renmin Hospital of Wuhan University, Wuchang District, Wuhan, China, Wuhan, China
Correspondence: L. Wang
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001382

Introduction: Sepsis induced cardiomyopathy (SIC) is characterized as high mortality and poor outcomes. Abnormal serum testosterone and soluble ST2 (sST2) have been reported related with cardiovascular events in sepsis. This study was performed to explore the relationship between testosterone and sST2 and all-cause mortality in SIC patients.
Methods: We conducted a prospective cohort study and enrolled 327 male patients with diagnosed SIC from January 2021 to March 2023 at a large academic medical center in Wuhan.The predictive values of testosterone and sST2 on mortality of SIC were estimated with Cox proportional hazards analysis and receiver operative characteristic curve (ROC).
Results: In present study, there were 87 deaths (26.6%) and 103 deaths (31.5%) that occurred during 28-day follow-up and 90-day follow-up, respectively. When grouped by tertiles of biomarkers, patients with higher testosterone and decreased sST2 had significantly lower 28-day and 90-day mortality (both $p < 0.01$). Kaplan–Meier analysis showed significantly higher 28-day and 90-day survival with higher testosterone and lowered sST2 (all $p < 0.001$). In logistic regression, body mass index, testosterone, sST2 and N-terminal pro-B-type natriuretic peptide (NT-proBNP) were risk factors of 28-day mortality ($p < 0.05$). The combination of testosterone and sST2 enhanced prediction of both 28-day mortality (AUC 0.805) and 90-day (AUC 0.833) mortality.
Conclusions: In this cohort of SIC patients, serum testosterone and sST2 predicted mortality independently and jointly. Their combination improved prognostic accuracy for 28-day and 90-day survival. These biomarkers may facilitate early risk stratification and identify patients who could benefit from targeted interventions.

Introduction: The emergence of bacterial resistance to antibiotics is a major problem that society will have to face in the coming years. Enterococci are opportunistic pathogens responsible for nosocomial infections.
Objectives: To analyse the situation of multi-resistance in an Intensive Care Unit (ICU) and the impact of measures taken to control an outbreak of vancomycin-resistant Enterococcus (VRE) detected during the study period.
Methods: Retrospective, observational study in a 14-bed ICU in Level II hospital. The analysis time is divided into two periods (2015–2018 and 2019–2022) separated by the implementation of measures following the outbreak of VRE (2017–2018). 2020 was excluded from the study period due to the barrier posed by the COVID-19 pandemic. Characteristics of the patients, severity (APACHE II), length of stay and previous use of antibiotics were collected.MDR isolates were collected from clinical samples and colonisation studies. Qualitative variables are described as percentages and quantitative variables as mean (SD). Rates of patients with MDRduring ICU admission are expressed per 1000 days of stay and per 100 patients.
The most relevant measures implemented were: intensification of hand hygiene training, increased supervision in the implementation of the cleaning protocol, Preventive Medicine carried out a control of surfaces by direct observation and the incorporation of tests to locate areas with a lack of cleanliness, cultures using RODAC plates and preventive decontamination systems (pulsed ultraviolet light and hydrogen peroxide vapour) were incorporated.
Results: First period, 545 patients, 63% male, mean age 64.02 years (±15.28). Mean APACHE 14.28 (±8.32) and mean stay 7.99 (±15.65) days. Antibiotic treatment was given in 55.47%. MDR were detected in 13.2%. The mean rate of patients with MDR previous ICU admission was 9.07% and 4.55% for intra-ICU acquisition. Most prevalent pathogens in 2015 were VRE (33.33%), Enterobacteriaceae BLEE (33.33%) and BGN-carbapenemases (33.33%). In 2016, detection of MRSA (33.33%) became more important. In 2017 and 2018 there is a very marked increase in the detection of EVR, 83.33% and 54.55% respectively. A total of 19 cases were detected between 2017 and 2018. Of the 19 cases of the outbreak, 11 (57.89%) were acquired in the ICU and involved infection in only 2 cases (10.52%).
Second period, 411 patients, 64.89% male, mean age 62.29 (±14.80) years. Mean APACHE 14.44 (±8.43) and mean stay 9.58 (+15.43) days. Antibiotics in 58.16%. MDR was detected in 10.70%. The mean rate of patients with MDR was 6.88% for pre-acquisition and 3.86% for intra-ICU acquisition. In 2019, MRSA predominates (33.33%), with EVR (22.22%) and multidrug-resistant Pseudomonas (22.22%) in second place. In 2021, the prevalence of MRSA increases, accounting for 40% of isolates, together with BGN-carbapenemase (40%). Finally, in 2022, 50% of BGN-carbapenemase isolates persisted, with a significant decrease in MRSA. Only 2 more cases of VRE have been identified in 2022.
Measures adopted, we analysed in more detail: adherence to hand hygiene (Table 1) and surface analysis (Table 2).
In relation to the impact of the measures adopted, the rate of patients with MDR with intra-ICU acquisition, during 2015, 2016, 2017 and 2018 was 3.51%, 8.44%, 5.75% and 9.98% respectively. In 2019, 2021 and 2021 was 7.82%, 2.82% and 3.20% respectively.
Conclusions: This study confirms the established problem of the emergence of bacterial resistance and the importance of maintaining prevention and control strategies. Also highlights the problem of the "exhaustion phenomenon" in the staff as a factor favouring the spread of MDR.The decrease in the rate of patients with intra-ICU acquisition after the implementation of measures demonstrates that preventive strategies work.

Table 1 (abstract 001383) Adherence to hand hygiene.

	Medical staff (%)	Nursing staff(%)	Auxiliary staff(%)
2015	85,71	86,36	50,00
2016	90,48	82,50	70,83
2017	62,50	73,08	84,21
2018	41,18	51,35	63,64
2019	73,33	79,17	60,61
2020	71,43	42,42	45,83
2021	70,00	66,67	66,67
2022	16,67	41,46	44,00

Table 2 (abstract 001383) Surface analysis

Detection limit : 5 UFC /cm²		
	CORRECT(%)	INCORRECT(%)
2018	80,45	19,55
2019	74,42	25,58
2020	68,89	31,11
2021	77,14	22,86

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001384

Introduction: Acute pancreatitis (AP) is a serious and potentially deadly condition and in up to 14% of the cases can be caused by hypertriglyceridemia. The risk of AP is higher in cases of severe hypertriglyceridemia (> 1000 mg/dL) and the severity of the disease is proportional to the elevation of the triglycerides. The presentation is like other causes of pancreatitis. The mortality rate is higher in the first 15 days due to the systemic inflammatory response syndrome and after this period the major causes of mortality are the complications of the disease (local or systemic).
Objectives: The aim of this study was to review all the cases of acute pancreatitis secondary to hypertriglyceridemia submitted to therapeutic plasmapheresis sessions in an intensive care unit (ICU).
Methods: This is an observational retrospective study conducted between April 2012 and March 2023 that included all the patients with AP by hypertriglyceridemia submitted to plasmapheresis sessions in the ICU. Only patients who underwent plasmapheresis outside the ICU were excluded.

Results: Of 18 patients, 88% were men (n = 16), with a median age of 43 years. The median body mass index of these patients was 28,43 kg/m2. The median APACHE II score was 8,3, that represent a predicted in-hospital mortality rate of 8% for nonoperative patients. All the selected patients had severe hypertriglyceridemia at admission and 33% (n = 6) had triglycerides over 4400 mg/dL. A total of 26 plasmapheresis sessions were carried out in the intensive care unit. Most patients did only one session (n = 12, 66,7%) but one third needed two sessions (n = 6). The most used replacement solutions were albumin (n = 11, 42,3%) and albumin/crystalloid (n = 11, 42,3%), followed by fresh frozen plasma (FFP) (n = 3, 11,5%) and a combination of albumin/crystalloid/FFP (n = 1, 3,8%). The reduction of the hypertriglyceridemia was effective, mainly over 50% (n = 21) and in some cases over 90% (n = 2). There were registered 22 interruptions of treatments, mainly for rupture of the filter (n = 13, n = 59%). The most frequent complication was hydroelectrolytic disturbances (n = 6, 23,1%) and coagulopathy or thrombocytopenia (n = 5, 19,2%), but there were no major complications that lead to interrupt the treatment.
Conclusions: Therapeutic plasmapheresis is a complex technique but effective in the treatment of acute pancreatitis by hypertriglyceridemia and is recommended as a first line treatment by the American Society for Apheresis for the treatment of the AP cases associated with severe hypertriglyceridemia. There were no severe complications related to the technique.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001385

Introduction: The adjustment of the maintenance immunosuppressive regimen for kidney transplant recipients (KTRs) requiring intensive care management is in continuous discussion.
Objectives: Thus, this study aimed to evaluate the acute rejection risks in KTRs followed until one year after an intensive care unit (ICU) discharge.
Methods: Single-center cohort study that enrolled 376 KTR admitted to the ICU (excluding immediate post-transplant period) between 2018 and 2019. Follow-up date was one year after the ICU admission. Patients were stratified according to immunosuppressive regimen adjustment during the ICU length of stay: sustaining the immunosuppressive regimen with two or three drugs vs. use of corticosteroids alone. The primary outcome was acute rejection (AR), while the secondary was graft loss (GL). The multivariable analysis was performed by logistic regression.
Results: KTRs were 57.4 (46.1–64.8) years old, 61.4% male and 42.8% were receiving tacrolimus, mycophenolate, and prednisone as the maintenance immunosuppressive regimen. Most had acute kidney injury (60.6%), and 19.1% required renal replacement therapy. During the ICU stay, 53.5% underwent corticosteroids alone. The one-year incidence of AR and GL was 4.3% and 9.6%, respectively. Compared with sustaining the immunosuppressive regimen, corticosteroid alone was not associated with a higher incidence of AR (5.7% vs. 3.0%, p = 0.19) or GL (8.0% vs. 10.9%, p = 0.33). In the multivariable analysis, AR after the ICU discharge was only associated with age (OR for each year = 0.96; p = 0.03) and the report of AR before the ICU admission (OR = 16.5; p < 0.001). Changing the immunosuppressive regimen during the ICU stay was not associated with AR.
Conclusions: For the critically ill KTRs admitted to the ICU, the adjustment of maintenance immunosuppressive regimen for corticosteroids alone, compared with sustaining double or triple immunosuppressive regimen was not associated with increased risk of acute rejection or graft loss until 1 year after the ICU discharge.

Carboxyhemoglobin, methemoglobin, and total bilirubin as markers for mortality and hemolysis in patients with ARDS and veno-venous ECMO

V. Bünger[1], O. Hunsicker[1], A. Krannich,[2], F. Balzer[3], C. Spies[4], WM. Kuebler[5], S. Weber-Carstens[6], M. Menk,[7], J. Graw[8]

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001388

Introduction: Hemolysis is common in intensive care patients and associated with adverse outcomes and mortality. Beside direct and precise but not routinely measured markers for hemolysis such as cell-free hemoglobin (CFH) and haptoglobin (Hp), other CFH-downstream products like carboxyhemoglobin (CO-Hb), methemoglobin (Met-Hb), and total bilirubin (tBili) are routinely monitored via blood gas analysis. Previous studies suggest an association of tBili and CO-Hb with hemolysis and mortality. Patients with ARDS and treatment with veno-venous ECMO (VV ECMO) are especially prone to hemolysis and might benefit from early detection of increased hemolysis and potential reactions to the causes of hemolysis.
Objectives: We aimed to identify cut-off values for CO-Hb, Met-Hb, and tBili that are associated with a significant increase of mortality in patients with severe ARDS and treatment with VV-ECMO.
Methods: Retrospective analysis of patients with ARDS admitted to a tertiary ARDS referral center from 01/2007 to 12/2018. All patients with CO-Hb, Met-Hb, tBili, Hp and CFH measurements within the first week of ECMO treatment were included. Cut-off values of mean

CO-Hb, mean Met-Hb and mean tBili concentrations over therapy time associated with significant increases in ICU mortality were calculated with recursive binary partitioning. If more than one splitting node was found, only the most significant, first cut-off value was considered. Patients were grouped according to their respective mean CO-Hb, mean Met-Hb, and mean tBili values. ICU mortality, mean CFH and mean Hp values were compared. A multivariate regression model of ICU mortality and the three marker variables with their cut-off values was implemented. The study was approved by the Medical Ethics Committee of the Charité-Universitätsmedizin Berlin (No. EA2/019/19).
Results: A total of 435 patients was included. For mean CO-Hb, a cut-off value of 2.007 was found to divide the cohort into two groups with significantly different ICU mortality (CO-Hb ≤ 2.007%: 37% [95% CI 31.2–44.1], n = 227 vs. CO-Hb > 2.007%: 63% [56.5–69.9], n = 208, p < 0.001). For mean Met-Hb, a cut-off value of 1.255 was calculated (Met-Hb ≤ 1.255%: 45% [39.4–50.1], n = 347 vs. Met-Hb > 1.255%: 70% [59.6–79.5], n = 88, p < 0.001) and for tBili a first significant cut-off value was found at 8.386 mg/dl (tBili ≤ 8.386 mg/dl: 43% [37.7–48.2], n = 361 vs. tBili > 8.386 mg/dl: 85% [75.5–92.0], n = 74, p < 0.001). Besides from mortality, all groups differed significantly in mean Hp (CO-Hb ≤ 2.007%: 0.75 g/l [IQR 0.34, 1.38] vs. CO-Hb > 2.007%: 0.47 g/l [0.23, 0.75], p < 0.001; Met-Hb ≤ 1.255%: 0.64 g/l [IQR 0.32, 1.15] vs. Met-Hb > 1.255%: 0.35 g/l [0.20, 0.67], p < 0.001 and tBili ≤ 0.957 mg/dl: 0.66 g/l [IQR 0.34, 1.18] vs. tBili > 0.957 mg/dl: 0.25 g/l [0.13, 0.44], p < 0.001). For the direct hemolysis marker mean CFH, only the Met-Hb and tBili groups differed significantly (Met-Hb ≤ 1.255%: 7.64 mg/dl [IQR 5.21–13.03] vs. Met-Hb > 1.255%: 13.14 mg/dl [8.52–31.00], p < 0.001 and tBili ≤ 8.386 mg/dl: 8.33 mg/dl [IQR 5.51, 14.06] vs. tBili > 8.386 mg/dl: 11.48 mg/dl [5.40, 19.35], p = 0.045). The cut-off values were independently and significantly associated with ICU mortality in the multivariate regression model (CO-Hb: OR 3.23 [95% CI 2.12–4.99], p < 0.001; Met-Hb: 3.36 [1.95–5.90], p < 0.001; tBili 7.13 [3.68–15.02], p < 0.001).
Conclusions: CO-Hb, Met-Hb and tBili are independently associated with hemolysis and mortality in patients with ARDS and treatment with VV ECMO. These easily and rapidly measurable routine laboratory parameters might help to identify patients at risk or trigger timely measurement of the direct hemolysis parameters CFH and Hp.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001389

Introduction: Patients with diabetic ketoacidosis (DKA) are often potassium depleted. Although routine treatment of DKA frequently includes intravenous potassium, patients are prone to hypokalemia during treatment. The reasons of hypokalemia are multifactorial, mainly kaliuresis, inadequate oral intake and gastrointestinal losses in addition to insulin supplementation during treatment. There is a concern that hypokalemia during DKA treatment can lead to havardous adverse events including arrhythmias and sudden cardiac death, but the actual effect of occurrence of hypokalemia during DKA treatment on mortality has not been well characterized. In this study, we assessed the outcomes of DKA hospitalizations whenever hypokalemia was present or not.
Objectives: To determine whether hypokalemia has deleterious effects during the treatment of DKA.
Methods: Using MDClone©, we retrieved all hospitalizations of adult patients (age over 18) with moderate or severe DKA (defined by a combination of clinical diagnosis of DKA in the electronic medical record, pH under 7.3, glucose > 250 mg/dl and IV insulin treatment) in Rambam medical center, a tertiary 1000-bed academic medical center between 2/2012–1/2020 and compared demographic variables, anthropometric variables, hospitalization variables, blood tests throughout admissions, 30 day mortality and total mortality between patients who did or did not develop hypokalemia.
Results: Results: In the defined time period, there were 456 DKA hospitalizations that filled all criteria and had no missing data. About two thirds of hospitalizations (304) were complicated by hypokalemia (Potassium < 3.5 meq/L within the 3 days before or after the time of the lowest pH). Compared to patients who did not develop hypokalemia, patients who did were, on average, younger (46.3 ± 19.3 vs52.3 ± 21.5, p = 0.003), had a lower pH (7.08 ± 0.14 vs 7.15 ± 0.11 p < 0.001), lower bicarbonate (8.99 ± 4.50 vs 12.3 ± 4.11, p < 0.001) and A significantly higher rate of patients who developed hypokalemia were admitted to ICU (36.8% vs 13.8%, p < 0.01), and higher maximal creatinine (2.18 ± 1.6 vs 1.82 ± 1.36, p < 0.05). In addition hypokalemia during DKA treatment was associated with a longer hospital stay.
The 30 day mortality was similar between the two groups (6.3% in the hypokalemia and 7.9% in normokalemia, P = 0.55) as was long term mortality (26.6% and 33.6% respectively, P = 0.13).
Conclusions: Hypokalemia occurs commonly during treatment of moderate to severe DKA and is associated with lower pH and bicarbonate, acute renal failure and higher rate of ICU admissions. However, it is not associated a higher short orlong-term mortality.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001390

Introduction: Extracorporeal membrane oxygenation (ECMO), is a cardiocirculatory and pulmonary support that began to be used at the end of the last century; but this complex medical tool requires specialized training for its daily management and control of complications, to this day, including tools such as advanced clinic simulation in ECMO.
Objectives: The objective was to evaluate the satisfaction, the perceived quality, as well as the methodology and teaching staff of 6 theoretical-practical courses on ECMO support based on advanced clinical simulation, to objectify the viability, interest, and quality of this interesting training model.
Methods: 6 theoretical-practical training courses were carried out, including high-fidelity clinical simulation workshops on ECMO between 2017 and 2023 (4 face-to-face courses and 2 in a mixed online and face-to-face format, that is, a hybrid model). Retrospective descriptive study, for which, after each course, the participants completed a satisfaction survey in which they had to assess satisfaction with the course, the contents, and the teachers, rating from 1 (worst score) to 5 (best score). Statistical analysis was performed with SPSS v24, using quantitative variables that were expressed as mean and SD.
Results: We carry out the training of 161 students, of which 135 answered the survey (83.8%). After the descriptive analysis (Table 1) we found that the courses reach the expectations of the students, with high satisfaction and overall assessment.
The very favorable score in the active participation of the students during the course stands out, one of the objectives sought with the methodology used, clinical simulation. Similarly, we highlight the interest and value of clinical simulation workshops with ECMO. Finally, the teaching staff and the simulation method carried out also received very positive evaluations.

Questions	Mean	Standar desviation
The course has reach your expectations	4.41	0.66
Overall satisfaction with the course	4.63	0.06
Interest of the topics covered	4.20	0.76
Understanding of theoretical aspects	4.46	0.58
Possibility of participation in workshops/exhibitions	4.75	0.50
Integration of teachers with assistants	4.63	0.59
General evaluation of the teaching staff of the theoretical topics	4.51	0.55
General evaluation of the teachers of the workshops	4.50	0.52
Possibility of practical application	4.38	0.64
The methodology has been adequate	4.27	0.70
ECMO clinical simulation workshop	4.20	0.76

Conclusions: The experience with a high number of participants shows the interest and feasibility of clinical simulation as a teaching tool. The ability to maintain these training models with ECMO simulation over time should encourage us to continue carrying out this type of training activities, especially in the field of clinical simulation, essential in highly complex techniques such as ECMO.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001391

Introduction: Creatinine (Cr) is a breakdown product of creatine phosphate from muscle and protein metabolism. It is removed from the body mainly by glomerular filtration and is also an indicator of kidney function. While elevated creatinine values are commonly associated with inflammation, low creatinine values may be associated with lower body weight, lower muscle mass, or immobility.
Objectives: The aim of this work is to confirm whether high or low Cr values were associated with the length of mechanical ventilation (MV) and mortality in neurosurgical patients admitted to the intensive care unit (ICU).
Methods: All neurosurgical patients admitted to the ICU from January 1, 2021, to September 30, 2022, were included in the analysis. Cr values (μmol/L) were normalized according to reference values for age and gender in all patients and were classified as low, normal, and high for specific analyses. The initial values of Cr were analyzed, as well as the repeated results of Cr measurements of those patients who stayed longer in the ICU. The lowest (Cr-min) and highest (Cr-max) values were recorded as well as the day of stay on which this value was measured. An association of these values with the duration of MV and survival was calculated.
Results: A cohort of 190 patients, 95 men, and 95 women, were admitted to the ICU. Total survival was 91.1% and the length of mechanical ventilation was 6 h [3–24 h]. Median baseline Cr values on admission did not differ between survivors and nonsurvivors (62 [48.0–79.0] vs. 80 [56.5–131.5], Mann Whitney *U* test (MW), $P = 0.05$). Nonsurvivors had higher Cr-max during the ICU stay compared to survivors (73 [58.5–101.5] vs. 151.5 [73.3–172.3], MW, $P = 0.01$). A significant, negative correlation was recorded between Cr and length of mechanical ventilation (Spearman's $\rho = -0.266$, $P = 0.03$), which confirmed shorter MV in patients with higher Cr levels.
For patients who had a decrease in Cr during the ICU stay, MV was significantly longer than in those who did not have a decrease ($\rho = 0.337$, $P < 0.001$). After the patients were classified according to the Cr-min values into groups with low, normal, and high creatinine values, the mortality during the ICU treatment was highest in the group with Cr-min in the low range vs groups with normal and higher Cr (56.3%, 25 and 18.8%, $\chi 2$ test, $P = 0.03$).
Conclusions: High values of the Cr-max in nonsurvivors suggest the existence of an acute muscle and kidney lesion and were most likely a manifestation of infections. Increased mortality in the group with Cr below the reference range can be associated with acquired muscle weakness in the ICU and was observed in patients who had prolonged MV. In addition to acute brain injury, muscle weakness may result from comorbidities. New studies should confirm the possibility of new treatment methods, such as physiotherapy, in preventing the onset of muscle weakness and the consequent drop in Cr values.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001392

Introduction: Hypophosphatemia is a major concerns during the initiation of nutritional support. We evaluated the correlation between fast duration before nutritional support initiation and hypophosphatemia occurrence during ICU admission and its effect on mortality.
Methods: A retrospective analysis that included ventilated for > 48 h patients' data who were admitted to a 16-beds mixed ICU. Data collected included demographic, APACHE-2 admission score, SOFA score at 24 h, hourly energy delivered & plasma phosphate levels from the first two weeks of admission, insulin delivered, length of ICU stay, length of ventilation, and mortality (ICU and 90 days). A survival analysis with competing risks was performed. Baseline characteristics and clinical outcomes were compared with Mann–Whitney or Chi-square tests.
Results: 462 patients were used in the analysis. 59.96% of the patients developed hypophosphatemia. They were younger (57.4 vs 61.3, $p < 0.001$), less obese (BMI 27.0 vs 29.3, $p < 0.001$), had lower APACHE II (21.6 vs 22.8, $p < 0.001$), lower kidney SOFA score (0.64 vs 1.26, $p < 0.001$), and higher SOFA score (8.61 vs 8.34, $p < 0.004$). They had less prevalence of diabetes (13.3% vs 23.3%, $p < 0.005$). Their admission time before ICU admission was lower (3.42 vs 6,17d, $p < 0.0001$).
surviving analysis with hypophosphatemia as a competing risk showed a protective effect of hypophosphatemia from mortality (HR 0.447, 95% CI 0.281,0.712) age, APACHE2 and SOFA score were found to be significantly associated with ICU mortality.
Evaluation of patients by several comparisons of minimal fast durations (at 12h intervals of fasting up to 72 h) demonstrated that hypophosphatemia prevalence was lower in the patients who were fasting (in each starvation duration—12h, 24h, 36h, up to 72 h) compared to those who were not fasting. Hypophosphatemia prevalence ranged from 26.08% (72h fast) to 54.65% (12h fast) compared to 35.43% (not fasting 72h) to 67.03% (not fasting 12h). These differences in hypophosphatemia prevalence were not significant.
time to hypophosphatemia appearance was significantly longer in the fasting patients compared to those who were not fasting, at all starvation duration examined up to fast of 48h (e.g.: time to hypophosphatemia was 90.59h in the patients who fasted for 24h, vs 79.7h in the patients that did not fast for 24h ($p = 0.004$).
Conclusions: Duration of starvation for up to 72 h in ICU before starting nutritional support did not effect hypophosphatemia occurrence. However, time to appearance of hypophosphatemia was longer in the fasting patients. Hypophosphatemia had a protective effect against mortality.

Fibrinolysis resistance duration after tranexamic acid administration: how is it affected by renal insufficiency?

A. Párkányi[1], E. Bíró[1], D. Skultéti[1], E. Kovács[1], A. Fehér[2], A. Kállai[1], Z. Iványi[1], J. Fazakas[1], J. Gál[1]
[1]Department of Anesthesiology and Intensive Therapy, Semmelweis University, Budapest, Hungary; [2]Department of Laboratory Medicine, Semmelweis University, Budapest, Hungary
Correspondence: A. Kállai
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001393

Introduction: Tranexamic acid (TXA) is often used during acute bleeding management in order to inhibit fibrinolysis. According to summary of product characteristics, the elimination half-life of TXA is approximately 3 h [1]. However, it can be prolonged in case of renal insufficiency. The TPA-test from ClotPro system provides a way to examine the inhibition of fibrinolysis, even in case of the administration of TXA.
Objectives: We used the TPA-test to examine the presence of fibrinolysis inhibition in patients who received TXA as part of bleeding management upon admission to the intensive care unit.
Methods: In our retrospective observational study data were collected from patients at the Central ICU of the Department of Anaesthesiology and Intensive Therapy at Semmelweis University. The patients received TXA as part of acute haemorrhage treatment or to lower the risk of potential bleeding during or prior to admission. The route of administration of the drug varied among the cases (chronic oral, intravenous, nasogastric, intratracheal). Only patients with at least two TPA test results were enrolled in the study, who were divided into two groups according to renal function (RI vs nonRI).
Categories for fibrinolysis resistance were defined based on the TPA test results: complete lysis resistance if maximum lysis (ML) < 12%, severe if ML 12%–50%, moderate if ML > 50% with lysis time (LT) > 900s, and mild if 900s > LT > 300s.
To compare the groups Mann–Whitney U (MW) test was applied.
Results: Altogether 17 patients were eligible (female/male: 14/3; mean age: 49,48 ± : 16,57)0.14 patients have received intravenous TXA, in 3 cases the route of administration was either nasogastric, intratracheal or prior to admission regularly oral. In patients with either acute or chronic renal insufficiency, the complete fibrinolysis resistance has persisted significantly longer after the intravenous TXA administration (difference of medians: 81 h, p: 0,004).
During ICU treatment, newly onset RI was detected in four cases. One patient passed away, and two patients became chronic haemodialysis dependent. In the fourth case, complete remission of fibrinolysis resistance was observed following a course of plasma exchange beside the slow restoration of kidney function.
In cases of chronic oral, nasogastric or intratracheal administration, persistent complete fibrinolysis resistance was observed between 50–130 h.
Conclusions: Tranexamic acid administration in case of renal insufficiency, can result in prolonged inhibition of fibrinolysis and may play a role in the development of permanent organ failure [2]. Further studies are needed to examine whether the reversal of prolonged fibrinolysis inhibition induced by TXA improves patients' long-term outcomes and quality of life.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001394

Introduction: Circulatory instability is commonly observed in patients admitted to Intensive Care Units (ICU). Nitric oxide (NO) is a vasodilator and the production is upregulated during critical illness (1). Asymmetric dimethylarginine (ADMA) is an endogenous inhibitor of NO production. Admission plasma concentrations of ADMA is increased in critically ill patients compared to healthy controls (2) and the increase is associated with mortality (2,3). The time course needs to be further investigated to decide for clinical relevance and potential of future intervention.
Objectives: The aim of this research project is to determine how endogenous NO-synthase inhibition, as measured by plasma ADMA, varies over the first five days of ICU admission, and identify subgroups with distinctive patterns.
Methods: We included adult patients admitted to the ICU of Copenhagen University Hospital—North Zealand from November 2016 to June 2019. We took blood samples during the first five days of admission. Plasma concentration of ADMA was analysed with enzyme-linked immunosorbent assay (ELISA). In subgroup analyses we further investigated the time course of plasma ADMA in patients with septic shock vs. without septic shock, in different stages of endotheliopathy (soluble thrombomodulin (sTM) < 4 ng/ml vs. 4–10 ng/ml vs. > 10 ng/ml), patients treated with dialysis vs. no dialysis and patients with acute kidney injury (AKI) vs. no AKI. We used linear mixed models to describe the time course of plasma ADMA and tested for subgroup effect using interaction tests.
Results: We included 567 mixed ICU patients with a total of 1924 blood samples. Median age was 71 years (interquartile range (IQR) 63–79 years) and 327 (57.7%) were male. Median SAPS 3 score was 64 (IQR 56–73). Plasma ADMA concentration increased during the first five days of ICU admission ($p < 0.001$), Figure 1. In subgroup analyses patients with AKI had significantly higher ADMA concentrations at ICU day 1 compared to patients without AKI ($p < 0.001$), however time course in the two groups were similar ($p = 0.854$), Fig. 2A. Likewise, patients with severe endotheliopathy (sTM > 10 ng/ml) had significantly higher day 1 ADMA concentrations compared to patients with plasma sTM < 4 ng/ml or 4–10 ng/ml ($p = 0.026$), Fig. 2B. Interaction between time and sTM group was non-significant ($p = 0.584$). When grouped by the need for dialysis at any day during the first five days of ICU admission there was both significant different ADMA concentrations at day 1 ($p = 0.014$) and significant different time courses ($p = 0.017$), Fig. 2C. The subgroup of patients with septic shock did not differ from the rest of the patients neither at baseline nor in time course ($p = 0.665$ and $p = 0.207$, respectively), Fig. 2D.
Conclusions: Endogenous NO inhibition, as measured by ADMA, increase during the first five days of ICU admission, and is amplified by AKI and endotheliopathy.

Figure 1: Time course of plasma ADMA concentration during the first five days of ICU admission. Median and interquartile range.

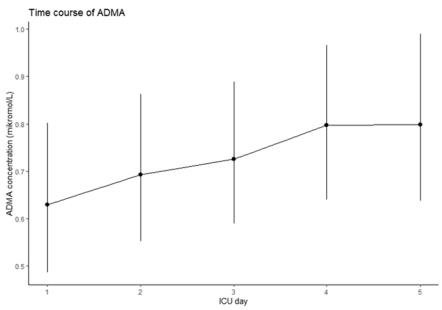

Figure 2: Time course of plasma ADMA concentration in different subgroups during the first five days of ICU admission. Median and interquartile range.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001395

Introduction: Improvement in oxygenation with prone position in patients with acute respiratory distress syndrome related to Coronavirus disease 2019 (C-ARDS) are inconstant. One of the other beneficial respiratory effects of prone position could be secondary to improvement in lung mechanics. However, these improvements are inconstant. Variables predicting the efficacy a priori before staring the prone position session could be useful.
Objectives: To investigate whether a significant improvement of the compliance of the respiratory system (Crs) and reduction of the driving pressure at the end of a prone position session is predicted by the potential of lung recruitment at baseline in supine position.
Methods: In this prospective, observational, monocentric study in patients who underwent prone position for C-ARDS, from January to

May 2021, respiratory variables were assessed just before prone positioning and at the end of the session. Respiratory variables included mechanical ventilation settings and variables of respiratory mechanics, including the recruitment-to-inflation ratio (R/I), an estimate of the potential of lung recruitment compared to lung overinflation.
Results: In 41 patients, 156 prone position sessions lasting 18.9 ± 2.7 h, were evaluated. Mortality at day 60 was 49%. Neuromuscular blockade agents were used in 91 (58%) sessions. At baseline, tidal volume was 6.1 ± 0.5 mL/kg of predicted body weight, PEEP was 14 ± 3 cmH2O and plateau pressure was 29 ± 4 cmH2O. The median of the R/I ratio was 0.53 (0.31–0.79), separating low- and high-recruiters. The airway opening pressure was present in 76 (49%) patients and was 6 (5–9) cmH2O in these patients. At the end of the prone position session PaO2/FiO2 increased from 111 ± 31 mmHg to 165 ± 67 mmHg ($p < 0.001$), with an increase > 20 mmHg in 96 (62%) sessions. The driving pressure decreased from 14.3 ± 4.4 to 13.7 ± 4.7 cmH2O ($p = 0.045$) and Crs increased from 32 ± 11 to 34 ± 11 ($p = 0.037$) ml/cmH2O. In a multivariate analysis, no respiratory or hemodynamic parameters at baseline could predict the improvement in oxygenation. Whereas the PaO2/FiO2 improved to the same extent in both low- and high-recruiters, driving pressure and Crs improved only in high-recruiters (from 14 ± 4 to 12 ± 4, $p = 0.027$, and from 34 ± 11 to 38 ± 13, $p = 0.014$, respectively).
Conclusions: Whereas oxygenation improve to the same extend in low- and high-recruiters with prone position in patients with C-ARDS, driving pressure and Crs improve only in high-recruiters patients. Benefits of prone position could be thus even greater in these patients.

A comparative study of Acinetobacter baumannii bacteremia in COVID-19 and non-COVID19 critically ill patients
T. Maniatopoulou[1], N. Lagos[1], N. Kazakos[1], A. Papathanasiou[1], G. Papathanakos[1], E. Priavali[2], V. Koulouras[1], I. Andrianopoulos[1]
[1]Intensive Care Unit, University Hospital of Ioannina, Ioannina, Greece; [2]Department of Microbiology, University Hospital of Ioannina, Ioannina, Greece
Correspondence: I. Andrianopoulos
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001396

Introduction: Acinetobacter baumannii, a multi-drug resistant (MDR) gram negative pathogen, is a common cause of infections in critically ill patients. The COVID-19 pandemic has led to an increase in the incidence of MDR gram- negative infections in critically-ill patients.
Objectives: Our objective was to examine the characteristics and outcome of COVID-19 critically-ill patients with Acinetobacter baumannii bacteremia and compare with a group of non-COVID-19 critically-ill patients.
Methods: We have performed a retrospective single-center study including all consecutively critically ill mechanically ventilated PCR SARS-COV-2 positive patients with Acinetobacter baumannii bacteremia that were admitted in Ioannina University Hospital ICU from 05/2021 to 07/2022. Patients' demographics, comorbidity including Charlson Comorbidity Index, source of bacteremia, ICU length of stay (LOS), ICU mortality and bacteremia complications such as sepsis, ARDS, hepatic dysfunction, coagulopathy or acute kidney injury (AKI) and the need for renal replacement therapy (RRT) were recorded for each patient. The same type of data were gathered from a non-COVID-19 group of critically-ill patients with Acinetobacter baumannii that were admitted in our ICU from 05/2017 to 05/2019. A statistical comparison was performed between the two groups using SPSS® 21.
Results: Overall 106 patients (average age of 65.4 ± 13.9 years) with Acinetobacter baumannii bacteremia were included. There were 75 COVID-19 and 31 non-COVID-19 Acinetobacter baumannii bacteremias. Among the two groups there was no difference in terms of age, gender, APACHE II score, Charlsons' Comorbity Index and comorbidities apart from the fact that more non-COVID-19 patients were receiving chronic corticosteroid therapy (1.33% vs 19.3%, $p = 0.003$). Almost all COVID-19 patients were medical patients (97% vs 77.5%, p 0.001) and were admitted because of acute respiratory failure (96% vs 35.5%, $p = 0.00001$). COVID-19 patients were significantly more likely to have pneumonia as the source of bacteremia compared to the non-COVID19 patients (41.3% 16.1%, p 0.00001). Both patient groups developed sepsis in the majority of cases (76% vs 80.6%), but COVID-19 patients developed ARDS (78.7% vs 29%, p 0.00001) and shock (81.3% vs 61.3%, p 0.011) more often. On the other hand COVID-19 patients developed less often Acute Kidney Injury (30.7% vs 58%, p 0.007) and required less frequently RRT (8% vs 32%, p 0.001). Mortality was high among both groups (69.3% vs 80.6, p 0.605) and there was no difference in the ICU or hospital LOS between the two groups.
Conclusions: Acinetobacter baumannii bacteremia is associated with high mortality in critically ill patients. COVID-19 patients are more likely to have pneumonia as the source of bacteremia and develop more frequently ARDS and shock. Better treatment options are required to improve the survival of these patients.

The clinical value of D-dimer for the diagnosis of deep vein thrombosis in intensive care unit
J. Jeon[1], B. Dabboubi[2]
[1]Intensive Care Medicine, Sheikh Khalifa Specialty Hospital, Ras Al-Khaimah, United Arab Emirates; [2]Abu Dhabi, Seha, Abu Dhabi, France
Correspondence: J. Jeon
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001399

Introduction: Deep vein thrombosis (DVT) can be safely and reliably excluded in patients with a low clinical probability and a negative D-dimer result, but the accuracy and utility of such a strategy is unclear in intensive care unit (ICU) patients.
Objectives: To determine the utility andlimitations of D-dimer testing fortheevaluation oflower extremityDVT in ICUpatients.
Methods: A retrospective analysis of the medical record evaluating consecutive ICU patients with.
suspected lowerextremityDVTbetween January 2015 and December 2022.
All patients underwent D-dimer test, portable extremity venous ultrasound or CT.
pulmonary embolism and deep vein thrombosis. The diagnosticsensitivity and specificity,
positive predictive value (PPV), and negative predictive value (NPV) were evaluated.
Results: A total of 136 patients were evaluated. DVT was diagnosed in 32 patients (26.47%). Although the sensitivity of the D-dimer test was high (96.88%), the specificity was significantly low (4.81%). The PPV was 23.85%, and the NPV was 83.33%.
Conclusions: Anegative D-dimer test resultin ICU patients does not reliably excludelower extremityDVT because the NPVof the test is significantly lower in ICU patients.
Table 1 (abstract 001399) Sensitivitiy, specificity, PPV and NPV of D-dimer

	image (+)	image (−)	Subtotal
D−dimer (+)	31	99	130
D−dimer (−)	1	5	6
Subtotal	32	104	136

Sensitivity(%)	96.88
Specificity(%)	4.81
Accuracy(%)	26.47
Positive predictive value (PPV)(%)	23.85
Negative predictive value (NPV)(%)	83.33
Prevalence(%)	23.53
Odds ratio	1.57
Relative risk	1.43

Cholesterol treatment increases cardiac Na + /K + ATPase activity and improves dobutamine responsiveness in septic rats

W. Pisciotta,[1], T. Saha[1], A. Wu[1], A. Kleyman[1], M. Singer[1]
[1]Bloomsbury Institute of Intensive Care Medicine, University College London, London, United Kingdom
Correspondence: A. Kleyman
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001400

Introduction: Plasma cholesterol levels drop during sepsis in both patients and our rat model of faecal peritonitis. This model displays increased tachycardia and decreased responsiveness to dobutamine. Septic rats also have decreased cholesterol levels in the cardiomyocyte cell membrane which may impact upon adrenergic receptor activation (1). Na + /K + ATPase activity impacts heart rate and cardiac contractility and depends on membrane lipid composition and cholesterol concentration (2). We assessed the impact of restoring membrane cholesterol levels in cardiomyocytes' NKA activity.
Objectives: To assess changes in cardiomyocyte cholesterol content, cardiac NKA activity, and dobutamine responsiveness in septic rats after intravenous cholesterol treatment.
Methods: Awake, instrumented male Wistar rats (300 ± 50 g) received an i.p. injection of faecal slurry. Fluid resuscitation commenced after two hours. At 6 h, baseline haemodynamic measures were performed (BP, echocardiography). Septic animals were then randomly stratified into placebo or cholesterol-treated groups (6–10 per group). Cholesterol-treated animals received a 15-h i.v. Infusion of bovine HDL-cholesterol (35 mg cholesterol/rat). Rats were then anaesthetised, allowed to stabilise and haemodyanmics were again measured before and after a 10 min infusion of dobutamine (10 mcg/kg/min). Animals were then sacrificed with heart tissue samples immediately frozen in liquid nitrogen. Cardiac NKA activity was measured using a published method (3) while cardiomyocyte membrane cholesterol was measured (after fractionation) by Amplex red. Control animals were treated identically, except for the administration of faecal slurry.
Results: At 21 h, non-treated septic rats had tachycardia, a fall in heart membrane cholesterol, an increase in cardiac NKA activity, and impaired responsiveness to dobutamine. HDL-Cholesterol treatment restored cardiac membrane cholesterol levels, increased NKA activity, and restored dobutamine responsiveness (Table 1).

	Sham	Sepsis	Sepsis + HDL-Ch
Heart rate (beats/min)	409 ± 67	486 ± 42 (a)	451 ± 27
Heart membrane cholesterol (mg chol/mg protein)	0.11 ± 0.02	0.08 ± 0.02 (b)	0.14 ± 0.06
Dobutamine response (% increase in stroke volume)	13.5 ± 12.3	5.5 ± 9.0 (b)	25.9 ± 14.9
NKA activity) (mMol/mg protein/ min × 10–^{3})	3.923 ± 0.93	3.715 ± 0.116	4.402 ± 0.736

a) $p < 0.05$ vs. sham, (b) $p < 0.05$ vs. Sepsis + HDL-Chol. One-way ANOVA test with multiple comparisons.

Conclusions: Infusion of HDL-cholesterol reversed the fall in cardiac membrane cholesterol, increased Na + /K + ATPase activity and improved dobutamine responsiveness.

Outreach in an ICU and mortality at 28 days and 3 months

J. E. Mateus[1], M. P. Vidal[1], G. C. Almeida[1], A. Santos[1], M. Simões[1], P. Casanova[1], P. Martins[1]
[1]Intensive Care Unit, Centro Hospitalar e Universitário de Coimbra, Coimbra, Portugal
Correspondence: J.E. Mateus
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001401

Introduction: Demand for ICU resources often exceeds supply. We must ensure that patients who occupy ICU beds are those most likely to benefit from the ICU's specialized technology and professionals. Triage algorithms and protocols can be useful but can never supplant the role of the skilled intensivist who decides whether to admit the patient, always taking into account the structure and size of the ICU in question.
Objectives: Analysis of admission decisions in the ICU of a tertiary hospital and evaluation of the mortality of patients observed in outreach at 28 days and 3 months.
Methods: Analysis of patient observation records by the outreach intensivist at the ICU, from December 1st 2022 to February 28th 2023. The form integrates an algorithm with 5 questions (reversibility of the acute illness, purpose of hospitalization in the ICU, comorbidities, functional reserve and intuitive planning by the intensivist). In addition, hospitalization priority is assigned (P1—ICU level III, P2—ICU level II, P3—ICU Trial, P4—no ICU indication: too well—TW / too bad—TB. Analysis of admission decisions in the ICU, mortality rate at 28 days (M28) and at 3 months (M3M).
Results: The outreach intensivist was requested on 203 occasions (daily average of 2.3 occurrences/day). The main observation sites were the emergency room (43%) and the wards (34%). Most requests occurred during the day (8am–8 pm; 73%). The median age of the patients observed was 71 years, 59% male, mostly due to medical pathology (68%), with acute reversible disease (68%) and with good functional reserve (62%).
P1 was attributed to 36.9% of the patients, P2 to 3.9%, P3 to 2.5% and P4 to 56.6% (TW 20.7%; TB 36.0%). M28 was 45.3% (P1: 34.6%; P2: 25.0%; P3: 80.0%; P4-TW: 9.5%; P4-TB: 76.7%) and M3M of 50.2% (P1: 40.0%; P2: 37.5%; P3: 80.0%; P4-TW: 14.3%; P4-TB: 80.8%).
Both M28 and M3M increased with the degree comorbidities decompensation, with M3M of 54.7% in patients with decompensated comorbidities and 75.0% in those with advanced disease. Functional reserve also negatively influenced both mortality rates, reaching 55.8% in partially dependent patients and 84.2% in totally dependent patients (M3M). There was agreement between 28-day and 3-month mortality and the physician's intuitive prognosis in 82.6% of cases.
Conclusions: Despite the complexity of the decision to admit patients to an ICU, our evaluation algorithm correlated well with hospital mortality. The reversibility of the acute illness, the functional reserve and the comorbidities have an impact on the prognosis and must be taken into account when making the decision. There was agreement between mortality and the intensivist's intuitive prognosis.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001404

Introduction: Infective endocarditis (IE) is an infection of the endothelium of the heart. Patients with the most severe forms of IE demand intensive care management and its characteristics are not so well described, namely complications and prosecution with established guidelines. 1,2
Objectives: Characterization and profile the population of critically ill patients with a diagnosis of IE admitted to our intensive care unit (ICU).
Methods: Cross-sectional investigation including all possible and definite IE cases among patients aged eighteen and over who were admitted to an ICU of a tertiary university hospital between January 2017 and March 2022.
Results: Forty-three patients were included with a mean age of 67 ± 16 (72% male). A definitive and possible diagnosis of IE (applying Duke Criteria) were made in 83.7% and 16.3% of the patients. Mean SOFA at admission was 9.56 and mean SAPS II was 59.72. Mean length of stay in the ICU was 13,60 days. In-hospital and six-month mortality rate were 39.5% and 60.5%, respectively. IE was considered hospital-acquired in 62.8% of the patients and community-acquired in 37.2% of the patients. Risk factor prevalence for IE were central venous catheter for more than 10 days (25.5%), recent immunosuppressive drug treatment (14%), regular dialysis program (14%), valve abnormalities (11.62%) and poor metabolic control (HbA1c > 7%) in patients with diabetes (11.6%). Most patients presented with shock (79.1%), respiratory failure (79.1%) and fever (58%). Vascular phenomena were present in 46.5%, with major arterial emboli (14%) being the most common. Echocardiographic findings showed valvular regurgitation in 46.5% of patients and decreased systolic function in 53.5%. Methicillin-sensitive Staphylococcus aureus was the predominant pathogen identified (34.9%). Applying current guidelines, surgical therapy indication was present in 39.5% of the patients, but only 3 patients (7%) were effectively submitted to surgery, with recent stroke being present as a contraindication in 2 patients.
Conclusions: In our cohort of critically ill-patients with a diagnosis of IE, mortality directly related to theprimary diagnosis was very high. This data might suggest that current guidelines for the treatment of IE, namely those concerning surgical recommendation, are not entirely adequate for patients with the most severe forms of the disease.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001405

Introduction: Patients suffering from intracerebral hemorrhage (ICH) with intraventricular hemorrhage (IVH), a devastating neurological condition associated with high rates of morbidity and mortality. In severe IVH with obstruction of the third or fourth ventricles, the placement of an external ventricular drain (EVD) can help lower raised intracranial pressure, the literature shows this reduces mortality, but poor outcomes remain a commonplace. Therefore, treating IVH may be a beneficial therapeutic target.
Objectives: We attempted to achieve an alternative for standard external EVD for IVH. A self-irrigation and drainage intraventricular catheter may be a good alternative for a standard EVD since it seems to avoid most of the difficulties present while using an EVD.
Methods: A retrospective observational cohort study of adult patients with IVH treated with IRRAFLOW® self-irrigation and drainage therapy, in our Intensive Care Unit (ICU) of a tertiary center in Portugal, between November 2020 and February 2023. Determination of intraventricular pressure is made in real time through the IRRAFLOW® double lumen catheter.
Results: We present 8 cases of IRRAFLOW® use in critical ill patients admitted with IVH in our ICU. In all of them, Ringer lactate was used for irrigation and high irrigation rates were used during the first days. We have controlled the positioning, hematoma or clot formation and hydrocephalus with serial neuroimagiologic control, throught the patient during ICU stay. All of the patients were submitted to serial biochemistry and microbiologic cerebrospinal fluid (CSF) control to rule out infection and control the CSF characteristics. Multimodal neurologic monitoring was performed in every patient. From the 8 patients admitted with IRRAFLOW®, 2 were female and 6 were male, with a median age of 55 (interquartile range, IQR 40–71) years old. The etiology of the ICH was arteriovenous malformations in 3 cases and spontaneous intracerebral hemorrhages in the 5 remaining patients. At the ICU admission, median initial Glasgow Coma Scale (GCS) was 8 (IQR 7–9). The median of days with IRRAFLOW® catheter was 11,1 (IQR

8–13) days. ICU length of stay was 19,8 (IQR 18.5–23) days. ICU mortality rate was 12,5% (only 1 patient) and mortality at 6 months was 25% (2 patients). At hospital discharge, 2 patients presented with GCS of 15, 2 with 10t, 1 with 9 and 2 with 6t. Follow-up at 6 months was done with 3 patients with Glasgow Outcome Scale (GOS) of 5. None of the catheters were complicated by obstruction or infection, and none of the presented patients needed ventriculoperitoneal shunt after IRRAFLOW® removal.

Conclusions: Intraventricular hemorrhage remains a devastating clinical condition with a terrible outcome**.** A self-irrigation and drainage intraventricular catheter appears to be safe and may be a good alternative for a standard external ventricular drainage in patients with severe IVH and at big risk of hydrocephalus. More experience is necessary to take more conclusions and to put this novel approach in the therapeutic scenario of IVH.

Introduction: The COVID-19 pandemic has presented extraordinary challenges to the healthcare systems worldwide. The high transmissibility and severity of the disease have required the rapid development of effective management strategies to reduce morbidity and mortality. Inflammatory biomarkers have emerged as an important tool in guiding clinical decision-making in COVID-19. They provide valuable information on disease activity, severity, and response to therapy, enabling clinicians to tailor treatment to individual patients.

Objectives: To explore the relationship between inflammatory and immunological indicators routinely utilized in clinical practice and outcomes in patients with severe coronavirus disease (COVID-19).

Methods: We performed a prospective observational study in the Intensive Care Unit (ICU) of a university hospital in Spain. Inclusion criteria: polymerase chain reaction (PCR)-confirmed SARS-CoV-2 infection with symptoms of COVID-19, time from positive PCR to ICU admission less than 14 days, and mechanical ventilation more than 48 h. Exclusion criteria: positive SARS-CoV-2 PCR without COVID-19 or need for MV due to causes other than COVID-19. Inclusion period: 01/11/2021 to 28/02/2022. Analytical determinations were performed on days 5, 15, and 25 of ICU stay and were compared between survivors and non-survivors. The patients were followed-up for a maximum of 90 days. The results are expressed as median (interquartile range) or frequency (%). We applied the Mann–Whitney U test for comparisons.

Results: From 52 eligible patients with positive SARS-CoV-2 PCR admitted to the ICU during the study period, 35 met the inclusion criteria: age 60 ± 9 years; 77% male; APACHE-II 13 (11–18); 100% received mechanical ventilation, with a duration of 23 (12–41) days; 28.5% required veno-venous extracorporeal membrane oxygenation (ECMO), with a duration of 19 (12–46) days; 90-day mortality was 17%. The inflammatory and immunological profile is described in the Table.

	ICU day 5			ICU day 15			ICU day 25		
	Survivors	Non-survivors	p	Survivors	Non-survivors	p	Survivors	Non-survivors	p
Ferritin, ng/ml	655 (362–1047)	1391 (527–1695)	0.09	424 (308–839)	1070 (866–2963)	0.02	403 (275–636)	1398 (869–2036)	0.01

Interleukin 6, pg/ml	15 (7–89)	21 (9–70)	0.57	22 (10–50)	92 (74–139)	0.02	6 (2–11)	77 (15–190)	0.08
Total immunoglobulin G (IgG)	830 (668–908)	544 (514–832)	0.41	708 (584–843)	832 (649–1010)	0.29	673 (554–851)	951 (640–1075)	0.33
Total immunoglobulin M (IgM)	94 (67–140)	79 (65–135)	0.76	88 (62–123)	79 (42–135)	0.77	84 (62–94)	114 (63–185)	0.32
Anti-S1 IgG, AU/ml	6664 (483–39,879)	2207 (451–8560)	0.43	10,243 (2605–39985)	8863 (5075–14561)	0.73	6474(5465–40,000)	17,017 (2783–19,061)	0.95
Anti-N IgG, AU/ml	3.4 (1.5–5.9)	4.7 (4.6–6.3)	0.14	6.3 (5.2–7.1)	5.7 (5.2–6.9)	0.74	6.6 (6.1–7.4)	7.7 (4.6–7.9)	0.55

Conclusions: In our study, patients with severe COVID-19 who died before 90 days had significantly higher levels of ferritin on ICU days 15 and 25, and significantly higher levels of interleukin 6 on ICU day 15. Triglycerides, humoral immune response markers, and antibody levels against SARS-CoV-2 did not correlate with survival status.

Right ventricular free wall longitudinal strain during weaning from mechanical ventilation using high flow versus conventional oxygen treatment: a pilot trial

E. Xourgia[1], A. Koroneos[1], K. Stamatis[1], A. Kotanidou[1], I. Siempos[1], C. Routsi[1]
[1]First Department of Critical Care Medicine National and Kapodistrian University of Athens, Evangelismos Hospital, Athens, Greece
Correspondence: C. Routsi
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001407

Introduction: Information on right ventricular (RV) response during weaning from mechanical ventilation is limited. Recent advancements in cardiovascular imaging, namely the use of two-dimensional speckle-tracking echocardiography (2DSTE), have provided novel parameters such as RV free wall strain (RVFWS) that that outperform conventional echocardiography measurements in the estimation of RV systolic function.

Objectives: We investigated RV function during weaning from prolonged mechanical ventilation in tracheostomized patients, comparing a high flow oxygen treatment (HFOT) system, through tracheostomy, with conventional T-piece oxygenation. Both conventional echocardiography and RV-2DSTE were used.

Methods: Patients underwent a 30-min spontaneous breathing trial (SBT), randomly conducted with either standard oxygen via T-piece, or by HFOT delivered via tracheostomy, followed by a washout period of 15 min on mechanical ventilation and 30 min receiving oxygen with the other modality. Blood gases, hemodynamic and respiratory measurements, i.e., breathing frequency (f) and tidal volume (VT) measured with a handheld Wright's spirometer through the endotracheal tube. Echocardiography was performed before and at the end of each SBT phase. A repeated SBT was performed on the following day with the opposite order of the respiratory support modality.

Results: Nine patients (median age 64 [52.5–70.0], 66% males) in whom 14 SBT sessions were completed uneventfully, were included in the analysis. During SBTs, PO2/FiO2 and VT did not change whereas f/VT ratio increased compared to mechanical ventilation [57 (44–68), 62 (47–77) versus 41 (35–56) breaths/min/L on HFOT, T-piece and mechanical ventilation respectively, $p = 0.004$]. RVFWS median values on mechanical ventilation, HFOT and T-piece were 22.3%, 25.0% and 24.6%, respectively. There was no statistically significant difference in conventional echocardiography parameters of RV function as well as in RVFWS among mechanical ventilation, HFOT and T-piece [$F(2,26) = 0.654$, $p = 0.568$]. Similarly, there was no significant difference among mechanical ventilation, HFOT and T-piece in basal [$F(2,26) = 1.048$, $p = 0.365$] and medial [$F(2,26) = 0.737$, $p = 0.488$] RV strain. Higher absolute RVFWS values (i.e., lower strain) along with the absence of conventional variables of RV dysfunction on mechanical ventilation were associated with weaning success within the next 24 h [$\chi 2(1) = 5.531$, $p = 0.019$].
Conclusions: RV function, as assessed by both conventional echocardiography and 2DSTE, was maintained during successful SBTs supported either by HFOT or conventional oxygenation via T-piece. Moreover, a lower baseline right ventricular strain was independently associated with weaning success.

The development and use of patient-centered observations to demonstrate the cumulative impact of critical care support

K. Fearron,[1], N. Gurung[1], A. Broderick,[1], K. O'reilly[1], S. Akhtar[2], A. Khatri[1], F. Bowtell,[3], I. Salako,[1], T. Lalmahomed,[1], P. Schalke,[1], M. Derupe[1], J. Fideles[1], R. Patel[1], R. Mehta[1], T. Best[1], D. Hadfield[4], P. A. Hopkins[5]

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001408

Introduction: The quality of critical care support can have profound implications on long-term health outcomes and costs (1, 2). Critical care decision making within daily workflow is generally centred around current acute pathophysiology, clinical problems and immediate priorities. At ward rounds, static pathophysiology may be emphasized over the cumulative impact of critical care on patients or formal assessment of reversibility. Here, we describe the development of a new paradigm in critical care observations which use patient-centered parameters to highlight the cumulative impact of critical care. We further explore the views of patients and interprofessional staff around the potential benefits of such observations and support for a future cluster-randomised step-wedge trial.
Methods: Research/QI approval was gained to develop cumulative impact observations using existing heathcare record data entry. The general data protection act was followed.
Mixed methods observational techniques were used to generate a list of patient-centred cumulative impact observations using round Tables, interviews and surveys. Delphi methodology was used to refine and rank a list of cumularive impact observations,
The calculations and SQL reporting functionality of a Best-Of Breed clnical data management system (Intellivue Critical Care and Anaesthesia, Philips Heathcare) were used to automatically generate the requested list of cumulative impact observations on the system flow sheet.
Feedback on the potential benefits and utilisation from 234 staff and 34 patients were obtained after a 6 month period of deploying the observations.

Results: Delphi-derived cumulative impact observations were:
Cumulative radiation exposure (years of back ground radiation equivalent); cumulative blood loss on litres (from tests/procedures); cumulative hypnotics/ analgesics-opiates-paracetamol/ pressors/antibiotics; antibiotics beyond prescribed duration; days of ventilation; days of renal replacement; days cardiovascular support; days of delirium; days of moderate or severe sleep disturbance; days of non-mobilisation from bed; days of uncontrolled pain (CPOT scoring); days of no speech; days of no oral fluids/food.; SOFA Score-daily and cumulative days of non-improvement.
The five top benefits from staff were vasopressor load, days of antibiotics beyond prescribed course; days of delirium; days of non-improved SOFA score and days of blood glucose outside target range. The five top benefits from patients who were interviewed were days of uncontrolled pain; days of delirium; total radiation exposure; days that not able to take oral fluids; and days of poor quality sleep.
Figures 1 and 2 illustrate typical cumulative impact observations from two different anonymised patients in critical care.
All healthcare professionals and patients interviewed indicated that cumulative impact observations have the potential to improve the understanding of critical care consequences on patients. 83% of healthcare professionals and 92% of patients believed that this understanding could be linked to improved quality of care and potential to improve outcomes. There was universal support for a step-wedge randomised controlled trial.
Conclusions: We were able to develop a list of twenty patient-centered observations. Further observations may be important, using the same principles and digital design. The cumulative impact observations were widely supported by both patients and staff and may form the basis of an important step-wedge randomised controlled trial in the future to provide clinically important benefits. We believe that cumulative observations provide a new paradigm for critical care observations that could be translated across healthcare settings, and provide improved insight into the consequences of critical care support for patients, and potentially improve the quality of supportive care and reduce healthcare costs.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001409

Introduction: The COVID-19 pandemic has had a significant impact on global health, with high morbidity and mortality rates, particularly in patients requiring admission to the Intensive Care Unit (ICU). The development of effective vaccines has provided hope in controlling the spread of the virus and reducing the burden on healthcare systems. Vaccination against SARS-CoV-2 has been shown to be highly effective in preventing severe illness and hospitalization. However, the impact of vaccination status on clinical outcomes in patients with severe coronavirus disease 2019 (COVID-19) requiring ICU admission remains uncertain.
Objectives: To evaluate the influence of SARS-CoV-2 vaccination status on the development of complications and clinical outcomes in patients with severe COVID-19.
Methods: We conducted a prospective observational study in the ICU of a university hospital in Spain. We included patients with confirmed COVID-19 diagnosis (molecular identification of SARS-CoV-2 with presence of symptoms), requiring mechanical ventilation for more than 2 days. We excluded patients with a SARS-CoV-2 test without COVID-19, or need for mechanical ventilation due to causes other than COVID-19. The inclusion period corresponded with the sixth wave of the disease in Spain (11/2021 to 02/2022), when the Omicron variant predominated. We measured IgG-class antibodies against S1 and N proteins of the virus on ICU days 5, 15, and 25. The results are expressed as mean ± standard deviation, median (interquartile range), or frequency (%). We applied χ^2, Student's T-test, or Mann–Whitney U test, as appropriate.
Results: We enrolled 35 patients during the study period, with a vaccination rate against SARS-CoV-2 of 45.7% (44% Comirnaty™, 19% Vaxzervia™, 19% combination of several, 12% Spikevax™, 6% others). Time from vaccination to microbiological diagnosis 150 (70–172) days. The temporal evolution of antibody titers is shown in the Table.

	Vaccinated patients	Non vaccinated patients	p-value

ICU day 15	5.33 ± 0.7	5.9 ± 0.5	0.43
ICU day 25	6.0 ± 0.9	6.6 ± 0.3	0.55

Clinical characteristics of vaccinated *vs.* non vaccinated patients: age 59.3 ± 1.9 *vs.* 61.3 ± 2.4 years old, p = 0.78; male sex 75 *vs.* 79%, p = 0.78; APACHE-II 13.5 (11.5–19) *vs.* 13 (11–18), p = 0.73, length of mechanical ventilation 23.5 (6.5–50) *vs.* 23 (15–30), p = 0.73; ICU length of stay 29.5 (8–53.5) *vs.* 26 (17–50) days, p = 0.87; time to negative SARS-CoV-2 test 27.5 (20.5–52.5) *vs.* 30 (19–39) days, p = 0.57; hospital mortality 12.5 *vs.* 31.6%, p = 0.18.
Complications in vaccinated *vs.* non vaccinated patients: hospital-acquired infection 56.3 *vs.* 94.7%, p < 0.01; delirium 62.5 *vs.* 42.1%, p = 0.23; ICU-acquired weakness 56.3 *vs.* 47.4%, p = 0.60; thrombosis 25 *vs.* 42.1%, p = 0.29; pulmonary fibrosis 12.5 *vs.* 21.1%, p = 0.50.
Conclusions: The vaccination rate in severe COVID-19 patients admitted to the ICU was low. Vaccination was associated with a significantly higher titer of anti-S1 IgG and a lower incidence of nosocomial infections. Mortality was higher in unvaccinated patients, although the strength of this association was not statistically significant.

Topic: Infections and prevention

Impact of hemoglobin levels on 28-day mortality in out-of-hospital cardiac arrest patients treated with extracorporeal cardiopulmonary resuscitation

K. Maekawa[1]
[1]Kita14joh nishi5 choume, Kita-ku, Sapporo City, Hokkaido, Department of Emergency Medicine, Hokkaido University Hospital, Sapporo, Japan
Correspondence: K. Maekawa
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001410

Introduction: Extracorporeal cardiopulmonary resuscitation (ECPR) is an advanced treatment option for out-of-hospital cardiac arrest (OHCA) patients. Hemoglobin (Hb) plays a crucial role in oxygen transport and tissue perfusion, and previous studies have reported an association between Hb levels and survival outcomes in OHCA patients. However, there is limited information on this relationship in OHCA patients undergoing ECPR.
Objectives: This study examines the association between lower Hb levels during hospitalization and survival in OHCA patients who underwent ECPR.
Methods: We conducted a post-hoc analysis of the multicenter retrospective observational cohort SAVE-J II study, including adult OHCA patients aged 18 years and over admitted alive for at least 3 days after being introduced to ECPR between January 2013 and December 2018. The primary outcome was 28-day all-cause mortality. Propensity score-weighted analysis was used to account for potential confounders.
Results: The final analysis comprised 630 patients, with a 28-day mortality rate of 43.3%. Non-survivors had significantly lower Hb levels on ICU day 0 and 1, and lower mean and lowest Hb levels during the first 3 days than survivors. In multivariate logistic regression, the lowest Hb level and the lowest Hb range ≤ 7 g/dL were independent predictors of 28-day mortality, with adjusted odds ratios of 0.85 per 1.0 g/dL increment (95% CI: 0.76–0.96) and 2.50 (95% CI: 1.27–4.91), respectively. After propensity score weighting, the 28-day survival time was significantly worse in patients with the lowest Hb range ≤ 7 g/dL.
Conclusions: Lower Hb levels during the first 3 days of hospitalization were independently associated with increased 28-day mortality in OHCA patients undergoing ECPR. These findings suggest that monitoring and optimizing Hb levels in the early phase of hospitalization may improve survival outcomes for this patient population.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001411

Introduction: Intensive care unit (ICU) patients were shown to have poor quality of sleep over the last three decades. However, to improve the sleep distortion in critical patients remains challenging. The aim of this study is to investigate the impact of continuous quality improvement on sleep distortion in critical patients in critical patients.
Methods: All consecutive patients form 2019–2021 in 6 adult ICUs were enrolled. The key interventions include novel sacral suspended decompression recumbent care, simple air pressure turning device, remote warning care system and using big data to monitor critical care warning indicators. The patients were divided into three periods: pre-intervention period from Jan to Dec 2019, intervention period from Jan to Dec 2020, and post-intervention period from Jan to Dec 2021.
Results: The sleep assessment ratio improved from 49.0% in pre-intervention period, to 67.5% in intervention period and to 95.1% in post-interventional period ($p < 0.0001$). The good quality sleep ratio improved from 70.4% in pre-intervention period, to 74.2% in intervention period and to 87.8% in post-interventional period ($p < 0.0001$). Average ICU stay decrease from 7.9 days to 6.9 days after intervention ($p < 0.05$). The incidence of ventilator-associated pneumonia decreased from 0.7‰ to 0.4‰ ($p < 0.05$). The mortality decreased from 7.6‰ to 5.2‰ ($p < 0.05$).
Conclusions: The study showed that implementation of continuous quality improvement using novel critical care system could increase sleep assessment ratio and good quality sleep ratio, and reduce average ICU stay. Furthermore, the incidence of ventilator-associated pneumonia and mortality also improved.

Topic: Sedation, analgesia and delirium

The association between admission clinical gestalt categories and multi-organ failure; an ICU cohort study

EGM. Cox[1], N. Campillo Llamazares[1], BC. Van Bussel[2], I. Van der Horst[2], J. Koeze[1]
[1]Department of Critical Care, University Medical Center Groningen, Groningen, Netherlands; [2]Department of Intensive Care, Maastricht UMC +, Maastricht, Netherlands
Correspondence: E.G.M. Cox
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**0001412

Introduction: In the intensive care unit (ICU), the clinical gestalt is an important part of the daily clinical examination physicians perform on critically ill patients. The clinical gestalt, at least unconsciously, affects physicians' patient assessment, clinical decisions, and treatment [1,2]. However, the association between objective clinical measurement of clinical gestalt and multi-organ failure in the ICU remains unknown, and if such an association is independent of laboratory and clinical ICU variables, it could provide evidence for the application of the clinical gestalt in clinical practice [3].
Objectives: To study whether the clinical gestalt is associated with multi-organ failure defined by the maximum Sequential Organ Failure Assessment (SOFA) score during the first 7 days of patient's stay in the ICU.
Methods: This study is part of the Simple Intensive Care Studies-II (SICS-II, NCT03577405), a single-center prospective cohort study [4]. All adult patients acutely admitted to the ICU between March 26, 2019, and July 10, 2019, were included. The clinical gestalt was assessed within three hours of admission using pictograms depicting the patient's facial expression (Figure 1), along with the SOFA score. Univariate, multivariate, and longitudinal analyses were performed.
Results: The study included 228 consecutive adult patients (median age, 64 years) acutely admitted to the ICU, of which 47% were mechanically ventilated. Fourteen patients (18%) with a pale face died in-hospital. Patients with their eyes open, has a lower SOFA score than patients with their eyes slinked (1.8 point; 95%CI 0.3–3.4), slumbered (1.5 point; 95%CI 0.3–2.6), closed (1.9 point; 95%CI 0.8–3.0), or ventilated (2.2 points; 95%CI 1.3–3.0) (Table 1). The maximum SOFA score was present at 1.7 days (SD ± 1.0), with a mean of 6.0 points (SD ± 3.3). SOFA score was significantly different between gestalt categories.

Table 1 (abstract 001412) Distribution of the different pictograms

	Open (~~1, 6, 11~~)			Slinked (~~2, 7, 12~~)			Slumbered (~~3, 8, 13~~)			Closed (~~4, 9, 14~~)			Ventilated (~~5, 10, 15~~)			Total		
	T	†	%	T	†	%	T	†	%	T	†	%	T	†	%	T	†	%
Vasoconstricted (1–5)	7	0	-	7	2	*29*	11	2	*18*	11	2	*18*	44	8	*18*	80	14	*18*
Normal (6–10)	7	0	-	14	1	*7.1*	16	0	-	20	2	*10*	48	9	*19*	105	12	*11*
Vasodilated (11–15)	10	1	*10*	4	0	-	4	1	*25*	10	1	*10*	15	0	-	43	3	*7.0*
Total	24	1	*4.2*	25	3	*12*	31	3	*9.7*	41	5	*12*	107	17	*16*	228	29	*13*

T: number of observations, + died in hospital

Conclusions: The clinical gestalt, particularly the state of the patient's eyes, may serve as a non-invasive marker for organ failure risk in critically ill patients. These findings highlight the potential importance of the clinical gestalt in the ICU and suggest the need for further research to validate these results and explore their potential clinical implications.

Caring and learning during the COVID-19 pandemic: a sociological analysis of critical care workers experiences

N. Pattison[1], A. M. Docherty[2], S. Humphreys[3], C. Mcculloch[4], S. Sturdy,[5], C. Montgomery[5]
[1]School of Health and Social Work, University of Hertfordshire/East and North Herts NHS Trust, Stevenage, United Kingdom; [2]Intensive care, University of Edinburgh Medical School, Edinburgh, United Kingdom; [3]School of Health and Social Work, University of Hertfordshire, Hertfordshire, United Kingdom; [4]Research, Lothian NHS Board, Edinburgh, United Kingdom; [5]Usher Institute (Sociology), The University of Edinburgh, Edinburgh, United Kingdom
Correspondence: N. Pattison
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**0001413

Introduction: Staff experience is critical to the quality of healthcare, and an important outcome in and of itself. COVID-19 placed unprecedented demands on critical care units in the UK and globally, with profound changes to the way NHS staff had to work. By understanding staff experiences we can learn lessons to inform how staff aare supported in critical care and plan for future large-scale challenges such as a pandemic.
Objectives: To understand, through a sociological lens: the experiences of frontline NHS staff in critical care in dealing with changed working conditions during the COVID-19 outbreak, to learn from frontline staff's accounts to improve pandemic response in critical care and finally to understand how can frontline NHS staff working in critical care be supported now and into the future.
Methods: We undertook semi-structured telephone interviews with 40 staff across 4 hospitals in Scotland and England. We employed purposive sampling to include critical care trained and redeployed staff, including nurses, medical staff, allied health professionals and ancilliary staff, e.g. ward clerks. We sought a breadth of experience in terms of age, gender, ethnicity, and experience working in critical care. we adopted Rapid Analysis techniques, informed by sociological theory.
Results: We identified six key themes: Learning & Preparation, Adjusting to new working, Information, Practicalities of Care, Communication/End of Life Care and Impact on Self and Wellbeing. These were viewed through the theory of Communities of Fate and Place and Body in Work, both used in pandemic and disaster sociology, where purposeful collective action is undertaken by a group of people facing a common or shared crisis situation. These communites of fate, applied to COVID-19 and ICU, indicated the structural importance of social and organisational working conditions, incluuding resourcing and the way surge plans are developed, and how organisations and individuals respond. We also found that individualised psychology-based interventions were likely to be ineffective unless social pre-conditions for wellbeing were established Moreover, the ICU does not exist independently of the constant embodied work of care and place-making which iteratively constitute critical care as a total system of relations.
Conclusions: COVID-19 immeasurably altered working practices in critical care and profoundly affected staff physically, mentally and emotionally. Analysis through a sociological lens identified how while people pull together in a community of fate, the need for adequate resourcing in terms of trained staff, appropriate equipment, and psychological support services should be made available to the health service to protect staff and mitigate the impact of pandemic-working. In addtiion, The ICU has become an increasingly data-driven place, meaning it is is all the more important to appreciate how healthcare practitioners incorporate new practices—including data practices—into their existing body work.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001414

Introduction: Guidelines suggest targeting oxygen saturation between 88 to 92%, for COPD patients who are critically ill and need oxygen therapy (1). However, whether this more restrictive target is superior to a more liberal target is uncertain (2–4).
Objectives: To investigate the effect of restrictive vs liberal oxygen therapy in hospital mortality of COPD patients with acute exacerbation who require invasive mechanical ventilation.
Methods: A retrospective cohort was conducted using TriNetX, a global health research network including data from 76 Health Care Organizations (HCO). The network was searched for people aged > 18 years with chronic obstructive pulmonary disease with acute exacerbation hospitalized and intubated receiving mechanical ventilation recorded in electronic medical records. The analysis included outcomes that occurred in the time window that started 1 day after the first occurrence of the index event and ended 5 years after the first occurrence of the index event. The index event was defined as use of mechanical ventilation with SpO2 higher than 93% that occurred within 2 months or any instance after diagnosis of hospitalized patients with COPD acute exacerbations in Cohort 1. It defines the point in time when each patient in the cohort enters the analysis. These patients were compared to controls or Cohort 2 with the same above index event definition, however with SpO2 higher than 88 and lower or equal 92%. Characteristics of the cohorts are balanced using propensity score matching with analysis of measures of association and survival. Variables used for matching were: age, sex, pneumonia, influenza, pleural effusion, pneumothorax, diseases of pulmonary intertitium, pneumonitis, ARDS, chronic lower respiratory disease, hypertensive diseases, heart failure, cardiomiopathy, atherosclerothic diseases, ischemic heart disease, cardia arrythmias, aortic aneurysms, disease of pulmonary circulation, cerebral infarction, diabetes mellitus, BMI, neoplasms and carbon dioxide.

Results: After propensity-score matching, 23,013 patients (mean age 66.4 ± 11.1; 50.4% male) with COPD acute exacerbations treated with invasive mechanical ventilation with SpO2 with higher than or equal to 93% were compared to 23,013 patients (mean age 66.5 ± 11; 50.5% male) with COPD acute exacerbations treated with invasive mechanical ventilation with SpO2 within 88 to 92% as shown in Table 1. 12,329 patients (53.6%) in Cohort 1 and 12,329 patients (53.8%) in Cohort 2 experienced the outcome of mortality within 5 years (risk difference of − 0.002, 95% confidence interval (CI) − 0.011, 0.007; p = 0.640 and relative risk of 0.996, 95% CI 0.979, 1.013). The median survival time was 559 days with 29.05% survival probability at the end of time window in Cohort 1 and 527 days with 28.72% in Cohort 2 with p = 0.051 (log rank test) and hazard ratio of 0.975, CI 0.951, 1.000; p = 0.206 as shown Figure 1.
Conclusions: Liberal oxygen therapy in patients hospitalized receiving mechanical ventilation with acute exacerbation of COPD was not associated with higher mortality when compared to conservative oxygen therapy.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001417

Introduction: The early mobilization of patients in the intensive care unit (ICU) was shown to be important in patients' recovery. The aim of this study in to investigate the efficiency of virtual reality (VR) early rehabilitation in cardiac intensive care units (CICU).
Methods: The consecutive patients in adult CICU were enrolled. The patients were divided into two groups virtual reality (VR) rehabilitation group and control group. The patients in VR rehabilitation group received respiratory, functional training with virtual reality (VR). Maximal inspiratory pressure (MIP), maximal expiratory pressure (MEP), SF-36, CICU stay and intubation days were collected.
Results: After VR training, the maximal inspiratory pressure (MIP) showed significant improvement ($p = 0.0088$) and maximal expiratory pressure (MEP) also improved significantly ($p = 0.0203$). Further, VR rehabilitation group also had better Barthel index ($p < 0.0001$), intensive mobility scale ($p < 0.0001$), shorter ICU stay ($p = 0.0063$), and intubation days ($p = 0.006$).
Conclusions: This study demonstrate VR rehabilitation in CICU improved exercise capacity, Barthel index, intensive mobility scale, ICU stay and intubation days.

Correspondence: M. Docci
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001418

Introduction: The measurement of functional residual capacity (FRC) may help optimizing lung protective ventilation in patients with acute respiratory distress syndrome, but it is not routinely performed in clinical practice yet (1). Oxygen (O2) washin/washout is a simple technique available at bedside to estimate FRC (2). However, it relies on sidestream gas analyzers, which lack of appropriate synchronous measurements of flow and gas concentration requiring complex calculations to correct for time, gas viscosity and pressure (3–5). Recently, a mainstream oxygen sensor prototype coupled in series with a fluximeter and a very fast time response and a good precision has been developed (named Italian Fast OXygen sensor—IFOx®).
Objectives: To explore the performance of IFOx® in measuring FRC using an O2 washin/washout technique as compared to predicted FRC in healthy volunteers.
Methods: Healthy volunteers breathed in an open circuit with IFOx® during a 20-min experiment. The study protocol was composed of 3 phases: (1) basal phase, breathing ambient air (FiO2 21%) for 4 min; (2) a washin phase, breathing a gas mixture of compressed air and oxygen with an FiO2 of 30% for 8 min; (3) a washout phase, breathing ambient air with an FiO2 of 21% for 8 min. A brief end-expiratory pause (3–5 s) between each step allowed to connect/disconnect the circuit to a reservoir filled with the 30% O2 70% N2 mixture and reach a steady state. Oxygen consumption (VO2) at baseline was measured during step1 and then used for the quantification of FRC according to Weismann et al. (5). VO2 and FRC measured by IFOx® were compared to their predicted values, in all volunteers and stratified by gender. Differences were assessed by unpaired Student's T-test or Mann–Whitney U test, as appropriate. Correlation between FRC measured with IFOx® and predicted values was expressed with the Pearson correlation coefficient.
Results: We enrolled 14 healthy volunteers, 8 female, with an overall height of 166 [156;183] cm (median and IQR). As shown in ** Figure 1A, the measurement of VO2 at rest did not differ between IFOx® and predicted value (i.e. 3.5 mL of O2 per kg of bodyweight) (6) either in all volunteers (P = 0.374) or by gender stratification (P = 0.602 for females; P = 0.127 for males). Similarly (Figure 1B), the estimation of FRC by IFOx® did not significantly differ from the predicted value (i.e. 35 mL per kg of predicted bodyweight) (7) either in all volunteers (P = 0.418) or stratified by gender (P = 0.950 for females; P = 0.189 for males). FRC measured with

IFOx® well correlated with the predicted value in all volunteers ($r = 0.78$; $P < 0.001$).

Conclusions: In this first-in-human study, FRC measured with IFOx® sensor prototype showed no statistically significant difference as compared with the predicted values in spontaneously breathing healthy volunteers. Further studies may test IFOx® versus other sidestream gas analyzers based washin/washout techniques available in mechanically ventilated patients with respiratory failure.

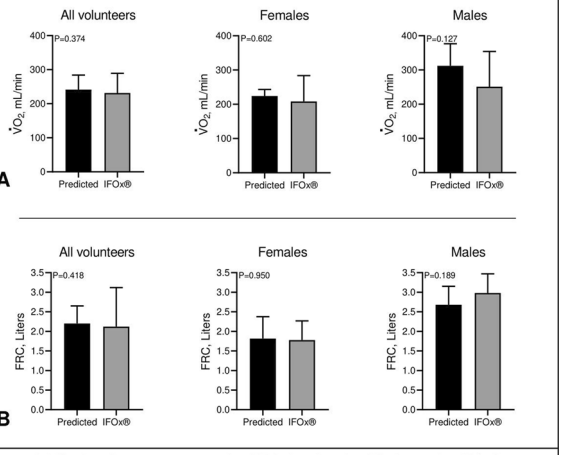

Fig. 1. $\dot{V}O_2$ and FRC measured with IFOx® versus predicted values

Venous excess ultrasound score is associated with acute kidney injury in critically ill patients

K. Trigkidis[1], I. Siempos[1], A. Kotanidou[1], C. Routsi[1]
[1]First Department of Critical Care Medicine National and Kapodistrian University of Athens, Evangelismos Hospital, Athens, Greece
Correspondence: C. Routsi
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001419

Introduction: Acute kidney injury (AKI) in intensive care unit (ICU) is a common problem and is associated with adverse outcomes (1). Among other causes, fluid overload (2) and venous congestion (3) have been implicated. Venous excess ultrasound (VExUS) grading system quantifies Doppler flow patterns of multiple ultrasound findings (hepatic veins, portal vein and intra-renal veins) reflecting right atrial pressure and venous congestion (4).

Objectives: The objective of this study was to determine whether VExUS score and the portal vein pulsatility index (PPI) are associated with the occurrence and severity of AKI in a general cohort of critically ill patients during the ICU stay.

Methods: We conducted a prospective observational study enrolling consecutive patients admitted to the ICU. Measures of venous congestion including hepatic and renal Doppler ultrasound assessments were performed within the first 24 h of ICU admission (Day1) and 24–72 h after admission (Day 2). Accordingly, VExUS score was calculated. PPI was calculated as the ratio between minimal and maximal variation of the portal blood velocity over the cardiac cycle. Clinical data including serum creatinine and urine output were recorded in order to define AKI and AKI stages according to the KDIGO defintion.

Results: From October 2022 to March 2023, we enrolled 66 patients (mean age 59.2 ± 15.4 years, 57.6% males), on mechanically ventilation because of respiratory failure of various etiologies. In the subgroup of patients who did not have AKI on ICU admission (n = 37, 56.1%), 18 patients (48.6%) developed AKI within 28 days of ICU admission and 8 (21.6%) required Continuous Renal Replacement Therapy (CRRT). In this subgroup, VExUS score on Day 2 was associated at a statistically significant level with the development (p 0.029) as well as with the severity of AKI (p 0.046). Moreover, in the same subset of patients the absolute difference of VExUS score between Day 2 and Day 1 was significantly associated with CRRT duration (p 0.0158) whereas the association of PPI value with subsequent AKI development and severity did not reach statistical significance.

Conclusions: VExUS score within 24–72 h after ICU admission was significantly associated with subsequent AKI development and AKI severity suggesting the venous congestion as an important cause or contributing factor. Therefore, these tools could provide a potential for guiding the clinical management aimed at preventing AKI in critically ill, mechanically ventilated patients.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001421

Introduction: Mechanical ventilation (MV) is frequently applied in the management of acute respiratory failure to improve patient outcomes. If not adequately monitored, MV has the potential to cause ventilator-induced lung injury. With over 20% of the patients admitted to the intensive care unit being obese, the impact of patients' weight on lung mechanics must be considered when devising a protective strategy for MV. The increased weight on the chest wall in obesity results in decreased lung volumes, increasing the risk for airway closure and atelectasis, potentially impairing gas/blood matching. Conversely, increased weight can be a protective factor by increasing chest wall elastance and leading to better gas/blood matching within the lung. The effect of obesity on pulmonary gas and blood distribution in mechanically ventilated patients has not been previously investigated and to what extent MV affects the distribution of gas and blood within the lung is generally not monitored in the clinical setting.
Objectives: This study aimed to evaluate the effect of obesity on pulmonary gas and blood distribution using dual-energy computer tomography (DECT).
Methods: This prospective single-center study included patients older than 18 years with severe COVID-19, admitted to the intensive care unit at the Uppsala University Hospital, Sweden, and underwent at least one chest DECT. Data was collected from April 7, 2020 to October 5, 2021. Patients were divided into three groups according to body mass index (BMI): underweight to normal weight with BMI < 25 kg/m^2, overweight to obese with BMI 25–40 kg/m^2, and morbid obese with BMI > 40 kg/m^2.
For each DECT investigation, 19 equally spaced DECT scans were selected between the apex and the diaphragmatic level. Inflation and perfusion maps were created for each scan representing the gas and blood distribution within the lung. For each map, a Hounsfield unit (HU) distribution was analyzed for the whole lung as well as at a regional level (10 levels along the gravitational axis). The gas/blood mismatch was calculated by comparing the HU distribution of gas and blood, where dead space was defined as gas exceeding blood and shunt, as blood exceeding gas. This analysis was performed for each BMI group separately.
Results: Data was collected for 118 patients and 142 DECT investigations were analyzed. The BMI > 40 kg/m^2 group had less hyperinflation in the non-dependent (ND) regions and poorly or non-inflated in the dependent regions (D), compared to BMI < 25 kg/m^2. BMI > 40 kg/m^2 showed more blood distribution away from poorly or non-inflated lung regions thereby, achieving less of a gas-blood mismatch (30%) when compared with the other two groups (36%).
Conclusions: This study demonstrated that morbid obesity improves gas/blood matching. DECT can be a useful tool, quantifying regional dead space and shunt thus providing additional information for a more individualized mechanical ventilation.

Mechanical ventilation induced increase in intrapulmonary postcapillary resistance plays a key role in diminishing left ventricle filling and cardiac output

A. Landesberg[1], O. Andriesse[1], N. Markovitch[1], A. Livneh[1], Y. Bar-Lavie[2]

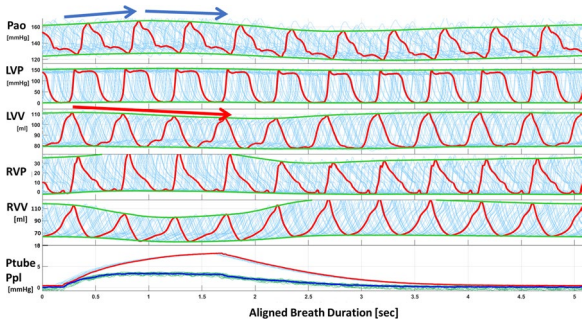
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001422

Introduction: Mechanical ventilation (MV) induced decrease in cardiac output (CO) is commonly attributed to a decrease in right ventricular (RV) preload and an increase in RV afterload. Moreover, the inspiratory increase in systolic pressure (Δup) is attributed to a temporary increase in left ventricular (LV) stroke volume (SV).
Objectives: We have hypothesized that MV directly reduces LV filling and CO by decreasing the intrapulmonary vascular transmural pressures, which increases the vascular resistance. The phenomenon is critical in the postcapillary vessels with the lower intravascular pressure, where it can lead to postcapillary collapse.
Methods: The hypothesis was validated in normal sheep (N = 6) under regular pressure-controlled ventilation (PEEP: 2.4 ± 0.89 cmH2O, driving pressure: 12.4 ± 0.89 cmH2O; inspiration/expiratory ratio 1:2). The effects of MV on pulmonary hemodynamics and cardiac function were measured by simultaneous recording of both right and left pressure–volume loops, utilizing two impedance catheters (CD-Leycom) within both ventricles.
Results: The aortic systolic pressure increased during inspiration (Δup = 6.36.4 ± 2.38 mmHg), but the peak always occurred before end inspiration (blue arrows in the Fig.). The pulmonary artery systolic pressure also increased during inspiration, despite the prominent inspiratory decrease in RV end-diastolic volume and SV. While the RV systolic pressure increased, there was significant decreases in the LV end-diastolic volume (EDV) and SV (− 5.57 ± 6.16 [ml], − 15.98 ± 19.16 [%]), measured at the time of peak inspiratory aortic pressure relative to the end-expiratory values. Interestingly, the progressive decrease in LV EDV that was followed by progressive decrease in LV-SV was observed immediately from the beginning of inspiration (red arrow in the Fig). LV filling decreases despite the increase in pulmonary artery pressure due to the increase in pulmonary vascular resistance. However, the immediate inspiratory decline in LV EDV and filling cannot be attributed to the effects of MV on RV function, which should appear with some delay. The

immediate decrease in LV filling strongly supports the immediate development of high resistance to flow from intrapulmonary postcapillary blood pool due to development of postcapillary high resistance to flow. The aortic systolic pressure (Δup, blue arrows) increased due to the increase in the intrathoracic pressure, and not due to an increase in LV-SV. The progressive decline the LV-SV leads to reversal of the trend and to decline in systolic pressure already during inspiration.
Conclusions: The inspiratory increase in systolic pressure (Δup) is not a reliable hallmark of an increase in LV-SV. MV can decrease the CO by increasing the postcapillary resistance which directly diminishes LV filling, even in the presence of significant Δup. This mechanism is critical in planning the optimal MV and oxygen delivery.



Mechanical ventilation (Peep = 2.0, driving pressure = 10.0 cmH2O) increases the systolic aortic pressure (Δup, blue arrows) during inspiration. However, there is an immediate decline of LV EDV form the beginning of inspiration (red arrow) due to the development of intrapulmonary postcapillary high resistance to blood flow. All the cardiac cycles (thin blue and bold red cycles) were aligned to the intratracheal tube pressure (Ptube, red). Pao-Aortic pressure, LVP– LV pressure, LVV- LV volume, RVP- RV pressure, RVV- RV- volume, Ppl- Pleural pressure (blue).

Organisation and reimbursement of intensive care across European countries

E. Berger[1], H. Lantzsch[1], M. Blümel[2], R. Busse[1]
[1]Health Care Management, Berlin Institute of Technology, Berlin, Germany; [2]Health Care Management, technische Universität Berlin, Berlin, Germany

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001425

Introduction: During the pandemic, intensive care units (ICUs) and especially their capacity was a heavily discussed topic in Europe. As a result, many European countries have increased their intensive care capacities to ensure treatment of all patients with a COVID-19 infection (Berger et al. 2021). A Belgian analysis, however, revealed that ICU organisational characteristics, among other factors, were associated with in-hospital mortality (Van de Voorde et al. 2020). This includes, for example, ICU overflow and a high proportion of additionally created ICU beds (Berger et al. 2021). As an internationally accepted definition of intensive care and its organisation and financing is missing, the Belgian Health Care Knowledge Centre (KCE) initiated the project "The organisation and reimbursement of intensive care in different European countries" which is integrated into a larger study.
Objectives: The aim of the project is to review international models for the organisation and reimbursement of intensive care.
Methods: Based on a scoping review a longlist of countries was compiled as a first step. For the longlist, we focused on a large regional coverage of European countries and further included countries with peculiarities in the organisation and remuneration of intensive care medicine. As a second step, a set of criteria was defined to select about 5–7 countries for the shortlist. The final sample includes the following countries: Denmark, England, France, Germany, Italy, the Netherlands, Sweden. For these countries, an international questionnaire-based expert survey has been carried out.
Results: For the countries included, the following main research questions will be answered:

1. How is intensive care legally defined?
2. How is intensive care organised?
3. How is intensive care reimbursed?
4. Are there internationally defined and available indicators to measure outcome quality of ICUs?

Conclusions: The results of this ongoing study should inform decision makers to tackle future crises and to improve the organisation and reimbursement of intensive care medicine in general.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001426

Introduction: Acute kidney Injury complicates approximately 5% of hospital admissions ad 30% of intensive care admissions.1 Hence, this renal dysfunction may result in accumulation of antimicrobial agents with resultant adverse effects if not dosed properly.2 The classical dosing of antimicrobials in Intensive care Unit depend upon the estimated Glomerular Filtration rate from steady state creatinine clearance equations namely Cokrauft-Gault, MDRD and CKD-EPI equations which fall short in estimating AKI. Kinetic GFR provides a reasonably good estimate of GFR in AKI.3
Objectives:

1. To assess the concordance—discordance between GFR Estimation by K-GFR, MDRD, CG and CKDEPI in AKI Patients.
2. Assess the clinical utility of k -GFR for Dosing Antimicrobials in Patients with Acute Kidney Injury Not Receiving Renal Replacement Therapy.
3. As a predictive tool and examine the association of k -GFR to adverse renal outcomes compared with measurements to traditional estimate

Methods: This is a prospective multicentric observational study being conducted in four tertiary care ICUs of Yashoda hospitals, Hyderabad, India. The study period is 2022 December to 2023 April. All AKI patients aged 18–70 years admitted to the ICU were included in this study. AKI was defines as per AKIN criteria and GFR was calculated on day 1 and day 2 of increase in creatinine with Cockrauft-Gault4, MDRD5, CKD-EPI6 and KeGFR7 equations. The concordance–discordance of eGFR

estimated from CG, MDRD and CKD-EPI equations with that calculated from KeGFR equation is calculated. The antimicrobial dosing estimated from the GFR calculated from CG, MDRD and CKD-EPI equations is compared with dosing estimated from GFR estimated from KeGFR equation. Prediction of adverse outcomes including requirement of renal replacement therapy and in-hospital mortality in AKI patients is calculated based on KeGFr and traditional estimating methods.
Results: A total of 311 ICU admitted patients with AKI were included in the study. Their concordance–discordance of GFR calculated with KeGFR equation with that of traditional methods is as follows.

eGFR estimated on Days 1 and 2 with various formulae

Day	Formula	mean eGFR	p value
Day 1	KeGFR	40.8	
	CG	43.23	0.153
	CKD-EPI	42.8	0.191
	MDRD	39	0.22
Day 2	KeGFR	45.4	
	CG	45.8	0.851
	CKD-EPI	44.3	0.563
	MDRD	40.9	0.02

Calculated antimicrobial dose with eGFR

Antibiotic	day	mean KeGFr dose	mean MDRD dose	p value
Meropenem	Day 1	2.06	2.01	0.38
	Day 2	2.13	2	0.03
Pip + Taz	Day 1	10.88	10.73	0.48
	Day 2	11.27	10.79	0.02
Teicoplanin	Day 1	749.6	747.02	0.82
	Day 2	736.3	742.57	0.62
Cef + Sul	Day 1	5.37	5.57	0.41
	day 2	5.34	5.63	0.57
Colistin (In MU)	Day1	5.53	5.47	0.06
	Day 2	5.46	5.43	0.81

Conclusions: Kinetic-GFR may be a better method to estimate GFR in acutely changing renal function- AKI patients for antimicrobial dosing.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001427

Introduction: ICU survivors suffer high rates of adverse outcomes, a variety of physical, mental and cognitive health impairments, collectively known as post intensive care syndrome (PICS). However, it is still not fully clear which factors are associated with the development of PICS. Identification and recognition of factors associated with the development of PICS potentially facilitates interventions to reduce the burden of PICS and thereby may improve patient outcomes. Furthermore, it may support caregivers in communication with patients and their relatives.
Objectives: Therefore, we performed a systematic review analyzing the QoL of ICU survivors six months or more after their unscheduled ICU admission. The aim was to identify factors associated with the development of new onset long-term physical, mental and cognitive problems.
Methods: Data sources: We searched PUBMED from inception to March, 2020.
Study Selection: All prospective observational studies concerning the acutely admitted adult ICU patient, describing any domain of Health Related Quality of Life (HRQoL) and a follow up of at least six months, were selected.
Data extraction: In different phases of the selection process one to four reviewers were involved in study selection and risk-assessment. For the final selection or the articles, a third and fourth researcher joined to reach agreement. Risk assessment was performed using the Critical Appraisal Tool for use in JBI Systematic Reviews, Checklist for Cohort Studies.
Results: After screening 4715 articles, 54 studies were included. 14 studies used SF-36/SF-12, 10 studies used EQ-5D-VAS, 6 studies used HADS and the remaining studies used other instruments. Furthermore, the timing of evaluation of outcome differed between studies evaluating at 3 months up to 2 years. Futher analysis is currently being performed.
Conclusions: One of the preliminary conclusions is the large variety in used instruments to evaluate long term outcomes which make different studies difficult to compare.
Full results will be presented during the congress.

Investigating long-term kidney function in intensive care survivors

R. Glendell[1], M. Andonovic[2], M. Shaw[3], K. Puxty[4]
[1]School of Medicine, University of Glasgow, Glasgow, United Kingdom; [2]Academic Department of Anaesthesia and Critical Care, University of Glasgow, Glasgow, United Kingdom; [3]Academic Unit of Anaesthesia,

Critical Care and Peri-operative Medicine, University of Glasgow, Glasgow, United Kingdom; [4]Intensive Care Unit, Glasgow Royal Infirmary, Glasgow, United Kingdom
Correspondence: R. Glendell
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001428

Introduction: There is limited evidence on long-term post-intensive care (ICU) outcomes and investigation of outcome predictors following acute kidney injury (AKI) in ICU has been identified as an area for further study (1).
Objectives: This study aimed to model the trend of post-ICU discharge kidney function in ICU survivors using estimated glomerular filtration rate (eGFR) as a measure; compare kidney function in those who experienced in-ICU AKI to those who did not; and investigate potential risk factors associated with kidney function decline in ICU survivors.
Methods: This retrospective observational cohort study identified all patients aged 16 or older admitted to two general adult ICUs in the West of Scotland between 1st July 2015 and 30th June 2018 who survived to 30 days following hospital discharge. Baseline serum creatinine and subsequent values were used to identify patients with AKI and calculate eGFR following hospital discharge. Outcomes were kidney function following hospital discharge based on eGFR decline, difference in decline between AKI and non-AKI patients, and risk factors which affected this decline. Mixed effects modelling was used to control for repeated measures and missing data, and to allow inclusion of several exploratory variables.
Results: 3649 patients with a median of 21 eGFR measurements up to 2000 days of follow-up were included, with 1252 (34%) experiencing ICU-associated kidney injury. eGFR declined at a rate of − 1.9 ml/min/1.73m^2/year (p-value < 0.001) in the complete dataset. Patients with AKI experienced an accelerated rate of eGFR decline of − 2 ml/min/1.73m^2/year compared to a rate of − 1.83 ml/min/1.73m^2/year in patients who did not experience AKI (p-value 0.007). A past medical history of diabetes or liver disease was associated with accelerated eGFR decline in both patients who did and did not experience AKI. Pre-existing malignancy and cardiovascular disease were also associated with accelerated decline in patients with kidney injury. Length of vasopressor support was associated with accelerated eGFR decline in both cohorts.
Conclusions: ICU survivors experienced accelerated decline in kidney function regardless of whether they experienced AKI whilst in ICU. Pre-existing comorbidities and increasing length of vasopressor support were associated with accelerated eGFR decline. Long-term follow-up is warranted in all ICU survivors to monitor kidney function and reduce morbidity and mortality associated with chronic kidney disease.

Impact of critical illness on subsequent cancer care in colorectal cancer patients

S. MacTavish[1], K. Puxty[2], C. Taylor[2]
[1]Medicine, University of Glasgow, Glasgow, United Kingdom; [2]Intensive Care Unit, Glasgow Royal Infirmary, Glasgow, United Kingdom
Correspondence: S. MacTavish
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001429

Introduction: One in six colorectal cancer (CRC) patients are admitted to critical care (1). While many patients have planned admissions for post-operative support, around one in ten of all CRC patients require organ support (2). Cancer care is assessed by quality performance indicators (QPIs). In this study QPIs were used to compare the cancer care of patients by critical care cohort.
Objectives: To explore the impact of critical illness on the management of CRC patients with a focus on adjuvant chemotherapy.
Methods: QPI and demographic data for 14,946 patients diagnosed with CRC in Scotland between 2013 and 2018 was extracted from the CORECT-R data set. Patients were subdivided into 3 critical care cohorts: patients who were never admitted to critical care, patients who were admitted to critical care but did not receive organ support, and patients who received organ support. Data variables were created for each QPI and patients were stratified by critical care cohort and nature of admission then QPI attainment was calculated.
QPI 11 was examined using stepwise multivariable logistic regression to determine factors associated with receiving adjuvant chemotherapy. Factors significant during univariate analysis ($p < 0.1$) were analysed in an initial multivariate model and then, if still significant, put into a final model. This model was used to determine factors significantly associated with receiving adjuvant chemotherapy.
Results: Over half (54%) of patients with CRC were admitted to critical care and 11% of all patients received organ support. Out of the 13 QPIs and their subdivisions (19 targets overall) elective and emergency cohorts respective attainment of the QPIs were 10 and 8 for the no critical care cohort, 11 and 9 for the critical care without organ support group, and 4 and 3 for the organ support group. QPIs 12 and 6 (4 targets) were assessed without dividing patients by admission nature due to small numbers. The no critical care cohort attained 2 targets while both critical care cohorts attained 3.
Being admitted to critical care and receiving organ support, along with increasing age, socioeconomic deprivation and being admitted to hospital were significantly associated with a decreased chance of receiving adjuvant chemotherapy. After adjustment, being critically ill was significantly associated with being less likely to receive adjuvant chemotherapy. This is shown separately for Dukes C cancer and high-risk Dukes B cancer in Figure 1.
Conclusions: Critically ill CRC patients have poorer cancer care compared to other counterparts. Given that CRC patients becoming critically ill is not a rare occurrence, future research should focus on the impact of not receiving adjuvant chemotherapy on mortality and morbidity.

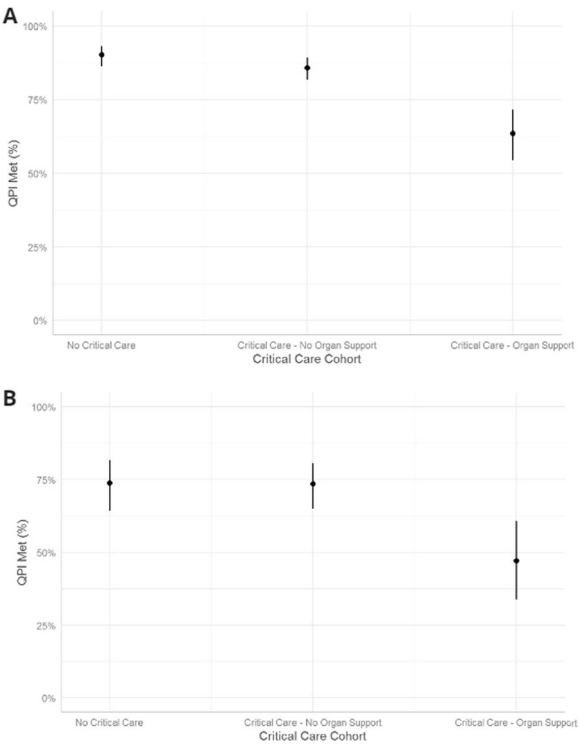

Figure 1 (abstract 001429) Predicted probabilities of patients attaining QPI 11 when adjusted for typical patient. **A.** Dukes C patients **B.** High risk Dukes B patients. Whiskers denote 95% confidence intervals.

One small sTEP… improving treatment escalation planning documentation in a Scottish District General Intensive Care Unit

R. Thomas[1], J. Selfridge[1]
[1]Intensive Care Unit, NHS Ayrshire and Arran, Crosshouse, United Kingdom
Correspondence: R. Thomas
Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001432

Introduction: Treatment escalation planning encourages an individualised, patient-centred approach to medical treatments rather than relying on futile or burdensome protocol-driven interventions. Adequate communication of these treatment escalation discussions is essential, allowing for greater decision-making security for out of hours staff and could reduce the distress which results from providing futile, interventionist care.
Objectives: The primary objective was to improve the documentation of treatment escalation decisions in this ICU.
Methods: Quality improvement methodology was utilised to develop change ideas. Nurses and junior doctors were surveyed to understand their current experience regarding treatment escalation documentation. Key stakeholders were consulted early in the process with change ideas including creation of a new ICU-specific Treatment Escalation Plan (TEP) proforma and concomitant delivery of multi-professional education. We measured the percentage of patients who had a treatment escalation plan clearly documented in the notes to analyse the impact of change ideas.
Results: 289 patient's notes were reviewed using convenience sampling. The results from the initial staff survey demonstrated that prior to the project less than one third felt treatment escalation plans were clear and easily accessible and over two thirds of staff worried that they were not always aware of the most up to date treatment escalation discussions. Baseline data over the first nine weeks confirmed these views demonstrating that 17% of patients had documented treatment escalation plans. All staff surveyed thought an ICU-specific TEP proforma would be useful. Significant improvement in treatment escalation documentation was demonstrated with 70% of patients having a documented treatment escalation plan following the TEP proforma introduction and multi-disciplinary education.
Conclusions: A simple ICU-specific TEP proforma was created with early involvement of key stakeholders. This TEP proforma alongside multi-professional education significantly improved documentation of treatment escalation planning decisions in our ICU.

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001433

Introduction: During the last decades, numerous factors and predictive mortality scores have been described in patients with acute coronary syndrome. Their current validity is in doubt due to changes in management in recent years, such as the speed in diagnosis and response within the infarction code.
Objectives: To obtain and reassess predictive factors for mortality in patients with acute coronary syndrome (ACS) admitted to our unit from 2019 to 2021.
Methods: Prospective, observational study conducted on a cohort of all patients with a diagnosis of ACS requiring catheterization from January 2020 to November 2021. Epidemiological and clinical data, several severity scales, as well as related variables and outcomes were collected. In the descriptive analysis, quantitative variables were expressed as mean with standard deviation (normal distribution) or as median with interquartile range (IQR), and qualitative variables as percentages.
The predictive factors for mortality were obtained through univariate logistic regression without adjustment, and subsequently through multivariate analysis from a maximum model that included those significant or nearly significant variables ($p < 0.1$) from the univariate analysis adjusted for comorbidity and those considered clinically relevant, through stepwise selection based on Akaike information criterion.
Results: 155 patients were included in the study. Age was 63 ± 12 years, and 79% were male. 93.7% had a CFS < = 3, and 53% had STEMI. 78% had Killip 1. Mortality in the ICU, at discharge, 6 months, and 12 months was 5.2%, 5.8%, 11%, and 15%, respectively. The ICU stay was 2 days IQR (1–3), and the hospital stay was 4 days IQR (3–6).
The following results were obtained in the multivariate analysis at twelve months mortality:
apacheii 1.11 (1.03–1.19).
nyha > = clase2 4.06 (1.23–12.95).
Conclusions: Based on our experience, despite examining multiple scores among patients with acute coronary syndrome, the only independent predictors of mortality were a prior NYHA score of > = 2 and the APACHE II score at admission.

Table 1 (abstract 001433) Univariate analysis at several times

OR CI (95%)	ICU MORTALITY	DISCHARGE MORTALITY	6 MONTHS MORTALITY	12 MONTHS MORTALITY
APACHE II	1.19 (1.10-1.31)	1.18 (1.01-1.30)	1.12 (1.05-1.20)	1.14 (1.07-1.23)
SAPSIII	1.17 (1.06-1.20)	1.11 (1.06-1.19)	1.06 (1.02-1.11)	1.06 (1.02-1.11)
ACEF (age/left ventricle ejection fraction)	4.83 (1.96-13.41)	4.70 (1.97-12.46)	3.77 (1.85-8.15)	3.35 (1.74- 6.77)
INVASIVE MECHANICAL VENTILATION	19.80 (3.23-118.00)	15.72 (2.67-86.53)	18.94 (4.12-103.01)	12.50 (2.81-65.83)
ELECTRICAL COMPLICATIONS	17.04 (3.66-121.61)	11.27 (2.76-56.63)	3.90 (1.29-11.35)	3.82 (1.42-10.04)
MECHANICAL COMPLICATIONS	8.98 (1.85-48.65)	11.85 (2.68-61.90)	5.93 (1.89-18.23)	3.38 (1.15-9.40)

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001437

Introduction: Mortality rates after burn injuries remains high (10–20%) even in well-equipped burn centers. Patients under mechanical ventilation (MV) after a burn injury have even higher mortality rates.
Severity scoring systems provide a basis for clinical decision-making, having to be based on objective criteria, be accurate and easy to use.
The Belgium Outcome Burn Injury (BOBI) score is a model that predicts mortality taking into account only three major risk factors: age (60 years or more); total burned surface area (TBSA) of at least 40% and presence of inhalation injury. The predictive value of this score in mechanically ventilated patients is still uncertain.
Objectives: The objective of this study is to access the capacity of the BOBI score in predicting in-hospital mortality in patients undergoing mechanical ventilation in a Burn Reference Center (BCR).
Methods: Retrospective study including all burn patients admitted to a BRC in a five year consecutive cohort (from 2018 to 2022), whom needed mechanical ventilation during the episode. Chi-square test was used for categorical variables, and analysis of variance for continuous variables. Binary logistic regression was used to control for confounding factors. The accuracy of BOBI score for prediction of in-hospital mortality was evaluated using the receiver operating characteristic (ROC) curve and computation of the area under the curve (AUC).
Results: A total of 151 ventilated patients were include, 68.2% of them were males. Mean age was 57.6 years-old. The median TBSA burned was 15,5% and 58.3% of the patients were ventilated in a pre-hospital set or at admission in urgency room, and for 41.7%, mechanical ventilation was initiated during the stay in burn unit.
In this cohort, the median length of stay at the burn unit was 22 days, with 13.8 ± 16 days of mechanical ventilation. The mean BOBI score was 3 The mortality rate during burn unit stay was 28.9% (43 patients). After a logistic regression, that controlled for potential confounding factors, the predictors of mortality in this cohort were a higher TBSA ($p = 0.001$), the need for antibiotic therapy ($p = 0.003$) and a higher BOBI score ($p = 0.001$).
Paying attention to the ROC, BOBI score proved to be a good mortality predictor the predictive value in the burn patients who needed mechanical ventilation during their stay at the Burn Unit (AUC 0.733, $p = 0.001$).
Conclusions: In this cohort the BOBI score showed a good predictive power when it comes to in-hospital mortality.

The influence of different lighting conditions on serum cortisol levels in mechanically ventilated critically ill patients

L. Hancke[1], F. Borchers[1], C. Spies[1], K. D. Wernecke[2], H. Piazena[1], A. Lütz[1]

Intensive Care Medicine Experimental 2023, **11 (Suppl 1):**001438

Introduction: Abnormal zeitgebers, such as inadequate lighting conditions in the ICU, are supposed to promote chronodisruption and poor outcomes in critically ill patients[1]. Cortisol and melatonin levels, which follow distinct circadian rhythms in healthy humans, exhibit pathological 24 h secretion patterns in ICU patients[2]. Studies revealed that bright light exposure significantly influences cortisol levels in healthy subjects[3,4].
Objectives: To evaluate the effect of different lighting conditions on cortisol levels in mechanically ventilated critically ill patients.
Methods: In 2013 we finished rebuilding two 2-bed ICU rooms. Among interventions for noise reduction and workflow optimisation, the modified rooms were equipped with a new light ceiling for dynamic bright light therapy. Light intensity was defined by calculating the circadian effective irradiance (EC) in standard and modified rooms. It uses spectral lighting data measured at the patient's eye level, weighted by the action spectrum of melatonin suppression[5]. We analysed cortisol data from a prospective observational cohort study (NCT02143661) approved by the ethical review committee (EA1/019/14). Mechanically ventilated patients with an expected ICU length of stay > 48 h were included. Amongst others, patients with substantial recent ICU exposure and patients who were unlikely to survive for 24 h were excluded. Serum cortisol levels were measured for a maximum of three 24-h periods (serum cortisol assessment period, SCAP-A, -B and -C) every four hours starting at 8am. Differences in cortisol levels between patients in standard and modified rooms were analysed using multivariate non-parametric covariance analysis of longitudinal data.
Results: Data from 74 patients ($n = 37$ standard vs. $n = 37$ modified room) were included in data analysis. Serum cortisol levels under the influence of EC were significantly different between patients in standard and modified rooms during the whole time course of SCAP-A ($P = 0.0055$) and SCAP-B ($P = 0.0087$) but not for SCAP-C ($P = 0.4628$). Patients in both groups showed systematic time effects for all SCAP's, referring to significant changes in cortisol levels in time ($P < 0.0001$). Significant interactions for all SCAP's ($P < 0.0001$) revealed that differences in cortisol between rooms are not the same over time but vary in specific periods (Table 1). There are distinct differences in relative effect sizes between rooms during 8am and 4 pm which disappear in the evening and night (Figure 1).

Table 1 (abstract 001438) Multivariate test statistics of serum cortisol under the influence of circadian effective irradiance (EC)

Hypothesis	P-Value SCAP-A	P-Value SCAP-B	P-Value SCAP-C
Difference between groups during entire SCAP	0.0055	0.0087	0.4626
Systematic time effect	< 0.0001	< 0.0001	< 0.0001
Interactions: Differences do change during SCAP between groups	< 0.0001	< 0.0001	< 0.0001

Comparison of cortisol levels between patients in standard (n = 37) and modified (n = 37) rooms. SCAP, serum cortisol assessment period: A, 1st day of intervention; B, 3rd day of intervention or later; C, 5th day of intervention or later.

Conclusions: Lighting conditions significantly influenced circadian cortisol levels in mechanically ventilated ICU patients. The 24-h patterns were different for patients with bright light therapy in the modified rooms compared to patients who received conventional lighting in standard rooms. As the modified rooms received various changes in design and equipment, observed effects on cortisol levels are not solely attributable to the different lighting conditions.

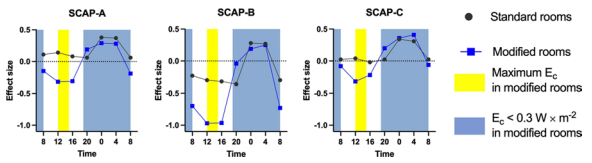

Figure 1 (abstract 001438) Relative effect sizes of serum cortisol levels under (Ec). SCAP, Serum Cortisol Assessment Period: SCAP-A, intervention or later; SCAP-C, 5th day of intervention or later. Comparison of cortisol levels between patients in standard (n = 37) and modified (n = 37) rooms.

Introduction: The relationship between Intracranial Pressure (ICP) and sodium disorders is well understood as regarded the role of osmolality changes in the brain swelling process. The maintenance of plasma sodium concentration within a precise range has entered a routine practice in the management of Trauma Brain Injury (TBI) in Intensive Care Unit (ICU)1. Indeed, among therapies to lower ICP, increasing evidence emerges about the administration of hyperosmolar solutions (i.e. hypertonic saline solution). Meanwhile, targeting plasma sodium concentration at higher levels has not demonstrated efficacy to prevent an increase in ICP 2 rather the acute difference generated after administration of hyperosmolar solutions seems to be effective in lowering ICP 3456. We investigated the association of sodium changes during the first week in the ICU defined as trajectories in which patients were evaluated for the probability to be allocated since admission to the ICU. For each trajectories, we secondarily investigated the association with the functional outcome as GOSE at 6 months.

Methods:. Patients from the CENTER-TBI cohort admitted to Intensive Care Unit (ICU) who had sodium measure for at least three days within the first week were included in the analysis. Candidate models were investigated by varying the number and the shape (linear or modeled by splines) of trajectories, and the inclusion of baseline covariates on trauma severity (e.g. age, pupil's reactivity, and Glasgow Coma Scale). Logistic regression was used to assess the association between identified patterns and poor neurological outcomes at 6 months.

Results: A total of 1376 patients, with 7040 sodium measurements, fulfilled the study criteria. The final model included three sodium trajectories labeled by the degree of sodium increase: "fast-increase" (class-1, n = 285.22%), "moderate-increase" (class-2, n = 777.60%), and "stability" (class-3, n = 235.18%). Patients were allocated and age, pupil reactivity, and Glasgow Coma Scale were selected as predictors of a trajectory group membership. The regression model found a significant association on poor outcomes only for class-1 compared with class-3 (OR = 4.9,95%CI = 2.73–6.81).

Conclusions: In TBI patients admitted to ICU, severity was a predictor of their sodium trajectory. The fast increase trajectory was significantly associated with unfavorable outcomes reflecting more severe patients and, probably, more aggressive treatment should be investigated.

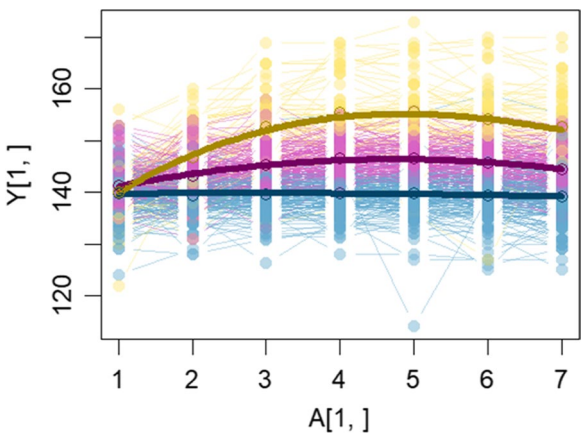

Figure 1 (abstract 001439) Graphical representation of sodium concentration (Y [1,]) changes trajectories:"fast-increase" (yellow ines), "moderate-increase" (purple lines) and "stability" (blue lines) within the first seven days (A[1,]).

Introduction: Numerous studies have shown beneficial effects of quality improvement initiatives (QII) for sepsis (1–6). Surviving sepsis campaign guidelines have recommended such initiatives for more than 10 years (7); whether these initiatives are applied or not remains unknown.
Objectives: The European Sepsis Care Survey was an initiative of the European Sepsis Alliance in the aim to investigate the current situation of sepsis care in a large sample of European and non-European hospitals. Presence of any kind of sepsis quality improvement initiatives and the existence of sepsis mortality recording were part of this analysis.
Methods: Between August 2021 and June 2022, the European Sepsis Care Survey investigated structures of sepsis care in acute care hospitals. The used online survey was primary addressed to European hospitals but non-European hospitals were also eligible. Participation was controlled by previous registration followed by a personalised invitation. The multidisciplinary cross-sectional questionnaire included 94 questions, harmonized by a multi-society (ESA, ESICM, ESAIC, ESCMID, EUSEM, ESS, ESPNIC and IFA) steering committee. Participating hospitals were grouped according to high- or middle-income countries and bed capacity (5 strata by number of hospital beds: 0–250, 251–500, 501–750, 751–1000 and > 1000).
Results: 970 hospitals from 68 countries were considered for this analysis. Of these, 705 (72.7%) hospitals were located in the European Union. The distribution of the different hospital sizes is shown in Figure 1. Overall, 31.3% (276/866) of the hospitals reported QII for sepsis. In high-income countries, QII were reported in 28.0% (176/629) and in middle-income countries in 39.4% ($p < 0.001$). Presence of sepsis QII differs depending on the hospital size ($p = 0.028$). A hospital size-related trend to higher rates of QII was observed in middle-income countries, but not in high-income countries (Fig. 2). Recording sepsis mortality was reported from 44.4% (431/970) of the hospitals, in high-income countries in 38.4% (262/682) and in middle-income countries in 58.7% (169/288) ($p < 0.001$). Presence of sepsis mortality recording also differed in hospitals of different sizes and between high- and middle-income countries (Fig. 3).
Conclusions: Sepsis quality improvement initiatives are not widespread, despite longstanding recommendations and numerous successful sepsis quality improvement studies in the past (1–6). Hospitals with any kind of quality improvement initiative for sepsis were outnumbered in this large sample of mainly European Hospitals. Perception is that there are more efforts in larger hospitals in middle-income countries compared to high-income countries.
Systematic recording of sepsis mortality as an important indicator of quality was scarce, especially in hospitals from high-income countries.
