ABSTRACT

The peculiar short gamma-ray burst (SGRB) GRB 170817A has been firmly associated to the gravitational wave event GW170817, which has been unanimously interpreted as due to the coalescence of a double neutron star binary. The unprecedented behaviour of the non-thermal afterglow led to a debate over its nature, which was eventually settled by high-resolution VLBI observations that strongly support the off-axis structured jet scenario. Using information on the jet structure derived from multi-wavelength fitting of the afterglow emission and of the apparent VLBI image centroid motion, we compute the appearance of a GRB 170817A-like jet as seen by an on-axis observer and compare it to the previously observed population of SGRB afterglows and prompt emission events. We find that the intrinsic properties of the GRB 170817A jet are representative of a typical event in the SGRB population, hinting at a quasi-universal jet structure. The diversity in the SGRB afterglow population could therefore be ascribed in large part to extrinsic (redshift, density of the surrounding medium, viewing angle) rather than intrinsic properties. Although more uncertain, the comparison can be extended to the prompt emission properties, leading to similar conclusions.

Key words. relativistic processes – gamma-ray burst: individual: GRB 170817A – stars: neutron – gravitational waves

1. Introduction

The discovery of the short gamma-ray burst (SGRB) GRB 170817A by *Fermi*/GBM (Goldstein et al. 2017) and INTEGRAL/SPI-ACS (Savchenko et al. 2017) in concert with the Advanced LIGO/Virgo gravitational wave (GW) event GW170817 produced by the merger of two neutron stars (Abbott et al. 2017b) unleashed a new era in multi-messenger astronomy (Abbott et al. 2017a). The γ -ray emission, delayed by 1.734 ± 0.054 s (Abbott et al. 2017a) with respect to the GW event chirp, consists of a short burst of duration $T_{90} \sim 2.0 \pm 0.5$ s, with evidence of a sub-structure characterised by a short (~ 0.5 s) hard spike followed by a longer and softer tail (Goldstein et al. 2017; Zhang et al. 2018). The 10–1000 keV peak flux (3.7 ± 0.9 ph cm⁻² s⁻¹) and fluence ($2.8 \pm 0.2 \times 10^{-7}$ erg cm⁻²), combined with the nearby distance of the source, make GRB 170817A several orders of magnitude less luminous and less energetic than typical short GRBs (Abbott et al. 2017a). With the spectral parameters provided by Goldstein et al. (2017) and assuming a luminosity distance $d_L = 41$ Mpc (Coulter et al. 2017), the isotropic equivalent peak luminosity is $L_{\text{iso}} = (1.4 \pm 0.5) \times 10^{47}$ erg s⁻¹ and the isotropic equivalent energy is $E_{\text{iso}} = (5.6 \pm 0.4) \times 10^{46}$ erg. The peak of the best fit $\nu F(\nu)$ spectrum during the initial hard spike is $E_{\text{peak}} = 185 \pm 62$ keV (Goldstein et al. 2017)¹.

The discovery of the associated optical transient AT2017gfo (Coulter et al. 2017; Valenti et al. 2017) about 12 h after the GBM trigger motivated an intense ultraviolet, optical, and infrared (UVOIR) follow-up campaign (e.g. Andreoni et al. 2017; Arcavi et al. 2017; Chornock et al. 2017; Covino et al. 2017; Díaz et al. 2017; Drout et al. 2017; Evans et al. 2017; Hallinan et al.

2017; Pian et al. 2017; Pozanenko et al. 2018; Smartt et al. 2017; Utsumi et al. 2017) – the results of which have been collected and homogenised in Villar et al. (2017) – which characterised in unprecedented detail the emission and colour evolution of the first ever spectroscopically confirmed (e.g. Pian et al. 2017; Cowperthwaite et al. 2017; Gall et al. 2017; Kilpatrick et al. 2017; McCully et al. 2017; Nicholl et al. 2017; Smartt et al. 2017) kilonova (KN), i.e. nuclear-decay-powered emission from the expanding ejecta produced in the double neutron star (NS–NS) merger (Li & Paczyński 1998; Metzger & Berger 2011; Metzger 2017).

Another emission component was detected by *Chandra* in X-rays ~ 9 days after the merger (Troja et al. 2017; Margutti et al. 2017; Haggard et al. 2017) and one week later in the radio by the *Karl G. Jansky* Very Large Array (JVLA; Hallinan et al. 2017). Subsequent monitoring of the flux density in several bands (e.g. Margutti et al. 2017, 2018; Troja et al. 2017, 2018a; Mooley et al. 2017; Lamb et al. 2019; Lyman et al. 2018; D’Avanzo et al. 2018; Dobie et al. 2018; Resmi et al. 2018) established the non-thermal nature of this emission component, but the community could not agree on its interpretation until more than 200 days post-merger. High-resolution very long baseline interferometry (VLBI) observations (Mooley et al. 2018; Ghirlanda et al. 2019) eventually provided strong support to the interpretation of this emission component as being synchrotron emission from the forward shock caused by a narrow, relativistic jet sweeping the interstellar medium (ISM). Within this scenario, the evolution of the flux density requires the jet to feature an angular “structure”, namely a narrow core (of half-opening angle $\theta_c \sim 3^\circ$) with an approximately uniform distribution of kinetic energy per unit solid angle $dE/d\Omega(\theta)$ and Lorentz factor $\Gamma(\theta)$ (here θ is the angle from the jet axis), surrounded by “wings” where both the kinetic energy density and Lorentz factor decrease steeply as a

¹ Similar results were obtained by an independent analysis by Zhang et al. (2018)

function of θ (e.g. Lazzati et al. 2018; Lyman et al. 2018; Troja et al. 2018a; Lamb et al. 2019; Resmi et al. 2018; Margutti et al. 2018; Hotokezaka et al. 2018; Ghirlanda et al. 2019; Ziaepour 2019).

Despite several uncertainties in the modelling and the large number of parameters, quite remarkably the analyses carried out by different groups with diverse methodologies largely agree about the general features of the jet structure (see Fig. S6 in Ghirlanda et al. 2019 for a visual comparison). In this work we address whether or not a jet with this structure, when observed on-axis, resembles the known SGRB population, and to what extent. We investigate this question for both the afterglow emission, by comparing the on-axis emission of a GRB 170817A-like jet to that of a large sample of SGRBs collected by Fong et al. (2015), and for the prompt emission, using an updated version of the SBAT4 sample (D’Avanzo et al. 2014) as comparison. These comparisons provide suggestive hints towards the possibility that most SGRBs possess very similar jets, implying that a large part of their diversity could be ascribed to extrinsic differences (viewing angle, ISM density, redshift).

2. Afterglow model

We describe here in brief the afterglow model we use to compute the light curves presented in this work. The model, based on standard GRB afterglow concepts, has been used previously in D’Avanzo et al. (2018) and Ghirlanda et al. (2019), and is in many respects similar to those of Lamb & Kobayashi (2017) and Gill & Granot (2018).

2.1. Dynamics

Let us define a spherical coordinate system whose z axis is aligned with the jet axis, and let us use θ and ϕ to denote the latitudinal and azimuthal angles, respectively. The observer lies on the (z, y) plane, their line of sight forming an angle θ_v with the jet axis. Let us refer to the part of the jet comprised between θ and $\theta + d\theta$ as the annulus. We consider each annulus independently, ignoring energy transport between adjacent annuli (i.e. we neglect the jet lateral expansion, which only affects the late-time behaviour of the light curves, and has no effect on our conclusions – we will present a model of lateral expansion in a future publication). The initial kinetic energy per unit solid angle in each annulus is $dE/d\Omega$, and its initial Lorentz factor is $\Gamma(0, \theta)$. As the annulus expands, it sweeps the ISM producing a shock. At a given radius R , the swept mass per unit solid angle amounts to

$$\mu(R) = \frac{R^3}{3} n m_p, \quad (1)$$

where n is the ISM number density and m_p is the proton mass (i.e. we assume the ISM is made of pure hydrogen). We compute the dynamics of the shocked material enforcing energy conservation, following Panaitescu & Kumar (2000) and Granot & Kumar (2003). This yields the Lorentz factor of the shocked material², namely

$$\Gamma(R, \theta) = \frac{\mu_0}{2\mu} \left[\sqrt{1 + \frac{4\mu(c^{-2}dE/d\Omega + \mu + \mu_0)}{\mu_0^2}} - 1 \right], \quad (2)$$

² The material behind the shock actually features a Lorentz factor profile (Blandford & McKee 1976). This energy conservation argument yields the average Lorentz factor. Since most material is concentrated right behind the shock, though, the result is close to the Lorentz factor just upstream of the shock.

where $\mu_0(\theta) = [dE/d\Omega(\theta)]/[\Gamma(0, \theta)c^2]$ and c is the speed of light. The shocked material is concentrated in a thin layer behind the shock (Blandford & McKee 1976), which we approximate as having a uniform radial density distribution within a thickness ΔR , which depends on θ , R , and Γ . By enforcing electron number conservation, we can relate this thickness to the other quantities defining the dynamics. We compute the electron number density n_s of the shocked material imposing the shock-jump condition (Blandford & McKee 1976)

$$n_s = \frac{\gamma_{\text{ad}}\Gamma + 1}{\gamma_{\text{ad}} - 1} n, \quad (3)$$

where γ_{ad} is the post-shock adiabatic index. We approximate γ_{ad} as a function of Γ using the fitting function by Pe’er (2012), which gives the correct post-shock adiabatic index under the assumption of (i) a strong shock and (ii) that the shocked particle energy distribution is dominated by a Maxwellian. This allows us to derive the thickness of the shocked layer as

$$\Delta R = \frac{R(\gamma_{\text{ad}} - 1)}{3(\gamma_{\text{ad}}\Gamma + 1)\Gamma}. \quad (4)$$

The shocked layer grows thicker as more and more ISM matter is swept, with the forward shock moving faster than the shocked material itself. Its Lorentz factor Γ_s can be related to Γ by (Blandford & McKee 1976)

$$\Gamma_s = (\gamma_{\text{ad}}(\Gamma - 1) + 1) \sqrt{\frac{\Gamma + 1}{\gamma_{\text{ad}}(2 - \gamma_{\text{ad}})(\Gamma - 1) + 2}}. \quad (5)$$

2.2. Equal-arrival-time surfaces

Photons emitted by the material behind the shock at a given time reach the observer at different arrival times. Let us assume, as a simplifying approximation, that all the emission comes from the shock surface, which is justified as the emitting layer is thin compared to the shock radius. The relation between the emission radii $R(\theta, \phi)$ and the arrival times t_{obs} is therefore

$$t_{\text{obs}}(R, \theta, \phi, \theta_v) = (1 + z) \int_0^R \frac{dR(1 - \beta_s \cos \alpha)}{\beta_s c}, \quad (6)$$

where z is the redshift, $\beta_s = (1 - \Gamma_s^{-2})^{1/2}$, $\cos \alpha = \cos \theta \cos \theta_v + \sin \theta \sin \phi \sin \theta_v$ (given our assumed geometrical setting), and we choose the integration constant so as to set $t_{\text{obs}} = 0$ for a photon emitted when the shock radius was $R = 0$. We write the shock surface brightness as $I_\nu(\nu, R, \theta, \phi) = \delta^3 \Delta R' j'_\nu(\nu/\delta)$, where $\delta(R, \theta, \phi, \theta_v) = \Gamma(R, \theta)^{-1} [1 - \beta(R, \theta) \cos \alpha]^{-1}$ is the Doppler factor (we note that it is computed using the shocked material velocity $\beta = (1 - \Gamma^{-2})^{1/2}$, as opposed to the shock velocity), $\Delta R' = \Gamma(R, \theta) \Delta R$, and j'_ν is the comoving emissivity, which we assume to be due to synchrotron emission as detailed in the following section. In order to compute the light curves, we set up a grid with N_θ latitudinal divisions θ_i , equally spaced in the logarithm so that $10^{-4} \leq \theta_i \leq \pi/2$, and N_ϕ azimuthal divisions ϕ_j with $-\pi/2 \leq \phi_j \leq \pi/2$ (i.e. we only cover half of the jet, to exploit the symmetry of the jet image under reflection across the (z, y) plane). We compute the surface brightness at each point of the grid, at radii corresponding to a given arrival time t_{obs} , and we finally integrate over the grid to get the flux density at that time:

$$F_\nu(\nu, t_{\text{obs}}) = 2 \times \frac{1 + z}{d_L^2} \int_0^1 d \cos \theta \int_{-\pi/2}^{\pi/2} d\phi R^2 I_\nu((1 + z)\nu, R), \quad (7)$$

where $R = R(\theta, \phi, t_{\text{obs}})$, i.e. the equal-arrival-time surface, is obtained by inverting Eq. (6), and the factor two is to recover the flux from the whole jet, as we only compute it on half of the solid angle, as explained above. To compute the flux from the counter-jet, which we assume to possess the same properties as the jet, we follow the same procedure, but setting $\theta_v \rightarrow \pi + \theta_v$.

2.3. Radiation

We model the emission from the shocked material (assuming only a forward shock is present) in a way similar to Sari et al. (1998) and Panaitescu & Kumar (2000). We assume shocked ISM electrons to be accelerated into a power-law distribution in Lorentz factor, namely

$$\frac{dn_s}{d\gamma} \propto \gamma^{-p}, \quad (8)$$

with $p > 2$ above a minimum (“injection”) electron Lorentz factor γ_m . We assume that their total energy density amounts to a fraction ϵ_e of the post-shock energy density, defined as $e = (\Gamma - 1)n_s m_p c^2$. These assumptions lead to the following definition of the injection Lorentz factor (Sari et al. 1998):

$$\gamma_m = \max \left[1, \frac{p-2}{p-1} (\Gamma - 1) \frac{m_p}{m_e} \right], \quad (9)$$

where m_e is the electron rest mass, and we ensure $\gamma_m \geq 1$. We assume the magnetic field upstream of the shock to be amplified by small-scale instabilities to an energy density $B^2/8\pi$ equal to a fraction ϵ_B of the post-shock total energy density e . With these assumptions, we can compute the comoving synchrotron emissivity of electrons behind the shock at the peak of their spectrum (from e.g. van Eerten et al. 2012, with the modification described in Sironi & Giannios 2013 to account for the “deep Newtonian” regime):

$$j'_{\nu, \text{max}} \approx 0.66 \frac{q_e^3}{m_e^2 c^4} \frac{p-2}{3p-1} \frac{B \epsilon_e e}{\gamma_m}, \quad (10)$$

where q_e is the electron charge. We then write $I_\nu(\nu) = \delta^3 \Delta R' j'_{\nu, \text{max}} \Sigma(\nu/\delta)$, where $\Sigma(\nu')$ is the normalized spectral shape, which can be approximated by a series of power laws (we implement all spectral orderings as listed in Granot & Sari 2002). The power-law branches connect at the break frequencies ν_m , ν_c , ν_a , and ν_{ac} defined as follows: ν_m is the synchrotron frequency corresponding to the injection Lorentz factor, namely $\nu_m = \gamma_m^2 q_e B / 2\pi m_e c$. Similarly, ν_c is the synchrotron frequency corresponding to the Lorentz factor γ_c above which electrons cool faster than the expansion dynamical timescale (i.e. the timescale over which new electrons are accelerated and injected into the shocked region – Sari et al. 1998), namely

$$\gamma_c = \frac{6\pi m_e c^2 \Gamma \beta}{\sigma_T B^2 R}, \quad (11)$$

where σ_T is the Thomson cross section. The frequencies ν_a and ν_{ac} are related to synchrotron self-absorption. In the slow-cooling regime ($\nu_m < \nu_c$), ν_a marks the frequency below which the emission is self-absorbed. We compute this frequency following Panaitescu & Kumar (2000). In the fast-cooling regime ($\nu_m > \nu_c$), an additional self-absorbed regime exists between ν_a and ν_{ac} , due to the inhomogeneous distribution of electrons at different cooling stages: we compute the latter frequency following Granot et al. (2000). All frequencies are computed in the

comoving frame, and then transformed to the observer frame according to $\nu = \delta \nu' / (1 + z)$. The slopes of the power law branches of $\Sigma(\nu')$ for all spectral orderings are given in Granot & Sari (2002).

3. Comparison with known SGRB afterglows

Fong et al. (2015) collected 103 short-duration GRBs with measured afterglow emission in the X-ray (71) UVOIR (30) and/or radio band (4). For a sub-sample of 32 events with well-sampled light curves, the modelling of their broadband emission with the standard afterglow model provided estimates of the isotropic-equivalent kinetic energy and circum-burst ISM density. In particular, 80–90% of these short GRBs show indications for a low-density ($n < 1 \text{ cm}^{-3}$) circum-burst environment with an average value of $n \sim (3-5) \times 10^{-3}$. Figure 1 shows the data points collected by Fong et al. (2015). The radio emission of SGRBs is detected only in a handful of events (Chandra & Frail 2012) and its different time evolution, with respect to the UVOIR and X-ray band emission, is typically due to self-absorption at relatively early times.

We compute the afterglow emission of a GRB 170817A-like structured jet model assuming the best-fit structure from Ghirlanda et al. (2019), defined by the angular distribution of kinetic energy density per unit solid angle

$$\frac{dE}{d\Omega}(\theta) = \frac{E_c/4\pi}{1 + (\theta/\theta_c)^{s_1}}, \quad (12)$$

and the angle-dependent initial bulk Lorentz factor

$$\Gamma(0, \theta) = 1 + \frac{\Gamma_c - 1}{1 + (\theta/\theta_c)^{s_2}}, \quad (13)$$

where θ is the angular distance from the jet axis. The best-fit parameter values are $\log(E_c/\text{erg}) = 52.4^{+0.6}_{-0.7}$, $s_1 = 5.5^{+1.3}_{-1.4}$, $\log(\Gamma_c) = 2.4^{+0.5}_{-0.4}$, $s_2 = 3.5^{+2.1}_{-1.7}$, and $\theta_c/\text{deg} = 3.4^{+1.0}_{-1.0}$ (one-sigma uncertainties). We use the central values to produce the light curves in Fig. 1. We place the jet at the median redshift ($z = 0.46$) and median ISM number density ($n = 5 \times 10^{-3} \text{ cm}^{-3}$) of the Fong et al. (2015) sample. The orange solid lines in the three panels of Fig. 1 represent the model afterglow light curves for an observer at $\theta_v = 15^\circ$, that is, the same viewing angle as GRB 170817A, while solid black lines are for an on-axis observer, and dashed black lines are for an observer just outside the core ($\theta_v = \theta_c$). Quite remarkably, the on-axis light curves fall right in the middle of the observed population. Intriguingly, some observed UVOIR and X-ray light curves show a decay slope more similar to that of the GRB 170817A-like jet seen just outside the core. This simple comparison provides a first hint that the GRB 170817A intrinsic jet properties could be representative of a quasi-universal structure, and that the diversity in the SGRB afterglows observed so far could be largely ascribed to extrinsic properties (i.e. redshift, ISM density, viewing angle). During the peer-review of this work, a preprint (Wu & MacFadyen 2019) was circulated, which reaches similar conclusions through a slightly different analysis, strengthening our results.

4. Comparison of prompt emission properties

4.1. The short GRB sample

The faintness of the afterglow emission of short GRBs hampers their prompt localisation and follow-up, thus limiting the possibility to measure their redshift. At present, such measurement

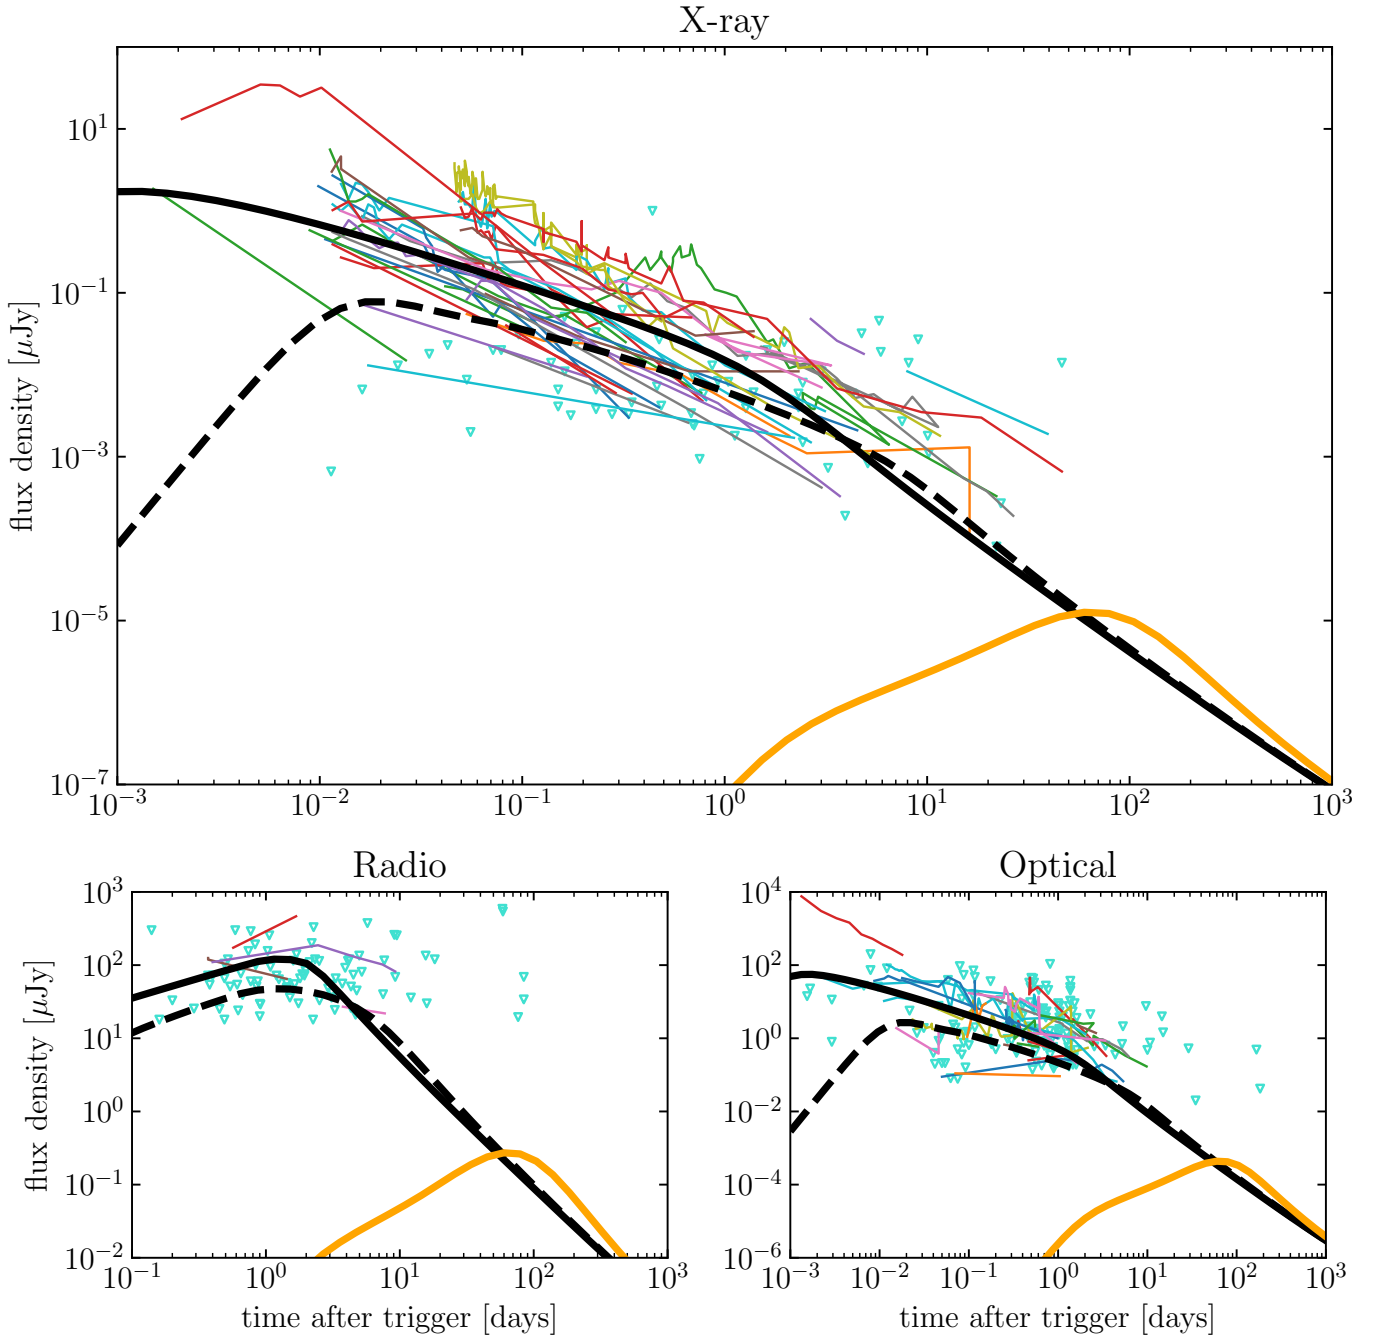

Fig. 1. Afterglow of a GRB 170817A-like jet compared to the archival SGRB data from [Fong et al. \(2015\)](#). The redshift and ISM density have been set equal to the medians of the [Fong et al. \(2015\)](#) sample, namely $z = 0.46$ and $n = 5 \times 10^{-3} \text{ cm}^{-3}$. Each panel shows data from a different frequency range: radio ($1.4 \leq \nu/\text{GHz} \leq 93$, bottom left-hand panel), UVOIR (mostly r filter $\approx 4.8 \times 10^{14} \text{ Hz}$, bottom right-hand panel), and X-ray ($1 \text{ keV} \approx 2.4 \times 10^{17} \text{ Hz}$, top panel). Upper limits are shown by empty turquoise downward triangles, while detections are shown by thin lines of different colours, each connecting data from a single SGRB. In each panel, thick solid black lines represent the GRB 170817-like jet light curve as seen on-axis, dashed black lines show the light curve for an observer at the border of the core, while solid orange lines show the light curve for viewing angle $\theta_v = 15^\circ$ which corresponds to the best-fit value for GRB 1708017A as given in [Ghirlanda et al. \(2019\)](#). The model light curves are computed for observer frequencies $\nu_{\text{obs}} = 6 \text{ GHz}$ (radio), $4.8 \times 10^{14} \text{ Hz}$ (optical) and $2.4 \times 10^{17} \text{ Hz}$ (X-ray).

has only been successful for a few dozen events. [D’Avanzo et al. \(2014\)](#) collected a small flux-limited sample of SGRBs detected by *Swift* under observing conditions favourable for the redshift measurement. The sample contains 36 SGRBs detected as of 2013 and has a redshift completeness of 45% which increases to 70% if only the 13 brightest short GRBs are considered. For the purposes of this work we expand this sample including a number of SGRBs with measured redshift; some of which how-

ever do not satisfy the selection criteria to be included in the complete sample of [D’Avanzo et al. \(2014\)](#). In order to compute their isotropic equivalent energy E_{iso} , we require the νF_ν peak energy of their prompt emission spectrum (E_p) to be measured. We therefore add ten new SGRBs to the sub-sample of the 13 brightest SGRBs of [D’Avanzo et al. \(2014\)](#). The redshift, peak energy and isotropic equivalent energy of the entire sample are reported in Table 1.

The lowest redshift in this sample is 0.122 (GRB 080905A) and the isotropic equivalent energies range from a few 10^{49} ergs to $\sim 10^{53}$ ergs. The νF_ν peak energies range from 100 keV to a few MeV (see also Ghirlanda et al. 2009).

In long GRBs the prompt emission peak energy E_p and the isotropic equivalent energy E_{iso} or isotropic equivalent luminosity L_{iso} are correlated (Yonetoku et al. 2004; Amati et al. 2002). Short GRBs seem to follow an $E_p - E_{\text{iso}}$ correlation similar to that of long events, but slightly displaced towards lower values of E_{iso} (D’Avanzo et al. 2014). This could be ascribed to the different durations and spectral evolution of long and short GRBs (Calderone et al. 2015; Ghirlanda et al. 2015). Fitting a relation $\log(E_p/100 \text{ keV}) = K + \alpha \log(E_{\text{iso}}/10^{52} \text{ erg})$ to the sample of short GRBs reported in Table 1, the parameters are $K = 0.95 \pm 0.07$ and $\alpha = 0.48 \pm 0.06$ (1σ errors).

While all GRBs in our sample are of short duration, this does not guarantee that their progenitor is a binary neutron star merger. Even though the duration distribution of GRBs is clearly bimodal (Kouveliotou et al. 1993), the two populations overlap significantly. The duration division line (customarily taken at $T_{90} = 2$ s), moreover, is detector-dependent (Bromberg et al. 2012). A more accurate classification needs to account also for the host galaxy properties, the location of the burst within the galaxy, the possibility to firmly rule out an associated supernova, and the statistical comparison of the prompt and afterglow properties of the burst with those of the reference population. Zhang et al. (2009; hereafter Z09) carried out an accurate analysis of all these properties for a sample of putative SGRBs with measured redshift, finding that only a small subset of them (which they dubbed “Type I Gold Sample”) could be securely classified as originating from a double neutron star merger (we marked these bursts with a (a) superscript in our Table 1, and with a cyan circle in Fig. 2). Following a different approach, namely modelling the probability distribution of GRBs in the hardness–duration plane, Bromberg et al. (2013, B13 hereafter) proposed a way to estimate the probability f_{NC} that a given GRB is of non-collapsar origin. We mark the bursts with $f_{\text{NC}} \geq 0.5$, as given in B13, with a (b) superscript in our Table 1, and with a green square in our Fig. 2.

4.2. Computation of the viewing-angle-dependent prompt emission

We here attempt a comparison of the putative on-axis prompt emission properties of our GRB 170817A-like jet with the sample described in the preceding section. While there is a broad consensus within the community over the interpretation of GRB afterglows as being due to synchrotron emission from non-thermal electrons accelerated at the external shock caused by the jet expansion in the surrounding medium (Meszaros & Rees 1993), the prompt emission mechanism remains elusive. The most common scenarios require partial conversion of the jet kinetic (e.g. through internal shocks – Rees & Meszaros 1994) or magnetic (e.g. through reconnection – Thompson 1994; Spruit et al. 2001) energy to internal energy (typically in the form of a non-thermal population of electrons), which is then radiated in the γ -ray band through synchrotron, inverse Compton, or both (Zhang 2014). Regardless of the details of the emission process, several studies seem to indicate that the radiated energy typically amounts to ~ 10 – 20% of the jet kinetic energy (usually estimated by comparing the prompt E_{iso} with the jet kinetic energy derived from modelling the afterglow, as in for example Fong et al. 2015; Beniamini et al. 2016). We thus assume that a fraction $\epsilon = 0.2$ of the kinetic energy in each jet solid angle element is radiated away

Table 1. Short GRB rest-frame energetics and prompt emission peak energy.

Notes. GRB 090426 and 100816 (in italics) are suspected long GRBs (see discussion in D14). ^(a)Belongs to the Type I Gold Sample of Z09. ^(b)Has $f_{\text{NC}} \geq 0.5$ in the sample of B13.

in the form of high-energy photons, while $(1 - \epsilon)$ remains in the form of kinetic energy that powers the afterglow. We assume the comoving emission to be isotropic, with an angle-independent comoving spectrum, so that the radiated energy per unit solid angle, per unit frequency, at observer frequency ν is given by

$$\frac{dE_\gamma}{d\Omega d\nu}(\theta, \nu, \theta_\nu) = \eta \frac{\delta^2(\theta, \phi, \theta_\nu)}{\Gamma(\theta)} \frac{dE}{d\Omega}(\theta) S((1+z)\nu/\delta), \quad (14)$$

where $\eta = \epsilon/(1 - \epsilon)$ and the comoving spectral shape $S(\nu')$ is normalised so that $\int_0^\infty S(\nu') d\nu' = 1$ (primed quantities are in the jet comoving frame). We assume a cut-off power-law comoving spectral shape, namely

$$S(\nu') \propto \nu'^a \exp[-(1+a)\nu'/\nu'_p]. \quad (15)$$

With these assumptions, we can compute the prompt emission isotropic-equivalent energy $E_{\text{iso}}(\theta_\nu)$ and the spectral energy distribution (SED) peak energy $E_p(\theta_\nu)$ as measured by observers at different viewing angles, following Salafia et al. (2015), that is,

$$\begin{aligned} E_{\text{iso}}(\theta_\nu) &= \int_0^1 d \cos \theta \int_0^{2\pi} d\phi \int_0^\infty d\nu \frac{dE_\gamma}{d\Omega d\nu} \\ &= \int_0^1 d \cos \theta \int_0^{2\pi} d\phi \eta \frac{\delta^3(\theta, \phi, \theta_\nu)}{\Gamma(\theta)} \frac{dE}{d\Omega}(\theta), \end{aligned} \quad (16)$$

Fig. 2. Possible prompt emission of a GRB 170817A-like jet compared to archival SGRB data. The *bottom and right-hand panels* show respectively the isotropic-equivalent energy $E_{\text{iso}}(\theta_v)$ and the rest-frame SED peak photon energy $E_p(\theta_v)$ as functions of the viewing angle θ_v (red solid lines) for the best-fit jet structure of Ghirlanda et al. (2019), along with their uncertainty regions (1σ – orange; 2σ – yellow). In the top-left panel, the red solid line shows the corresponding track and uncertainty regions on the (E_{iso}, E_p) plane. The plots are joined to ease the determination of the viewing angle that corresponds to a given point on the (E_{iso}, E_p) track. The blue cross shows the observed properties of GRB 170817A, while black crosses show the SGRBs from our sample (Sect. 4.1). Cyan circles mark bursts which belong to the Type I Gold Sample in Z09, while green squares mark bursts that have $f_{\text{NC}} \geq 0.5$ in the analysis of B13.

and

$$E_p(\theta_v) = h \times \text{argmax} \left(\nu \frac{dE_\gamma}{d\nu} \right), \quad (17)$$

where h is Planck's constant, and

$$\frac{dE_\gamma}{d\nu} = \int_0^1 d \cos \theta \int_0^{2\pi} d\phi \frac{dE_\gamma}{d\Omega d\nu}. \quad (18)$$

Let us note that the comoving spectral shape $S(\nu')$ is needed only to compute the dependence of the SED peak energy E_p on

the viewing angle, so its detailed shape is unimportant. We set the comoving peak photon energy to $h\nu'_p = 3$ keV and the low-energy spectral index to $a = 0.3$, which is typical for observed spectra of SGRB (Nava et al. 2011). The result is shown in Fig. 2, where red solid lines refer to the central values of the best-fit parameters, while the shaded regions stem from the uncertainty in the jet model parameters from Ghirlanda et al. (2019). The regions are constructed by randomly selecting 1000 posterior samples from the Markov chain Monte Carlo of Ghirlanda et al. (2019) and computing the corresponding $E_{\text{iso}}(\theta_v)$ and $E_p(\theta_v)$.

The shaded regions in Fig. 2 show the areas containing the 68% (labelled “ 1σ ”) and 95% (labelled “ 2σ ”) of the resulting curves.

The predicted energy and SED peak for an on-axis observer (top-right end of the red curve in the upper panel of Fig. 2) fall right in the middle of the known population (represented by black crosses in Fig. 2), and the lower-energy SGRBs in our comparison sample seem to follow the curve that connects E_{iso} and E_p as seen by observers at different viewing angles. This is reminiscent of previous results (Salafia et al. 2015) that showed that the Amati correlation (Amati et al. 2002) can be interpreted as a viewing-angle effect in the quasi-universal structured jet scenario. The highest E_{iso} and E_p in the sample are about an order of magnitude larger, but they are still consistent with the one-sigma uncertainty in the structure, and they can easily be accommodated if some scatter in the quasi-universal structure properties is allowed. The values of E_{iso} and E_p predicted by our simple model for an observer at 15-20 degrees (i.e. the inferred viewing angle of GRB 170817A – Ghirlanda et al. 2019; Mooley et al. 2018) on the other hand, are not consistent with the observations of GRB 170817A. In particular, the predicted E_{iso} is too high, while E_p is too low.

Let us note nevertheless, that our simplifying assumption of angle-independent efficiency and comoving spectrum is probably not realistic: most popular prompt emission scenarios – dissipation of jet energy by internal shocks (Rees & Meszaros 1994) or magnetic reconnection (e.g. Zhang & Yan 2011; Lazarian et al. 2003), happening either above or below (Rees & Mészáros 2005) the photosphere, followed by emission by synchrotron (Ghisellini et al. 2000; Rivasio et al. 2018; Oganesyan et al. 2019) or photospheric radiation – lead to some dependence of the typical photon energy on the jet luminosity and magnetisation (for a comprehensive discussion, see Zhang & Mészáros 2002).

Indeed, while the discrepancy in E_{iso} can be alleviated by introducing a steepening of the kinetic energy structure at large angles, for example by assuming a Gaussian structure instead of a power-law one (Gaussian structures have been successfully used in fitting the GRB 170817A afterglow light curves – see e.g. Troja et al. 2018a; Hotokezaka et al. 2018 – and are compatible with the results of Ghirlanda et al. 2019, as shown in their Fig. S6), a possibly more natural approach would be to assume an angle-dependent efficiency $\epsilon = \epsilon(\theta)$ that decreases away from the jet axis. This might be easily justified in both the internal shock scenario (since the wings are slower on average, implying a necessarily lower contrast in relative Lorentz factors between subsequent ejection episodes) and in the magnetic reconnection scenario (where magnetisation in the wings could be lower due to entrainment of ambient material as the jet punches out of the merger ejecta). Let us note that a low prompt emission efficiency at large angles is supported by several observational arguments also in long GRBs (Beniamini & Nakar 2019), and that it may be a requirement to explain the SGRB luminosity function within the structured jet scenario (Beniamini et al. 2019). A lower magnetic field and/or a lower emission efficiency at large angles would also imply a less effective electron cooling: this in turn would lead the comoving typical photon energy $h\nu'_p$ to increase with the angular distance from the jet axis, thus also solving the underprediction of E_p (see e.g. Ioka & Nakamura 2019 – which circulated in pre-print form during the preparation of this work – where the authors indeed assume the comoving peak photon energy to increase away from the jet axis in order to reproduce the observed quantities). An anti-correlation between the source luminosity and the peak of its SED is already seen in Blazars, where it can be explained in a similar manner (Ghisellini et al. 1998, 2017).

Alternatively, the process that produced the GRB 170817A prompt emission could be different from that of its on-axis siblings. A possible candidate could be emission associated to the cocoon shock breakout (see e.g. Kasliwal et al. 2017; Gottlieb et al. 2018), which may dominate only for off-axis observers.

5. Discussion

5.1. Plausibility of a quasi-universal jet structure in SGRBs

The possibility of a quasi-universal jet structure in SGRBs is directly related to the degree of diversity in their progenitors. If neutron star binaries are the main progenitors of SGRBs, and if their component masses are narrowly distributed around typical values, then the merger outcome will be similar in most cases, thus leading to similar jets. On the other hand, relatively small variations in the component masses could lead to qualitatively different outcomes, such as different merger remnants (a black hole, a meta-stable proto-neutron star, a stable neutron star – e.g. Bartos et al. 2013), each potentially leading to very different jet properties. Still, it may be the case that a GRB jet is produced only if certain conditions are met, for example not in the case of a direct collapse to a black hole nor in the case of a long-lived neutron star: this would again narrow down the range of properties of SGRB progenitors. The existence of a quasi-universal jet structure could be unveiled by joint detections of SGRBs and GWs during the next decade (Beniamini et al. 2019), and would provide powerful insight into their progenitors.

5.2. How likely is the detection of an associated kilonova if the jet is observed on-axis?

Several possible detections of kilonovae associated to known cosmological SGRBs have been claimed in the literature: GRB 130603B (Tanvir et al. 2013; Berger et al. 2013), GRB 050709 (Jin et al. 2016), GRB 060614 (Jin et al. 2015; Yang et al. 2015) and GRB 150101B (Troja et al. 2018b; Rossi et al. 2019)³. Ascenzi et al. (2019) constructed a distribution of the peak absolute magnitude and peak time of kilonovae under the assumption that all these claims are correct, and using other non-detections as upper limits.

Within the assumption of a quasi-universal structure, it is interesting to ask how often we should expect such a detection to be possible, given that the properties of the SGRB afterglow depend mainly on the extrinsic parameters. Since the KN and the GRB jet are located at the same distance, the only relevant extrinsic parameters are the viewing angle and the ISM density. For the usual SGRBs at cosmological distances the former is necessarily $\theta_v \lesssim \theta_c$. The latter, on the other hand, can vary by orders of magnitude, and is therefore the dominant parameter for what concerns the SGRB.

The kilonova emission is unaffected by the ISM density, and is also not affected significantly by relativistic beaming, given the small velocities involved ($\lesssim 0.1c$). Viewing-angle effects on the light curve could arise due to projection effects and to different optical depths to be crossed by photons emitted at different angles (e.g. Wollaeger et al. 2018). These effects are still a matter of debate, but they are expected to be small. For this reason, we take AT2017gfo as representative of a typical SGRB-associated kilonova seen on-axis, and we consider the distributions by Ascenzi et al. (2019) as an estimate of the range of

³ Recently Rossi et al. (2019) found further possible kilonova candidates in association with several other GRBs.

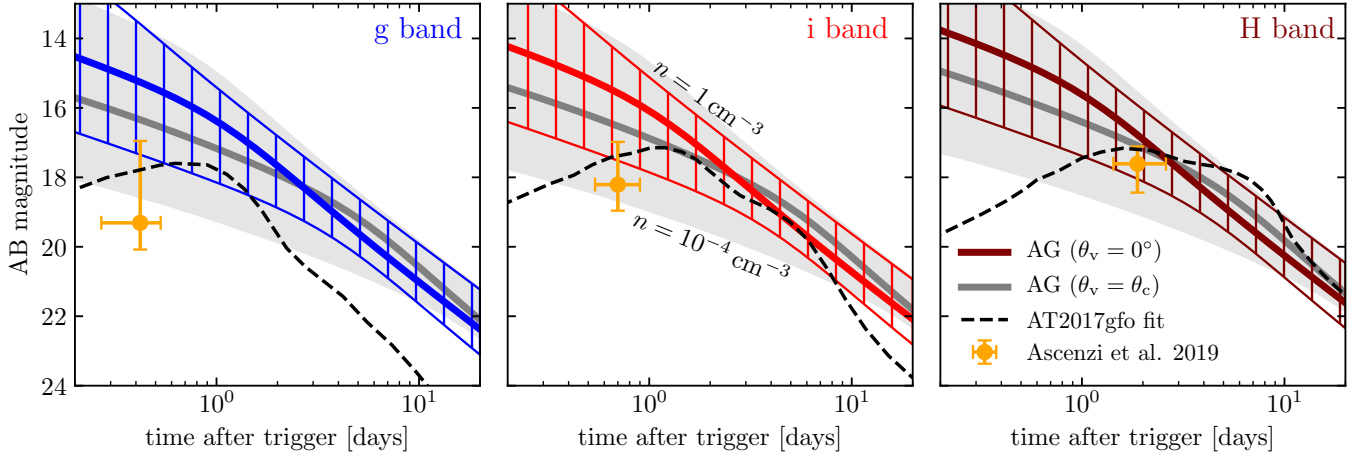

Fig. 3. Comparison of the on-axis afterglow of a GRB 170817A-like jet with an AT2017gfo-like kilonova. Each panel shows light curves in a different band, as indicated in the upper right corner. Solid coloured lines represent the on-axis ($\theta_v = 0^\circ$) jet afterglow (with best-fit parameters and $n = 5 \times 10^{-3} \text{ cm}^{-3}$), with the hatched region showing the portion of the plane span when assuming ISM densities between $n = 10^{-4} \text{ cm}^{-3}$ and $n = 1 \text{ cm}^{-3}$. Grey solid lines and the grey shaded region show the same information for a jet seen at the core border ($\theta_v = \theta_c$). Black dashed lines show the AT2017gfo kilonova best-fitting model from Villar et al. (2017). The orange points show the median kilonova peak magnitudes and peak times in the three bands, as inferred by Ascenzi et al. (2019) and the error bars enclose 68% of the events according to their distributions.

variability of SGRB-kilonovae in general. We compute the afterglow light curves of our GRB 170817A-like jet as seen on-axis and just outside the core, varying the ISM number density between 10^{-4} cm^{-3} and 1 cm^{-3} , and keeping the luminosity distance fixed at $d_L = 40 \text{ Mpc}$. The resulting afterglows span the hatched (on-axis jet) and grey shaded (off-core jet) regions in Fig. 3 when observed in the *g*, *i*, and *H* bands. In each panel of the figure, we also plot the AT2017gfo best-fitting model from Villar et al. 2017 (dashed black lines) and the medians of the distributions of peak times and peak magnitudes from Ascenzi et al. 2019 (orange dots), where the error bars show the 1σ scatter. This simple comparison suggests that (in the quasi-universal jet hypothesis) an on-axis SGRB afterglow most often outshines the typical kilonova in the bluer bands, unless the progenitor neutron star merger takes place in a very low ISM density region. Infrared observations at a few days post-trigger may be the most favourable option when looking for a kilonova signature associated to an SGRB afterglow. This is consistent with the fact that the first and most solid claim of such a detection (in GRB 130613B, Tanvir et al. 2013) is indeed due to an excess in the light curve at $\sim 9 \text{ d}$ as seen in the WFC3/F160W filter of HST, whose central wavelength is $\sim 1500 \text{ nm}$, that is, close to the H band.

6. Conclusions

Despite more than sixty years of observations and theoretical work, several questions about gamma-ray bursts remain unanswered. The diversity in their population in terms of energy, luminosity, duration, variability, and afterglow decay rate seems to contradict the narrow range of properties expected from their progenitors – either neutron star mergers or pre-collapse Wolf-Rayet stars. Starting about twenty years ago, several authors (the first possibly being Lipunov et al. 2001; Rossi et al. 2002; Zhang & Mészáros 2002) suggested the possibility to trace back this diversity to the jet viewing angle, as in the unification scheme of active galactic nuclei (Urry & Padovani 1995).

Our results, summarised in Figs. 1 and 2, show that GRB 170817A would appear as a standard SGRB if seen on-axis, providing support to this scenario. The population of SGRB jets observed off-axis will soon increase in number, as the sensitivity of gravitational wave interferometers improves. We expect a large diversity in their properties, but due to extrinsic parameters only, such as the viewing angle and circum-merger medium density.

Acknowledgements. We thank the anonymous referee for insightful comments which helped to improve the manuscript.
