Abstract

Since its launch, the Alpha Magnetic Spectrometer-02 (AMS-02) has delivered outstanding quality measurements of the spectra of cosmic-ray (CR) species, e^\pm , \bar{p} , and nuclei (H–Si, S, Fe), which have resulted in a number of breakthroughs. Besides elemental spectra, AMS-02 also measures the spectra of light isotopes albeit within a smaller rigidity range. In this paper, we use the precise measurements of He isotopes and the $^3\text{He}/^4\text{He}$ ratio by AMS-02, together with Voyager 1 data, and investigate their origin. We show that there is an excess in ^3He at higher energies compared to standard calculations assuming its fully secondary origin, which may indicate a source of primary ^3He , or signify a change in the propagation parameters over the Galactic volume probed by the $^3\text{He}/^4\text{He}$ ratio. We provide updated local interstellar spectra (LIS) of ^3He and ^4He in the rigidity range from 2 to 40 GV. Our calculations employ the self-consistent GALPROP–HELMOD framework that has proved to be a reliable tool in deriving the LIS of CR e^\pm , \bar{p} , and nuclei $Z \leq 28$.

1. Introduction

Precise data at low and high energies delivered by modern space instrumentation have triggered a number of discoveries of new features in the spectra of cosmic-ray (CR) species. The combined data from individual experiments covers an enormous range of rigidities, from a few MV to tens of TV, where the individual spectra of CR species are shaped by many different processes. These data enable the probing of the stellar nucleosynthesis, properties of the interstellar medium (ISM), and the origin of CRs.

The AMS-02 collaboration has now completed a series of papers on CR species H–Si, S, and Fe (M. Aguilar et al. 2021a, 2021b, 2021c, 2021d, 2023). Besides the elemental spectra, AMS-02 also measures the spectra of light isotopes, albeit in a smaller rigidity range. In this paper, we use precise measurements of He isotopes and the $^3\text{He}/^4\text{He}$ ratio by AMS-02 (M. Aguilar et al. 2019), together with Voyager 1 data, to test their origin. We also provide new and updated ^3He and ^4He local interstellar spectra (LIS) in the rigidity range from 2 to 40 GV. Our calculations and interpretation employ the GALPROP⁹–HELMOD¹⁰ framework, which has proven to be a reliable tool

for modeling the LIS of CR species (M. J. Boschini et al. 2019, 2020a).

2. Calculations

In this work we employ the same CR propagation model phenomenology with distributed reacceleration and convection from our previous analyses (for more details see M. J. Boschini et al. 2017, 2018a, 2018b, 2020a, 2020b, 2021, 2022), but use the latest version 57.1 of the GALPROP code for Galactic propagation of CRs and diffuse emissions as described in detail by T. A. Porter et al. (2022); see also M. J. Boschini et al. (2020a), and references therein. This GALPROP release also includes new and improved parameterizations for calculations of the total inelastic cross sections for $p + A$ and $\text{He} + A$ reactions, together with new routines for the production cross sections for isotopes of hydrogen $^2,^3\text{H}$ and helium $^3,^4\text{He}$ in $p + A$ and $\text{He} + A$ reactions, as well as ^2H production in the pp -fusion reaction. Therefore, the accuracy of calculations of production and propagation of isotopes of helium is significantly improved compared to earlier GALPROP releases. These cross sections are the best available so far.

Full details of the HELMOD code version 4 for heliospheric propagation are provided by M. J. Boschini et al. (2019). It solves the Fokker–Planck equation for heliospheric propagation in Kolmogorov formulation backward in time (P. Bobik et al. 2016). The last version of the code was presented in M. Boschini et al. (2024) where the computational algorithm is redesigned to work on GPU architecture. Moreover, in M. Boschini et al. (2024), HELMOD parameters are revisited using the updated daily proton flux measured by AMS-02 (M. Aguilar et al. 2021d) and focusing on the descending phase of solar cycle 24, i.e.,

Table 1
Best-fit Propagation Parameters for the Standard and Alternative Models

Parameter	Units	Model	
		Standard	Alternative
z_h	kpc	4.0 ± 0.6	4.0 (fixed)
$D_0(R = 4 \text{ GV})$	$10^{28} \text{ cm}^2 \text{ s}^{-1}$	4.3 ± 0.7	5.9 ± 1.0
δ	...	0.415 ± 0.025	0.19 ± 0.06
V_{Alf}	km s^{-1}	30 ± 3	27.3 ± 5
dV_{conv}/dz	$\text{km s}^{-1} \text{ kpc}^{-1}$	9.8 ± 0.8	2 ± 2
η	...	0.70	1.2

from ~ 2015 to 2020. The updates are motivated by the latest high-precision measurements from the AMS-02 detector, which revealed for the first time the fine features of GCR fluxes' evolution during a period of positive interplanetary magnetic field polarity. The accuracy of the solution was tested in P. Bobik et al. (2016) using the Crank–Nicholson technique and found to be better than 0.5% at low rigidities. In M. Boschini et al. (2024) we demonstrate that the uncertainties of the numerical solution decrease with increasing energy and are lower than the equivalent Poisson uncertainties evaluated using the number of simulated Monte Carlo events. The large number of simulated events (>5000) ensures that the statistical errors are negligible compared to the other modeling uncertainties.

When comparing our calculations with data collected over an extended period of time, variations in solar activity are addressed in the following way. The propagation equation is solved for each Carrington rotation, and the numerical results are then combined with the instrument exposure over the appropriate time period. This approach is equivalent to using a weighted average that accounts for both exposure time and absolute counting rate variations.

The CR propagation model parameters in the ISM, along with their confidence limits, are derived from the best available CR data for all species H–Ni, and all rigidities from a few MV to TV range using a Markov Chain Monte Carlo (MCMC) routine. We use the same method as described by M. J. Boschini et al. (2017). The five main propagation parameters that affect the overall shape of CR spectra were left free in the scan, using GALPROP running in 2D mode: the Galactic halo half-width z_h , the normalization of the diffusion coefficient D_0 at the reference rigidity $R = 4 \text{ GV}$ and the index of its rigidity dependence δ , the Alfvén velocity V_{Alf} , and the gradient of the convection velocity dV_{conv}/dz ($V_{\text{conv}} = 0$ in the plane, $z = 0$). Their best-fit values tuned to the AMS-02 data are listed in Table 1 (labeled as the “standard model”) and are the same as those obtained by M. J. Boschini et al. (2020a). The radial size of the Galaxy does not significantly affect the values of these parameters and was set to 20 kpc. We also introduced a factor β^η in the diffusion coefficient, where $\beta = v/c$ is the particle velocity in units of the speed of light, and η was left free. The latter improves the agreement at low energies and slightly affects the choice of injection indices γ_0 and γ_1 .

The corresponding B/C ratio also remains the same (see Figure 4 of M. J. Boschini et al. 2020a), and compares well with all available measurements: Voyager 1 (A. C. Cummings et al. 2016), ACE-CRIS¹¹ (K. A. Lave et al. 2013), AMS-02 (M. Aguilar et al. 2018), ATIC-2 (A. D. Panov et al. 2009), CREAM (H. S. Ahn et al. 2008, 2009), and NUCLEON

(V. Grebenyuk et al. 2019). The particular choice of the production cross-section parameterization has a minor effect on the derived propagation parameters given that they are all reproducing the available experimental data (for more details see M. J. Boschini et al. 2020a).

For the calculations, we use our standard configuration. The convection velocity is assumed to increase linearly with distance z from the plane, $V_{\text{conv}}(z) = V_0 + z \cdot dV_{\text{conv}}/dz$. The spatial diffusion coefficient is parameterized as $D_{xx} = \beta^\eta D_0 R^\delta$. If reacceleration is included, the momentum-space diffusion coefficient D_{pp} is related to D_{xx} as $D_{pp} = p^2 V_{\text{Alf}}^2 / (9D_{xx})$ (V. S. Berezhinskii et al. 1990; E. S. Seo & V. S. Ptuskin 1994). See also a review by A. W. Strong et al. (2007) and our papers cited at the beginning of this section.

The injection spectra of CR species are parameterized as:

$$q(R) \propto (R/R_0)^{-\gamma_0} \prod_{i=0}^2 [1 + (R/R_i)^{\frac{\gamma_i - \gamma_{i+1}}{s_i}}]^{s_i}, \quad (1)$$

where R is the rigidity, $\gamma_{i=0,1,2,3}$ are the spectral indices, $R_{i=0,1,2}$ are the break rigidities, s_i are the smoothing parameters (s_i is negative/positive for $|\gamma_i| \leq |\gamma_{i+1}|$). The source abundance of each species is defined as the number of injected particles in the energy range from 100 MeV/n to 100 GeV/n normalized to hydrogen ($H = 10^6$).

Note that the breaks in the injection spectrum are phenomenological to provide the agreement with CR measurements at 1 au. Here is our justification (I. V. Moskalenko 2023): While the supernova remnants (SNRs) are widely recognized as the main sources of CRs, the isotopic and spectral anomalies observed recently force us to look at other sources, especially local, which can also contribute to the observed CRs. These are primarily Wolf–Rayet stars (currently 354 are known) and O-stars (20,000 observed), which over their fairly short lifetimes provide, respectively, 10^{51} erg and 10^{50} erg in high-velocity winds reaching $(2-4) \times 10^3 \text{ km s}^{-1}$, pulsars (~ 1500 observed) with their total rotating power reaching 4×10^{49} erg (Crab), and novae providing 10^{45} erg (estimated frequency 30–50 yr⁻¹, ~ 350 observed). For comparison, countless stellar flares can provide up to 10^{36} erg each, and can also add to low-energy CRs. Therefore, there is no reasonable way to derive the injection spectrum from the first principles, especially at low rigidities.

3. Results and Discussion

The standard model results using the propagation parameters from Table 1 are shown in Figures 1 and 2 (left). The calculated spectra of total He and ⁴He reproduce the data quite well. Meanwhile, the difference between the PAMELA (W. Menn et al. 2016) and AMS-02 (M. Aguilar et al. 2019) data for ⁴He and ³He fluxes in the overlapping region *increases* with rigidity, while the solar modulation effect *decreases* with rigidity—the modulated spectra for appropriate modulation levels are shown by the solid red lines. This indicates possible systematic issues with the highest rigidity data points (2–3 GV) by PAMELA, which is a much smaller instrument than AMS-02.¹²

¹² The AMS-02 experiment uses modern technology, it has a stronger magnet, its response was thoroughly simulated and tested, and it also has several independent systems that allow for data cross-checks. Besides, the significantly larger acceptance area of AMS-02 and much longer exposure provide incomparable statistical accuracy. In turn, the large statistics combined with several detection systems, which can be used independently for cross-checks, improve the rejection power of the instrument and its accuracy.

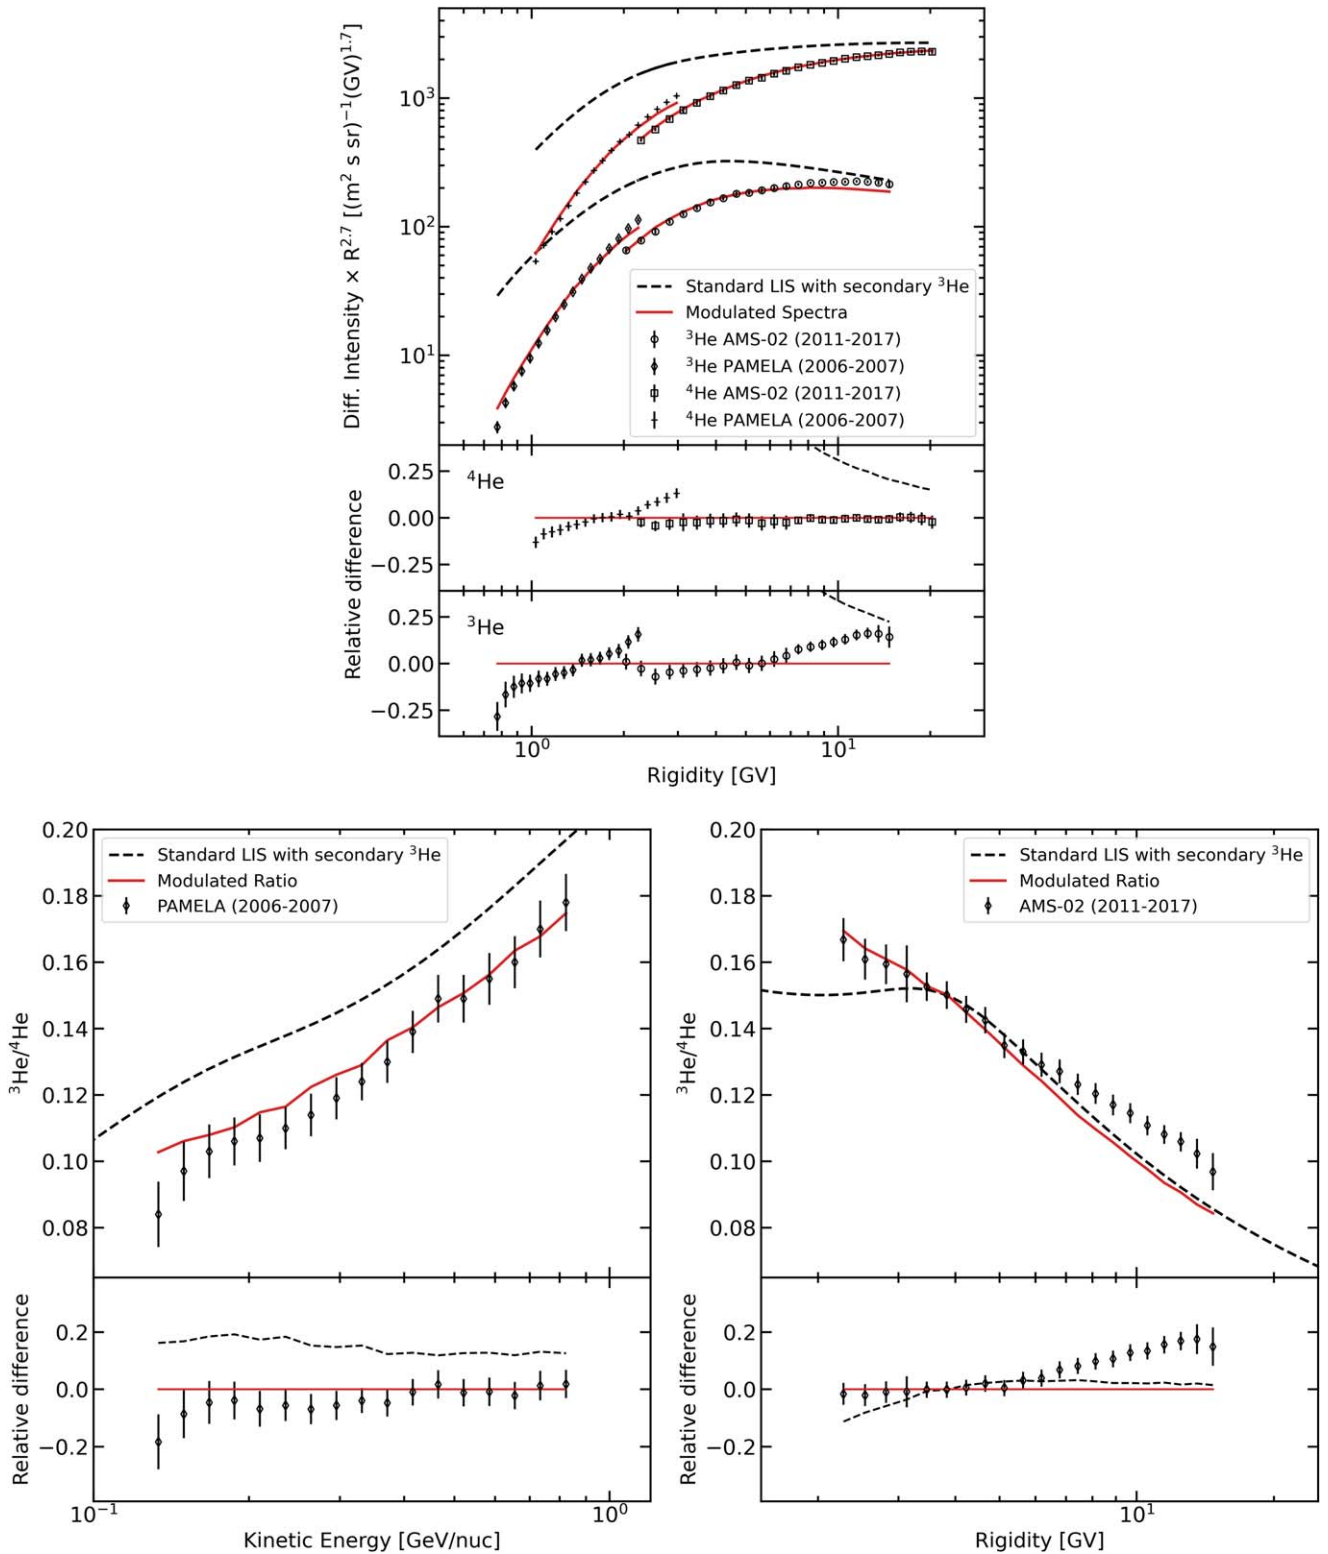

Figure 1. Comparison of the standard calculations with fully secondary ${}^3\text{He}$ with data. The upper panel shows a comparison of the calculated ${}^3\text{He}$ spectra with PAMELA (W. Menn et al. 2016) and AMS-02 (M. Aguilar et al. 2019) data. The dashed black lines show the LIS, and the solid red lines—the corresponding modulated spectra. The lower panels show a comparison of the ${}^3\text{He}/{}^4\text{He}$ ratio with PAMELA and AMS-02 data. Note the different units in the PAMELA and AMS-02 plots. The relative differences between our calculations and the data sets are shown in the bottom part of each panel.

At the same time, the predicted spectrum of ${}^3\text{He}$ in the standard calculation (Table 2; see also M. J. Boschini et al. 2020a) exhibits a significant excess above 7 GV. This may be an indication of the presence of an additional source of these

particles besides the fully secondary ${}^3\text{He}$ produced in fragmentations of $Z \geq 2$ nuclei or something else.

We see three possibilities that may be responsible for the observed ${}^3\text{He}$ excess: (i) the accuracy of the He production and

Figure 2. Left panel: comparison of the standard calculations with fully secondary ^3He with Voyager data (A. C. Cummings et al. 2016; W. R. Webber et al. 2018; E. C. Stone et al. 2019). The same model as in Figure 1, but shows a comparison of the total He spectrum, and isotopes ^3He with Voyager 1, 2 data. Right panel: model with primary ^3He . The primary ^3He component is shown by the blue solid line, while the solid red line shows the secondary component. The thick dashed black line is the total ^3He . The contribution of the primary ^3He component is negligible below $\approx 5 \text{ GeV/n}$.

Table 2
Injection Spectra of Primary $^3,^4\text{He}$ Isotopes

Model	Source Abundance	Spectral Parameters													
		γ_0	R_0 (GV)	s_0	γ_1	R_1 (GV)	s_1	γ_2	R_2 (GV)	s_2	γ_3	R_3 (GV)	s_3	γ_4	
^4He	standard	1.026×10^5	2.10	1.0	0.20	1.81	7.5	0.30	2.41	340	0.13	2.12	30000	0.10	2.37
^3He (prim.)	standard	295	0.50	8.5	0.29	1.0	12	0.20	2.41
^4He	alternative	1.60×10^5	2.05	1.0	0.26	1.85	7.5	0.27	2.51	350	0.17	2.14	30000	0.10	2.37

Note. The ^3He (prim.) row shows the injection spectrum for a primary ^3He component (see Section 3.2). The source abundances are relative (see Table 3 in M. J. Boschini et al. 2020a). For parameter definitions see Equation (1). Shown are $|s_i|$ values, note that s_i is negative/positive for $|\gamma_i| \leq |\gamma_{i+1}|$.

fragmentation cross sections, (ii) the primary ^3He component with a harder injection spectrum, and (iii) a nonuniform propagation probed on different spatial scales by light isotopes ($^3,^4\text{He}$) and heavier species (e.g., the B/C ratio). Below we discuss these possibilities in detail.

3.1. The Accuracy of Cross Sections Hypothesis

The accuracy of the ^3He production and nuclear fragmentations cross sections were significantly improved in the latest version of GALPROP. Moreover, the basic energy (rigidity) dependence of the relevant cross sections and of the discussed ^3He excess provide an additional argument against this hypothesis.

A fundamental property of the production and fragmentation cross sections is their energy independence above $\sim 1-2 \text{ GeV/n}$. One can see the examples of the total fragmentation cross sections of different isotopes in T. A. Porter et al. (2022) in Figures 10 and 11. Examples of the ^3He production cross sections in reactions with ^4He and heavier species can be seen in Figures 12 and 15 of the same paper. Although some of the mentioned plots lack data points in the relevant energy range, the

proposed approximations are consistent with a number of other cross-section measurements.

For the flat cross sections, the slope of the $^3\text{He}/^4\text{He}$ ratio depends only on the power-law index of the diffusion coefficient and the Alfvén speed. The latter makes the slope of the $^3\text{He}/^4\text{He}$ ratio (2–20 GV) somewhat steeper than it is dictated by the rigidity dependence of the diffusion coefficient (Figure 1, lower right panel), while the effect of the solar modulation on the $^3\text{He}/^4\text{He}$ ratio at $\gtrsim 3 \text{ GV}$ is weak.

The excess in the ^3He spectrum and the $^3\text{He}/^4\text{He}$ ratio is observed above 7 GV, which corresponds to $\gtrsim 3.8 \text{ GeV/n}$ for ^3He , and $\gtrsim 2.7 \text{ GeV/n}$ for ^4He and for other most abundant heavier projectiles ($A/Z \approx 2$), such as ^{12}C , ^{16}O , ^{24}Mg , ^{28}Si . In the same figure, one can see a good agreement with standard calculations below 7 GV, which also includes the rigidities where the production and fragmentation cross sections have already become *energy-independent* (*rigidity-independent*), and the flattened $^3\text{He}/^4\text{He}$ ratio above this rigidity, i.e., *rigidity-dependent* excess. Therefore, the *energy-independent* (*rigidity-independent*) cross sections cannot be the reason for the observed *rigidity-dependent* ^3He excess. The latter rules out the hypothesis of the accuracy of the cross sections.

3.2. The Hard Spectrum Component Hypothesis

The second hypothesis implies that there is a hard spectrum component, which is either accelerated by a source enriched with ^3He (primary ^3He) relative to an “average” Galactic CR source or is produced through ^4He fragmentation in/near the source. Figures 2 (right) and 3 show calculations with the primary ^3He , where we used the standard parameters listed in Table 1. For a comparison, the lower right panel in Figure 3 shows also the ratio for fully secondary ^3He as in Figure 1. The injection spectra of $^{3,4}\text{He}$ isotopes are tuned to the AMS-02 data and provided in Table 2.

Although this case produces an excellent fit to the data, the idea of additional production of ^3He through ^4He fragmentation in/near the source has significant drawbacks. The most serious issue arises from the fact that the $^{3,4}\text{He}$ fragmentation cross sections and the cross section for production of ^3He in the reaction $^4\text{He} + p \rightarrow ^3\text{He}$ are quite small and much smaller than the cross sections for fragmentation of heavier species (C, N, O) and production of secondary isotopes of Be and B. Therefore, any process that effectively produces ^3He by fragmentation of nuclei $Z \geq 2$ produces Be and B even more efficiently given that C, N, O, and heavier species are also present in the CR source.

However, such an overproduction of heavier species (Be, B) can be avoided in a scenario, where a local source is enriched with ^3He relative to an “average” Galactic CR source. In this case, ^3He is “disconnected” from heavier species and such a scenario cannot be ruled out.

Indeed, the hypothesis of possible enrichment of a CR source environment with the ^3He isotope looks plausible. The closest example is the solar energetic particle events. Some of them exhibit resonant enhancements of $^3\text{He}/^4\text{He}$ up to 10,000-fold, which could even make ^3He dominant over H in rare events. Even after fifty years of studies, the mechanism of this enhancement is not fully understood. A concise review of studies of ^3He -rich events can be found in D. V. Reames (2021). Therefore, under certain circumstances, a similar mechanism could inject the ^3He -rich material into the ISM, where it can be picked by a propagating shock, or injected directly into the shock at the CR accelerator. While it is not clear how much such events could contribute to the particle spectra emergent from a source, it is evident that some level of enrichment of ^3He by similar events may be plausible.

3.3. The Inhomogeneous Diffusion Hypothesis

The third hypothesis is that the properties of the ISM are not uniform throughout the Galaxy and that the CR propagation parameters vary across different spatial scales as a consequence. The latter can be tested using the secondary/primary nuclei ratios with significantly different inelastic cross sections (G. Jóhannesson et al. 2016), such as \bar{p}/p , $^3\text{He}/^4\text{He}$, B/C (or B/O), F/Ne (or F/Si), (Sc+V)/Fe. In the ratios \bar{p}/p and $^3\text{He}/^4\text{He}$, the involved species have the smallest inelastic cross sections and thus can be used to test the propagation parameters over the largest Galactic volume, while (Sc+V)/Fe over the smallest. However, the low-energy feature (excess) found recently in the CR iron spectrum (M. J. Boschini et al. 2021), presumably associated with the local SNR event(s) 1–2 Mya, may hamper a straightforward interpretation of the (Sc+V)/Fe data.

Figure 4 shows calculations with propagation parameters derived from the $^3\text{He}/^4\text{He}$ ratio itself assuming a fully secondary ^3He (Table 1, “alternative model”).¹³ To do so, first, we performed a calculation of secondary ^3He (the so-called “background”) produced by fragmentation of nuclei $Z > 2$ with fixed standard propagation parameters (Table 1, “standard model”) and source abundance of ^4He set to 0. Second, we performed an MCMC scan to derive the alternative propagation parameters with fixed halo size $z_h = 4$ kpc, free source abundance of ^4He , and abundances of nuclei $Z > 2$ set to 0. The spectrum of ^3He was calculated as a sum of the background, the fixed secondary component calculated in the first step, plus secondary ^3He produced in the fragmentation of ^4He with alternative propagation parameters. The alternative propagation parameters derived in this calculation are shown in Table 1 together with standard parameters for a side-by-side comparison.

The observation of the $^3\text{He}/^4\text{He}$ excess over the calculation with standard propagation parameters, which is also observed in the \bar{p}/p ratio (I. V. Moskalenko et al. 2002, 2003; V. S. Ptuskin et al. 2006), implies an effectively smaller diffusion coefficient, at least below ≈ 20 GV, over the Galactic volume that is probed by it in a model-independent way—provided that we have similar scenarios in cases of lighter (^3He) and heavier (B) secondary species (CR source distribution, injection spectra, halo size z_h , etc.). Such an idea was first proposed by G. Jóhannesson et al. (2016). Indeed, their analysis showed that the propagation parameters that the best-fit \bar{p}/p and He data are significantly different from those that fit heavier elements, including the B/C and $^{10}\text{Be}/^9\text{Be}$ secondary-to-primary ratios normally used to calibrate the parameters of CR propagation models. The GALPROP version 55 was used for that study along with data available at that time: ACE-CRIS, ISOMAX, PAMELA, HEAO-3, CREAM-I, II. AMS-02 data were not available at the time that the lengthy model scanning made by G. Jóhannesson et al. (2016) was begun.

More recent analyses using the $^3\text{He}/^4\text{He}$ ratio and other AMS-02 data (M. Aguilar et al. 2019, 2021d) were performed by M. Korsmeier & A. Cuoco (2022) with the v56 GALPROP release, although both versions 55 and 56 did not include the latest cross-section updates, and by D. M. Gomez-Coral et al. (2023) who also employed GALPROP v56, but in that work the ^2H and ^3He production and fragmentation cross sections were modified according to B. Coste et al. (2012). The former analysis confirms the difference in the propagation parameters derived using different groups of nuclei, while the latter found an excess in ^3He above 5–6 GeV/n over the calculations with the propagation parameters derived from the B/C ratio (M. J. Boschini et al. 2020a)—in agreement with our conclusions.

3.4. The Outcome

Table 1 shows that the propagation parameters for the standard and alternative models are different. To make a consistent comparison, the halo size in the alternative model was fixed to the same value $z_h = 4$ kpc derived in the standard model. The diffusion coefficient normalization D_0 is larger for the alternative model, but both normalizations are consistent within the error bars. Significantly different are the indices of

¹³ Currently, there is no way to derive the spatial dependence of propagation parameters from the first principles. Observations of CRs could provide such information. Meanwhile, the interpretation of the observed CR spectra may depend on the assumed propagation model.

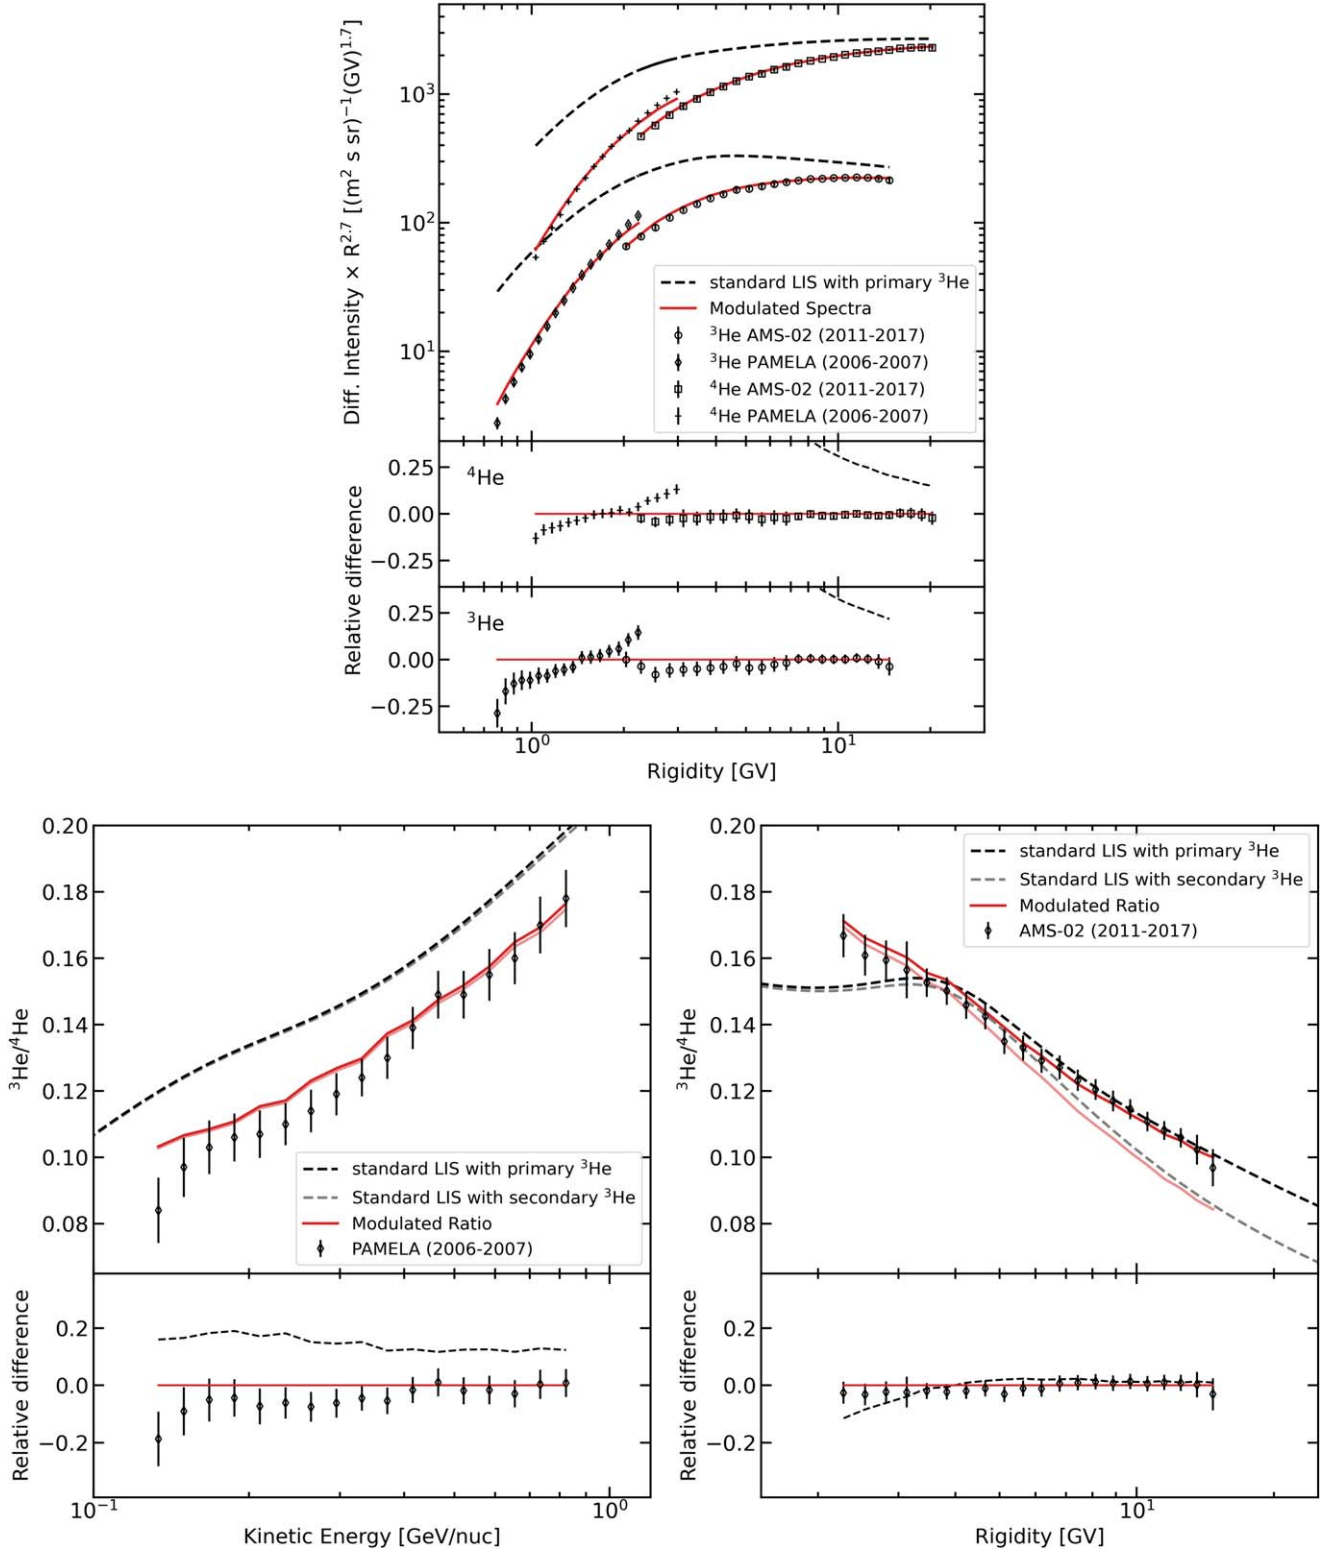

Figure 3. Calculations with the primary ^3He component. The upper panel shows a comparison of the calculated $^{3,4}\text{He}$ spectra with PAMELA (W. Menn et al. 2016) and AMS-02 (M. Aguilar et al. 2019) data. The dashed black lines show the LIS, and the solid red lines—the corresponding modulated spectra. The lower panels show a comparison of the $^3\text{He}/^4\text{He}$ ratio with PAMELA and AMS-02 data for two cases: fully secondary ^3He as in Figure 1 and with primary ^3He component. Note the different units in the PAMELA and AMS-02 plots. The relative differences between our calculations and the data sets are shown in the bottom part of each panel.

the diffusion coefficient δ and convection gradients dV_{conv}/dz . The index of the diffusion coefficient in the alternative model $\delta = 0.19$ is 2 times smaller than that in the standard model

$\delta = 0.415$, which implies a flatter $^3\text{He}/^4\text{He}$ ratio, as observed. The convection gradient affects the spectral shape at low rigidities. The larger value for the standard model is responsible

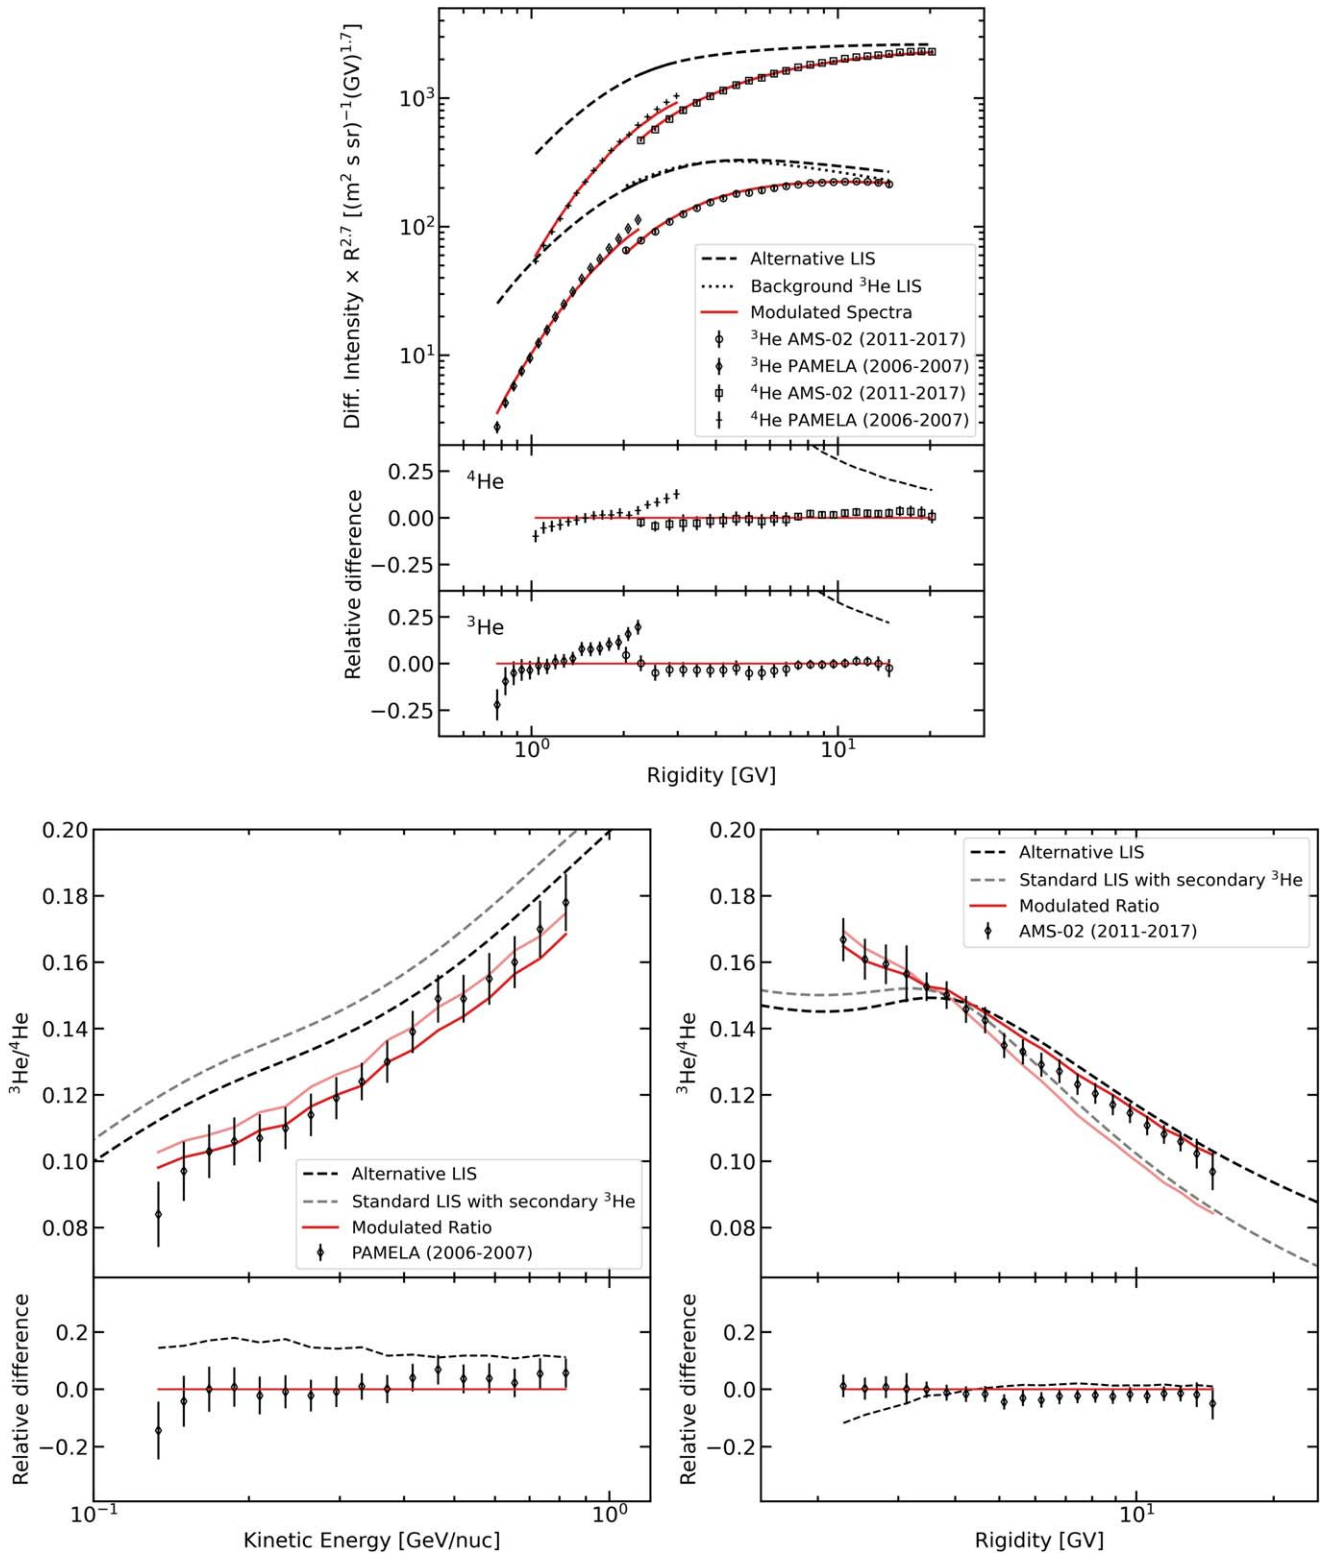

Figure 4. Calculations in the alternative model based on the measured ${}^3\text{He}/{}^4\text{He}$ ratio. The upper panel shows a comparison of the calculated ${}^3,4\text{He}$ spectra with PAMELA (W. Menn et al. 2016) and AMS-02 (M. Aguilar et al. 2019) data. The dashed black lines show the LIS and the solid red lines are the corresponding modulated spectra. The dotted line shows a contribution to the ${}^3\text{He}$ from the fragmentation of the $Z > 2$ species calculated in the standard model (the so-called background ${}^3\text{He}$ LIS). The lower panels show a comparison of the calculated ${}^3\text{He}/{}^4\text{He}$ ratio in the alternative and standard models with PAMELA and AMS-02 data. Note the different units in the PAMELA and AMS-02 plots. The relative differences between our calculations and the data sets are shown in the bottom part of each panel.

for a slight hardening of the ${}^3\text{He}/{}^4\text{He}$ ratio below ~ 4 GV. The alternative model matches the data at low rigidities and, therefore, an additional flattening is not required.

In Appendix A, we provide a comparison of all three model predictions for the ${}^3\text{He}$ and ${}^4\text{He}$ fluxes with 21 AMS-02 data sets, each representing the averages over four Bartel rotations

(≈ 4 months). One can see that the standard model calculations show the excess in the ${}^3\text{He}$ spectra above 7–8 GV for each plotted period, while ${}^4\text{He}$ spectra agree well with the data (Figure 5). The discrepancy is also reflected in the $\chi^2/\text{degrees of freedom}$ (of) plot, which shows unacceptably large values for the ${}^3\text{He}$ spectra. In the cases of a calculation with the primary ${}^3\text{He}$ component (Figure 6) and an alternative propagation model (Figure 7) the agreement with data is significantly better and the χ^2/dof for the ${}^3\text{He}$ spectrum drops to values similar to ${}^4\text{He}$.

In Appendix B, we provide numerical tables for all three cases, which tabulate the isotopic ${}^3,{}^4\text{He}$ LIS and atomic He LIS in kinetic energy per nucleon E_{kin} and in rigidity R in the standard model (Tables 3–8), ${}^3\text{He}$ LIS and atomic He LIS for a model with the primary ${}^3\text{He}$ component (Tables 9–12), and an alternative model with fully secondary ${}^3\text{He}$ and adjusted propagation parameters (Tables 13–18). The tables for the alternative model are truncated near the spectral break rigidity at ~ 300 GV. The ${}^4\text{He}$ LIS is identical in the standard model and in a model with the primary ${}^3\text{He}$ component, so it is provided only once in kinetic energy per nucleon E_{kin} and in rigidity R variables.

4. Discussion of Other Approaches

Some recent papers present claims for models that obtain consistency for the B/C and ${}^3\text{He}/{}^4\text{He}$ ratios that use different approaches. We elaborate on these further below.

N. Weinrich et al. (2020b) based their calculations on earlier papers (L. Derome et al. 2019; Y. Génolini et al. 2019; N. Weinrich et al. 2020a). The latter employ different options for parameterizing the isotopic production and total inelastic cross sections that are derived from those available with an earlier version of GALPROP, transforming them using the so-called “normalization, scale, and slope” method (L. Derome et al. 2019). This process modifies the normalization, energy scale, and shape of the cross sections through nuisance parameters, which are then tuned to the CR data using a sampling algorithm. At the same time, they also utilize the method of “proxy reactions,” where a modified cross section of a single dominant channel for producing a given CR species is used to represent products over many channels. Additionally, the solar modulation is treated using the force-field approximation with modulation potential as another nuisance parameter. However, this method appears to need fine-tuning to recover even mock data (L. Derome et al. 2019). Still, the ${}^3\text{He}/{}^4\text{He}$ ratio obtained by N. Weinrich et al. (2020b) reproduces the data from ≈ 5 to 10 GeV/n but with a deficit from ≈ 1 to 2 GeV/n to 5 GeV/n (their Figure 8). The cost of this approach is that there are uncontrolled modifications to the cross-section parameterizations, which translate directly into the derived propagation parameters and calculated CR spectra.

M. Di Mauro et al. (2024) use the latest version 57 of GALPROP, but modify the cross sections for the production of secondary species (${}^3\text{He}$, Li, Be, B) and secondary components in C and N. In particular, the normalizations A_{XS} and modifications of slopes δ_{XS} of the production cross sections below 5 GeV/n are their nuisance parameters. The typical normalizations are $A_{\text{XS}}({}^4\text{He} \rightarrow {}^3\text{He}) \approx 1.2\text{--}1.3$, $A_{\text{XS}} \rightarrow \text{Li} \approx 1.3$, $A_{\text{XS}} \rightarrow \text{Be} \approx 1.05$, $A_{\text{XS}} \rightarrow \text{B} \approx 1.03\text{--}1.05$, $A_{\text{XS}} \rightarrow \text{C} \approx 0.4\text{--}1$, and modifications of the slopes reach $\delta_{\text{XS}}({}^4\text{He} \rightarrow {}^3\text{He}) \approx 0.25$, $\delta_{\text{XS}} \rightarrow \text{Li} \approx 0.3$, $\delta_{\text{XS}} \rightarrow \text{Be} \approx 0.2$, $\delta_{\text{XS}} \rightarrow \text{B} \approx 0.13$, $\delta_{\text{XS}} \rightarrow \text{C} \approx 0.25$ for some models. The largest adjustments are required for ${}^3\text{He}$ and Li

production cross sections, which support our findings of ${}^3\text{He}$ and Li excesses (for Li excess; see M. J. Boschini et al. 2020b). Interestingly, their calculated ${}^3\text{He}/{}^4\text{He}$ ratio shows a discontinuity at ≈ 5 GV (their Figures 8, 9).

These few papers stand out in the literature as positing that the CR data are more reliable and use them for adjusting the cross-section parameterizations rather than using the extensive nuclear physics data that are employed by most authors. While we do not agree with the methods employed by these works, that they need to significantly modify the cross-section modeling to reconcile the different secondary-to-primary ratios in CRs (${}^3\text{He}$, Li, Be, B) within a single propagation model supports our conclusions: i.e., that there is a difference in the propagation properties of the ISM on different scales, or that primary components in ${}^3\text{He}$ and Li are needed.

5. Conclusion

Using the combined data of AMS-02 (M. Aguilar et al. 2021a), PAMELA (W. Menn et al. 2016), ACE-CRIS (K. A. Lave et al. 2013), and Voyager 1 (A. C. Cummings et al. 2016) we analyzed the spectra of He and its isotopes ${}^3,{}^4\text{He}$ over a wide rigidity range ≥ 100 MV. We found that the He and ${}^4\text{He}$ spectra agree well with the predictions made with the GALPROP–HELMOD framework, while the ${}^3\text{He}$ spectrum shows a significant excess above 7 GV in rigidity and up to 13 GV where AMS-02 data are available.

We further show that this excess can be plausibly explained by assuming a primary ${}^3\text{He}$ component with a harder injection spectrum, or a nonuniform propagation probed on different spatial scales by light isotopes (${}^3,{}^4\text{He}$) and heavier species (e.g., the B/C ratio). Meanwhile, the accuracy of the He isotopic production and fragmentation cross sections as the main reason for the observed excess can be ruled out based on the energy (rigidity) dependences of the relevant cross sections and of the discussed ${}^3\text{He}$ excess.

Finally, we note that the exploration of the newly discovered features in the spectra of CR species has just begun, thanks to the data from the interstellar probes Voyager 1 and 2, and precise measurements by AMS-02, ACE-CRIS, and other instruments. These features harbor the keys to understanding our local Galactic environment and the history of the formation of the solar system. The increase in the collected statistics and reduction in the systematic errors will help to establish the precise spectral shapes of observed features and to facilitate their interpretation.

Appendix A ³He and ⁴He Fluxes Averaged Over Bartel Rotations

The reliability of our results can be verified through a comparison of all three model predictions for the ³He and ⁴He fluxes and the ³He/⁴He ratios with the AMS-02 data averaged over four Bartel rotations (~4 months). In particular, we compare our results with Bartel rotation average fluxes for Bartel rotations: 2426–2429, 2430–2433, 2434–2437, 2438–2441, 2442–2445, 2446–2449, 2450–2453, 2454–2457, 2458–2461, 2462–2465, 2466–2469, 2474–2477, 2478–2481, 2482–2485, 2486–2489, 2490–2493, 2494–2497, 2498–2501, 2502–2505, 2506–2509, 2510–2513, as

reported in M. Aguilar et al. (2019). We also report the χ^2/dof calculated for each Bartel rotation period for both ³He and ⁴He spectra.

One can see that the standard model calculations show the excess in the ³He spectra above 7–8 GV for each plotted period, while ⁴He spectra agree well with the data (Figure 5). The discrepancy is also reflected in the χ^2/dof plot, which shows unacceptably large values for the ³He spectra. In the cases of a calculation with the primary ³He component (Figure 6) and an alternative propagation model (Figure 7), the agreement with data is significantly better and the χ^2/dof for the ³He spectrum drops to values similar to ⁴He.

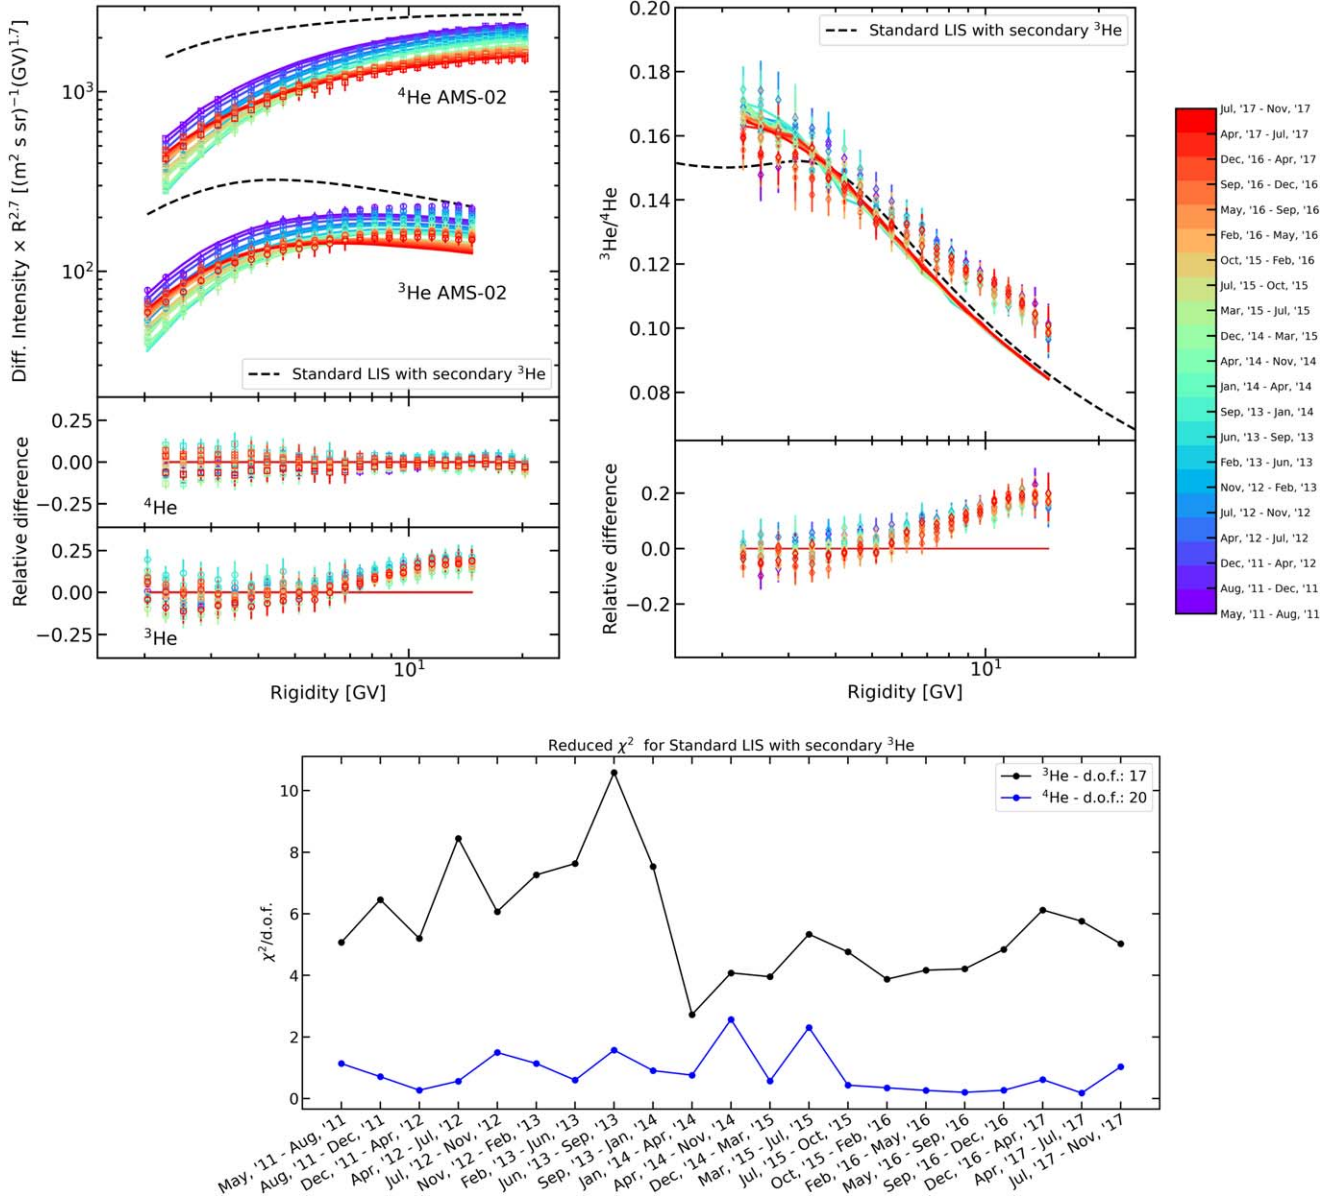

Figure 5. Comparison of the standard calculations for the ³He and ⁴He fluxes (upper left panel) and the ³He/⁴He ratio (upper right panel) with the AMS-02 data (M. Aguilar et al. 2019) averaged over four Bartel rotations. The dashed black lines show the LIS (left) or the LIS ratio (right), and the solid colored lines are the corresponding modulated values. Note that the fluxes in the left panel shown with colored lines and corresponding data points are renormalized with a factor 0.98^n each for clarity, here $n = 0 \dots 20$ is the data set number. The color coding scales and the corresponding periods are shown on the right. The relative differences between our calculations and the data sets are shown in the bottom part of each panel. The lower panel shows the χ^2/dof calculated for each Bartel rotation period for both ³He and ⁴He spectra.

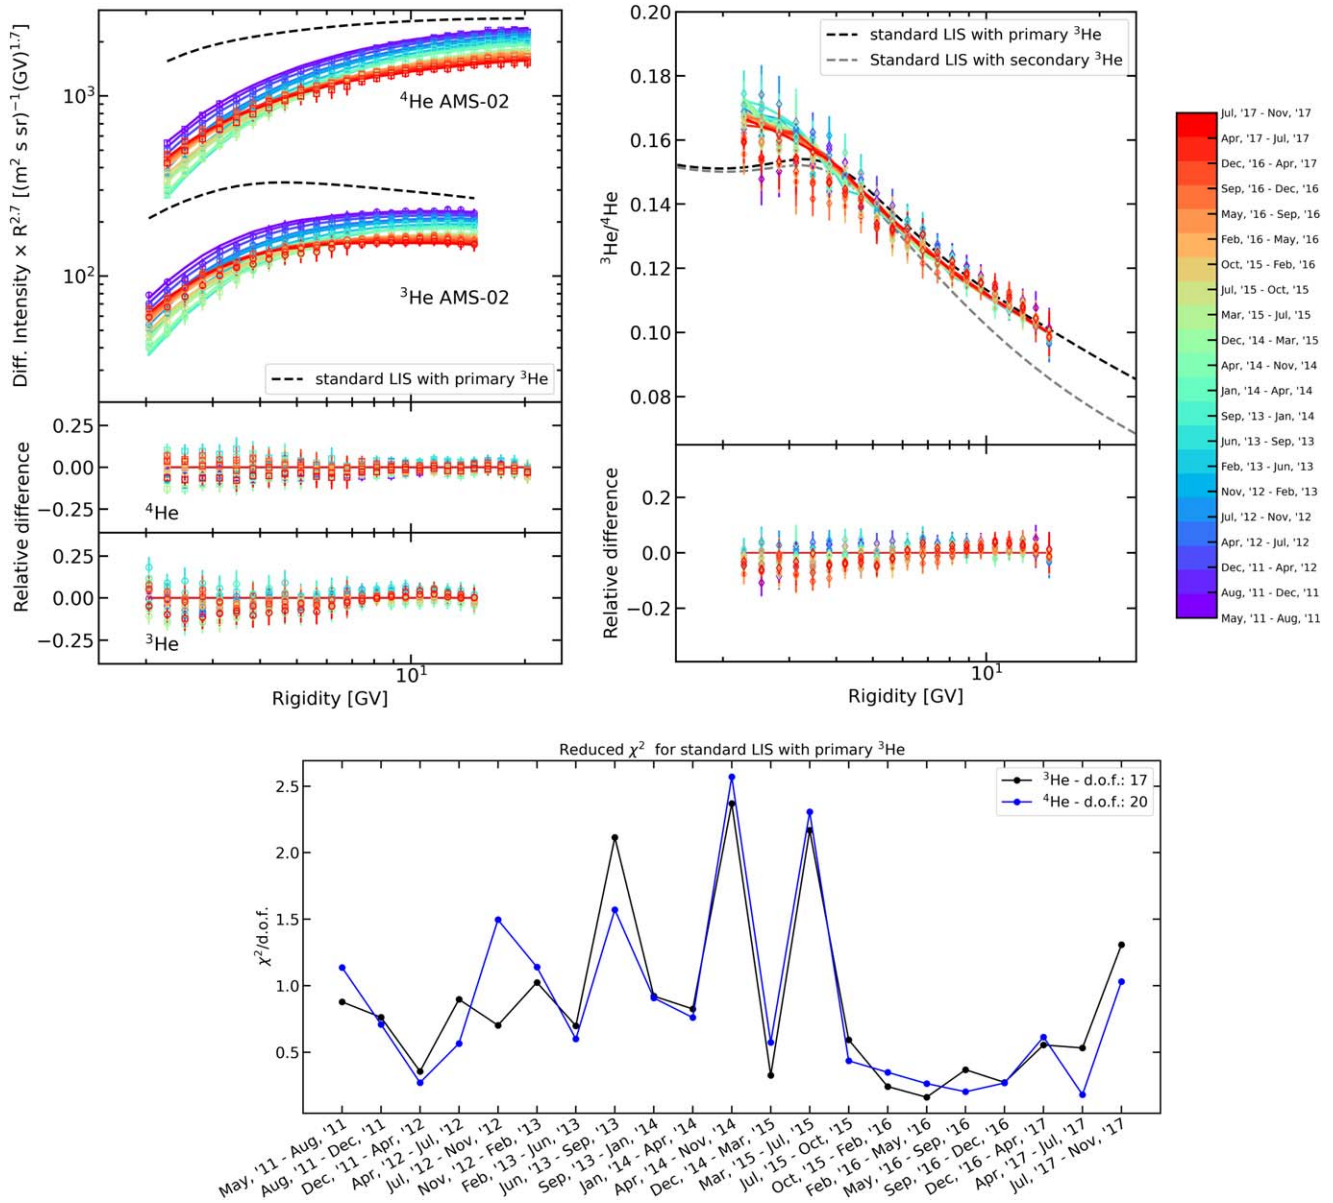

Figure 6. Calculations with the primary ^3He component. Shown is a comparison of calculations for the ^3He and ^4He fluxes (upper left panel) and the $^3\text{He}/^4\text{He}$ ratio (upper right panel) with the AMS-02 data (M. Aguilar et al. 2019) averaged over four Bartel rotations. The dashed black lines show the LIS (left) or the LIS ratio (right), and the solid colored lines are the corresponding modulated values. Note that the fluxes in the left panel shown with colored lines and corresponding data points are renormalized with a factor 0.98^n each for clarity, here $n = 0 \dots 20$ is the data set number. The color coding scales and the corresponding periods are shown on the right. The relative differences between our calculations and the data sets are shown in the bottom part of each panel. The lower panel shows the χ^2/dof calculated for each Bartel rotation period for both ^3He and ^4He spectra.

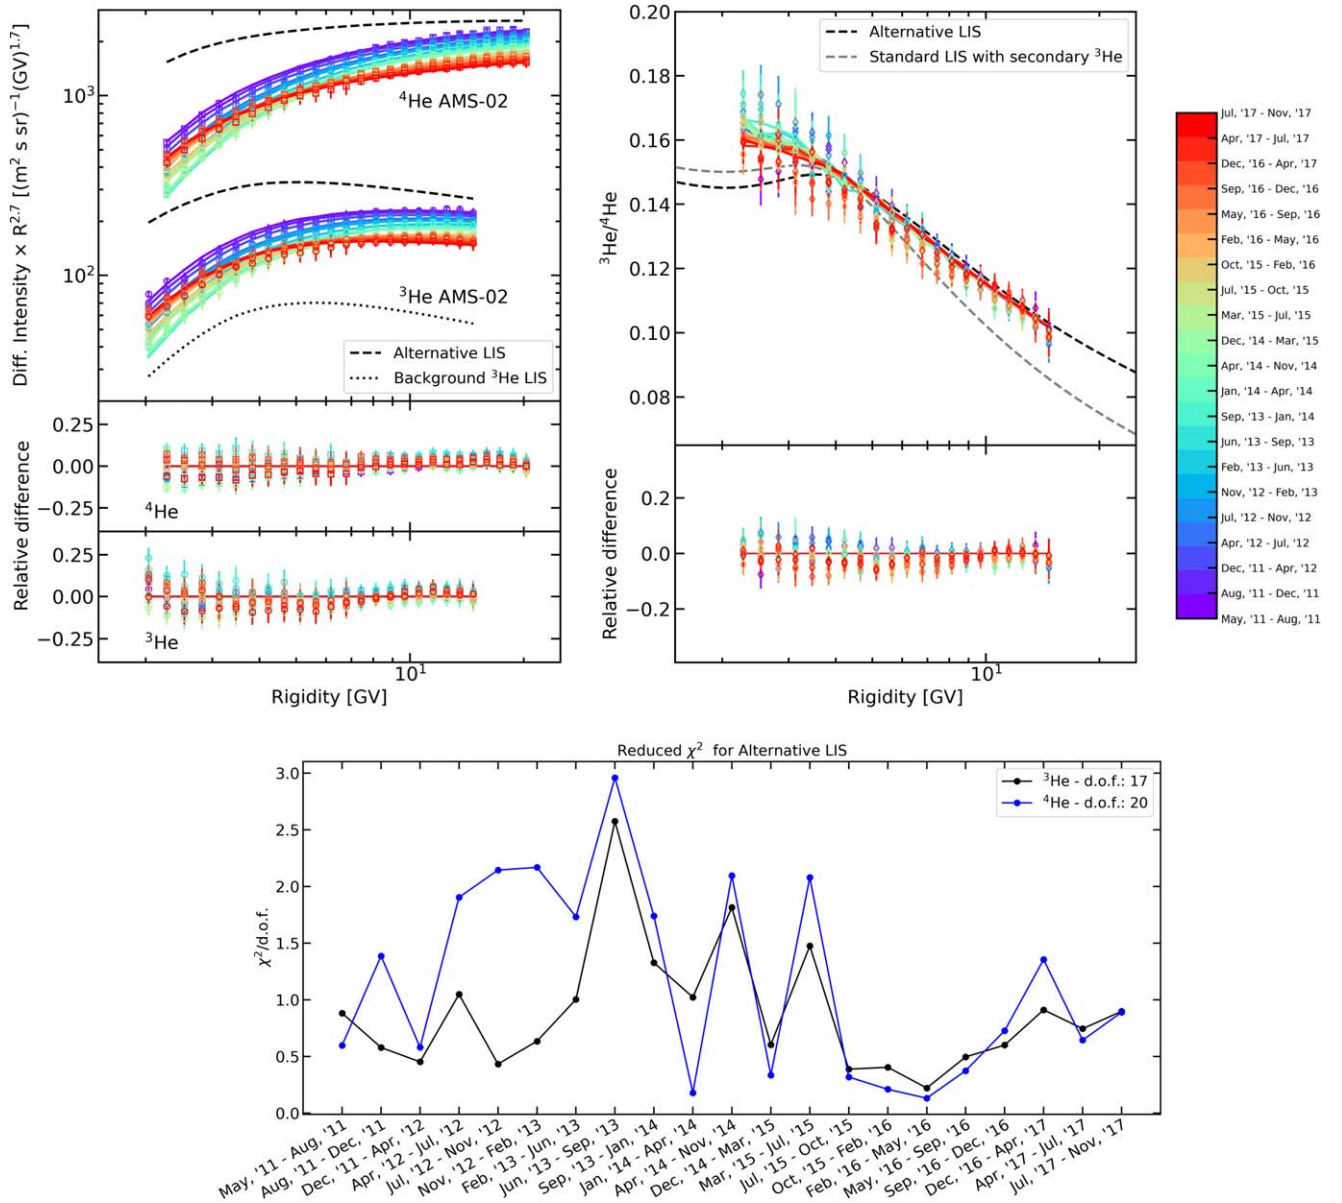

Figure 7. Calculations in the alternative model based on the ${}^3\text{He}/{}^4\text{He}$ ratio. Shown is a comparison of calculations for the ${}^3\text{He}$ and ${}^4\text{He}$ fluxes (upper left panel) and the ${}^3\text{He}/{}^4\text{He}$ ratio (upper right panel) with the AMS-02 data (M. Aguilar et al. 2019) averaged over four Bartel rotations. The dashed black lines show the LIS (left) or the LIS ratio (right), and the solid colored lines are the corresponding modulated values. Note that the fluxes in the left panel shown with colored lines and corresponding data points are renormalized with a factor 0.98^n each for clarity, here $n = 0 \dots 20$ is the data set number. The color coding scales and the corresponding periods are shown on the right. The relative differences between our calculations and the data sets are shown in the bottom part of each panel. The lower panel shows the χ^2/dof calculated for each Bartel rotation period for both ${}^3\text{He}$ and ${}^4\text{He}$ spectra.

Appendix B

Numerical Tables of the ${}^3,{}^4\text{He}$ and Atomic He LIS

Here we tabulate the LIS in kinetic energy per nucleon E_{kin} and in rigidity R , in the standard model (Tables 3–8), for a model with the primary ${}^3\text{He}$ component (Tables 9–12) and an alternative model with fully secondary ${}^3\text{He}$ and adjusted

propagation parameters (Tables 13–18). The tables for the alternative model are truncated near the spectral break rigidity at ~ 300 GV. The ${}^4\text{He}$ LIS is identical in the standard model and in a model with the primary ${}^3\text{He}$ component, so it is provided only once in kinetic energy per nucleon E_{kin} and in rigidity R variables.
